Preface

Part I Getting Started with Fusion Web Applications

1 Introduction to Building Fusion Web Applications with Oracle ADF

2 Introduction to the ADF Sample Application

Part II Building Your Business Services

3 Getting Started with ADF Business Components

4 Creating a Business Domain Layer Using Entity Objects

5 Defining SQL Queries Using View Objects

6 Defining Master-Detail Related View Objects

7 Defining Polymorphic View Objects

8 Testing View Instance Queries

9 Tuning View Object Performance

10 Defining Validation and Business Rules Declaratively

11 Working Programmatically with View Objects

14 Sharing Application Module View Instances

15 Creating SOAP Web Services with Application Modules

Part III Using the ADF Model Layer

18 Using ADF Model in a Fusion Web Application

19 Using Validation in the ADF Model Layer

20 Designing a Page Using Placeholder Data Controls

21 Creating ADF REST Data Controls from ADF RESTful Web Services

22 Consuming ADF RESTful Web Services

Part IV Creating ADF Task Flows

23 Getting Started with ADF Task Flows

24 Working with Task Flow Activities

25 Using Parameters in Task Flows

26 Using Task Flows as Regions

27 Creating Complex Task Flows

28 Using Dialogs in Your Application

Part V Creating a Databound Web User Interface

33 Using Command Components to Invoke Functionality in the View Layer

34 Displaying Master-Detail Data

37 Creating Databound Calendar and Carousel Components

38 Creating Databound Chart, Picto Chart, and Gauge Components

42 Creating Databound Gantt Chart and Timeline Components

43 Creating Databound Hierarchy Viewer, Treemap, and Sunburst Components

44 Creating Databound Diagram Components

45 Creating Databound Tag Cloud Components

46 Using Contextual Events

Part VI Completing Your Application

47 Enabling ADF Security in a Fusion Web Application

51 Customizing Applications with MDS

52 Allowing User Customizations at Runtime

53 Using the Active Data Service

54 Configuring High Availability for Fusion Web Applications

55 Deploying Fusion Web Applications

57 Tuning Application Module Pools

Part VII Appendixes

A Oracle ADF XML Files

B Oracle ADF Binding Properties

C ADF Security Permission Grants

D Most Commonly Used ADF Business Components Methods

G Performing Common Oracle Forms Tasks in Oracle ADF

H Deploying ADF Applications to GlassFish

Preface

Welcome to *Developing Fusion Web Applications with Oracle Application Development Framework*.

Audience

This document is intended for enterprise developers who need to create and deploy database-centric Java EE applications with a service-oriented architecture using the Oracle Application Development Framework (Oracle ADF). This guide explains how to build Fusion web applications using ADF Business Components, ADF Controller, ADF Faces, and JavaServer Faces.

Documentation Accessibility

For information about Oracle's commitment to accessibility, visit the Oracle Accessibility Program website at `http://www.oracle.com/pls/topic/lookup?ctx=acc&id=docacc`.

Access to Oracle Support

Oracle customers that have purchased support have access to electronic support through My Oracle Support. For information, visit `http://www.oracle.com/pls/topic/lookup?ctx=acc&id=info` or visit `http://www.oracle.com/pls/topic/lookup?ctx=acc&id=trs` if you are hearing impaired.

Conventions

The following text conventions are used in this document:

Convention	Meaning
boldface	Boldface type indicates graphical user interface elements (for example, menus and menu items, buttons, tabs, dialog controls), including options that you select.
italic	Italic type indicates book titles, emphasis, or placeholder variables for which you supply particular values.
`monospace`	Monospace type indicates language and syntax elements, directory and file names, URLs, text that appears on the screen, or text that you enter.

What's New in This Guide for Release 12c (12.2.1.4.0)

The following topics introduce the new and changed features of Oracle JDeveloper and Oracle Application Development Framework (Oracle ADF) and other significant changes, which are described in this guide. This document in previous JDeveloper releases had been titled *Fusion Developer's Guide for Oracle Application Development Framework*.

New and Changed Features for Release 12c (12.2.1.4.0)

Oracle Fusion Middleware Release 12c (12.2.1.4.0) of Oracle JDeveloper and Oracle Application Development Framework (Oracle ADF) includes the following new and changed development features, which are described in this guide.

- ADF REST Framework Runtime and Design Time
  - New runtime support for REST resources is provided with the addition of four new ADF REST framework versions. By declaring a default framework version to process requests, the REST application developer may opt into the features introduced by a specific ADF REST framework. The default ADF REST framework version is defined by the application in the `adf-config.xml` file. In JDeveloper release 12.2.1.4.0, framework versions 4, 5, 6, and 7 were added to existing versions 1 through 3.
    - Versions 4 and later enables exception details to appear in the response when the ADF REST request is made for either `application/vnd.oracle.adf.error+json` or `application/json` media types. See Obtaining an Exception Payload Error Response.
    - Versions 5 and later supports filtering resources by using a row match finder to access nested LOV resources, for example: `/rest/v1/Cities?finder=ByState;name='California'`. Starting with this version, row context LOV URLs are no longer returned in the payload or in the describe. Only LOV resource URLs that point to top-level resources are described and included in payloads. See Retrieving LOV-Enabled Attribute Values with Framework Version 5 and Later.
    - Versions 6 and later makes it easier to differentiate between resource fields and item context information, such as links and headers. A new element `@context` is introduced in this version and all the information for an item is moved under `@context`. Version 6 also supports obtaining warning details in the response. See Fetching a Resource with Grouped Context Information and Obtaining Warning Messages in the Payload Response.
    - Version 7 (latest version in release 12.2.1.4.0) supports top-level LOVs, and removes row-level LOV resource descriptions in the ADF REST describe and removes LOV links from the resource item payload links section. Earlier framework versions support LOV in a context of a row in the REST resource. See What You May Need to Know About Versioning the ADF REST Framework.

For an overview of the features introduced by all available framework versions, see What You May Need to Know About Versioning the ADF REST Framework.

  - A variety of new ways to limit the ADF REST resource catalog describe are available. The catalog describe can now be obtained by retrieving only minimal details (a minimal describe), or by retrieving based on resource visibility—private, public, or both (as specified on the resource at design time), or by retrieving parent resources and optionally excluding or including nested, child resources. See Retrieving the ADF REST Catalog Describe.
  - A variety of new ways to describe ADF REST resources are available. The resource describe can now be obtained by retrieving two or more named resources, by using parameters `filters` or `partialDescription` to limit the resource describe, and by retrieving resources based on ETag values as assigned by the web server to identify specific versions of a resource. See Retrieving the ADF REST Resource Describe.
  - The ADF REST resource describe now identifies whether or not an attribute is mandatory using the property “`mandatory`”. The “`mandatory`” property in the resource describe is based on the view object attribute metadata specified at design time. See What You May Need to Know About Mandatory Attributes in the ADF REST Resource.
  - A new Upsert mode on a POST method lets you merge payload content to either update resource items that exist, or if not, create the resource items. See Updating or Creating Resource Items (Upsert).
  - The use of special characters in the query parameter string of an ADF REST GET request is supported by the use of single quotes (in framework version 2 and later) to define literal values. See GET Method Operations.
  - Case-sensitive sorting of resource items of type String is now supported by the `orderBy` query string parameter of an ADF REST GET request. By default, the `orderBy` clause sorts the records with uppercase letters first and then lower case letters. To achieve case-insensitive sorting, the `orderBy` clause can be combined with `upper(`*`attrName`*`)` or `lower(`*`attrName`*`)`. See Sorting a Resource Collection.
  - The ADF REST framework now supports configuration options for `Cache-Control`. You can specify these additional configuration options in the REST resource source editor. When defined on the resource, the `Cache-Control` header will be added in the payload of the ADF REST response. See What You May Need to Know About the Cache-Control Header.
  - The JDeveloper wizard Create Business Components from Tables combines generating the various business components together with creating ADF REST resources in a single end to end process. This wizard helps you to create ADF REST resources quickly and easily. See How to Create ADF REST Resources Using the Create Business Components from Tables Wizard.
  - Attribute hints defined in the JDeveloper overview editor for view objects can now optionally appear as attribute properties in the REST resource describe. See What You May Need to Know About ADF REST Attribute Hints.

- ADF Business Components
  - The ADF application now supports custom script expression classes to define a class that can be used by other script classes. A script class file allows you

    to maintain common Groovy script expressions that can be called from within any business component class. See How to Create a Script Expression Class File.

  - The ADF application now allows the user to turn on/off data security of a View Object by setting a flag `EOSecurityOverride`. This is a metadata level setting on the `viewdef.xml` of the View Object. See What You May Need to Know About Overriding Security for Entity Objects.

- ADF Task Flows
  - The ADF application now supports EL expressions set on the optional task flow binding property `processRegionForRefresh` to determine if the associated ADF region should participate in a refresh operation. By default, the ADF region participates in refresh operations. See How to Configure the Refresh of an ADF Region.

- ADF Web User Interface
  - The ADF application now supports creating an `af:inputSearch` LOV component to fetch list data from a REST URL on LOV-enabled attributes defined as type `inputSearch`. See How to Provide af:inputSearch LOV Component the REST URL.

Other Significant Changes in this Document for Release 12c (12.2.1.4.0)

For Release 12c (12.2.1.4.0), this document has been updated in several ways. Following are the sections that have been added or changed.

Part II Building Your Business Services

- Removed sections related to creating custom methods for ADF REST resources. This is no longer supported in release 12.2.1.4.0.
- Removed sections that described obsolete use cases for bind variables. The generation of bind variables on custom view object classes is no longer an option in the Select Java Options dialog that you open from the Java page of the view object overview editor in JDeveloper. The recommended way to allow UI fields to update bind parameter values is through view criteria.

Part III Using the Model Layer

- Revised the ADF REST batch requests section to remove the resource version in the payload sample that also shows the resource version in the POST URL to clarify that only the POST URL must provide a resource version. See Making Batch Requests.
- Revised the ADF REST headers section to update the list of available headers for REST requests and responses. See ADF REST HTTP Headers Support.
- Removed sections related to executing custom methods for ADF REST resources. This feature is no longer supported in release 12.2.1.4.0.

Part IV Creating ADF Task Flows

- Revised the ADF skins style properties section to remove the deprecated `web.xml` context parameter `oracle.adf.view.rich.remote.PRODUCER_STYLESHEET_DEBUG_LEVEL`. See What You May Need to Know About ADF Skins and Remote Regions.

- Revised the ADF Region refresh sections as follows:
  - Revised sections to clarify that **ifNeeded** is recommended over a **RefreshCondition** expression when choosing an option to determine region refresh behavior. See step 3 of How to Configure the Refresh of an ADF Region and see also What You May Need to Know About Configuring an ADF Region to Refresh.
  - Added a section to clarify the behavior of ADF regions in a page refresh. To avoid refreshing the regions that are not visible in the active view tree, set the `oracle.adfinternal.controller.regionPruning` parameter value to `true`. See What You May Need to Know About Refreshing an ADF Region.

Part VI Completing Your Application

- Revised the passivating transient view objects section to note that to enable a transient view object to passivate or activate correctly, requires a non-null key attribute value. See What You May Need to Know About Passivating Transient View Objects.

Part VII Appendices

- Revised the topic on `EntityImpl` methods to note that downcasting the return value of an `EntityImpl.getStructureDef()` method invocation to `EntityCache` is not supported. To obtain the instance of `EntityCache` invoke an existing `getEntityCache()`method on the `EntityImpl` object. See Methods You Typically Call on EntityImpl.

Part I

Getting Started with Fusion Web Applications

This part describes the architecture and key functionality of Oracle Application Development Framework (Oracle ADF) when used to build a Fusion web application that uses ADF Business Components, ADF Model, ADF Controller, and ADF Faces (the full Fusion technology stack).

Part I contains the following chapters:

1

Introduction to Building Fusion Web Applications with Oracle ADF

This chapter describes the architecture and key functionality of Oracle Application Development Framework (Oracle ADF) when used to build a Fusion web application that uses ADF Business Components, ADF Model, ADF Controller, and ADF Faces, in other words, the full Fusion technology stack. It also provides high-level development practices.

This chapter includes the following sections:

For definitions of unfamiliar terms found in this and other books, see the Glossary.

Introduction to Oracle ADF

Oracle ADF is a commercial Java framework for building enterprise applications. It supports rapid application development based on ready-to-use design patterns, metadata-driven and visual tools.

The **Oracle Application Development Framework** (Oracle ADF) is an end-to-end application framework that builds on Java Platform, Enterprise Edition (Java EE) standards and open-source technologies. You can use Oracle ADF to implement enterprise solutions that search, display, create, modify, and validate data using web, wireless, desktop, or web services interfaces. Because of its declarative nature, Oracle ADF simplifies and accelerates development by allowing users to focus on the logic of application creation rather than coding details. Used in tandem, Oracle JDeveloper and Oracle ADF give you an environment that covers the full development lifecycle from design to deployment, with drag and drop data binding, visual UI design, and team development features built in.

> **Tip:**
>
> You can also develop ADF applications using Oracle Enterprise Pack for Eclipse (OEPE). OEPE is a set of plug-ins designed for the Eclipse IDE to support Java EE development. OEPE also includes support for ADF application development, though that support is more limited than that provided by JDeveloper. See `http://www.oracle.com/technetwork/developer-tools/eclipse/overview/index.html`.

You can develop Fusion web applications, which are applications built with the full Fusion technology stack—ADF Business Components, ADF Model, ADF Controller, and JavaServer Faces pages with ADF Faces components. As a companion to this guide, you can download and view the Summit sample applications for Oracle ADF, which help to illustrate the concepts and procedures in this guide (and other Oracle Fusion Middleware developer guides). The examples in this sample application are built using the Fusion web application technology stack. Screenshots and code samples from this application are used throughout this guide to provide you with real-world examples of using the Oracle ADF technologies. For information about downloading and using the Summit ADF sample applications, see Introduction to the ADF Sample Application.

Oracle ADF Architecture

Oracle ADF architecture is based on Model-View-Controller (MVC) design pattern that consists of four layers – Model, View, Controller, and Business Services. Separating applications into these layers helps in the maintenance and reusability of components across applications.

In line with community best practices, applications you build using the Fusion web technology stack achieve a clean separation of business logic, page navigation, and user interface by adhering to a model-view-controller architecture. As shown in Figure 1-1, in an MVC architecture:

- The model layer represents the data values related to the current page, along with the model-level business rules, security, and application logic used against the data values.
- The view layer contains the UI pages used to view or modify that data.
- The controller layer processes user input and determines page navigation.
- The business service layer handles data access and encapsulates business logic.

Figure 1-1 MVC Architecture Cleanly Separates UI, Business Logic and Page Navigation

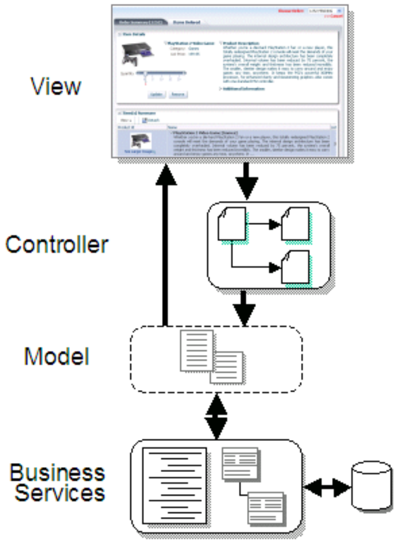

Figure 1-2 illustrates where each ADF module fits in the Fusion web application architecture. The core module in the framework is ADF Model, a data binding facility. ADF Model enables a unified approach to bind any user interface to any business service, without the need to write code. The other modules that make up a Fusion web application technology stack are:

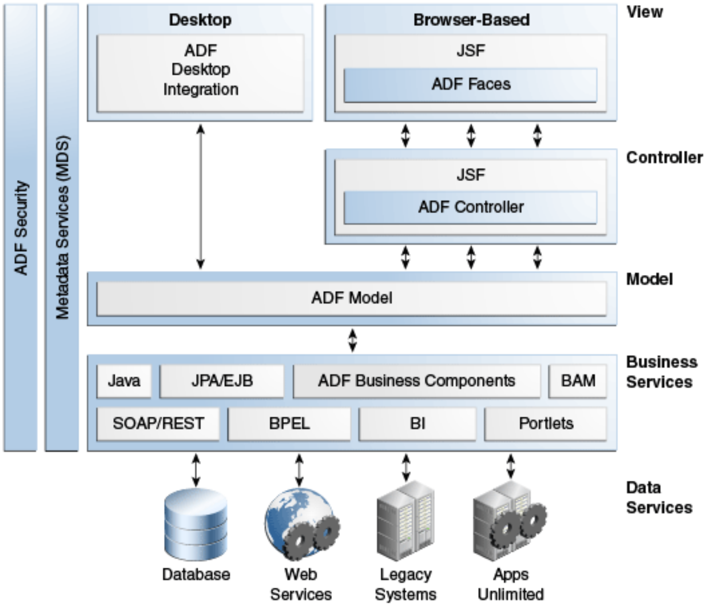
- **ADF Business Components**, which simplify building business services.
- **ADF Faces**, which offers a rich library of ajax-enabled UI components for web applications built with JavaServer Faces (JSF).
- **ADF Controller**, which integrates JSF with ADF Model. ADF Controller extends the standard JSF controller by providing additional functionality, such as reusable task flows that pass control not only between JSF pages, but also between other activities, for instance method calls or other task flows. The ADF Controller also works with the data model to ensure the proper data is used for each request or **region**.

> **Note:**
>
> In addition to ADF Faces, Oracle ADF also supports using the Java and standard JSF view technologies. For information about these technologies, see Getting Started with Developing Java Applications in *Developing Applications with Oracle JDeveloper*. Oracle ADF also provides support for using Microsoft Excel as a view layer for your application. See About ADF Desktop Integration with Microsoft Excel in *Developing Applications with Oracle ADF Desktop Integration*.

Figure 1-2 Simple Oracle ADF Architecture



For information about the Oracle ADF architecture and the individual ADF technologies, see Overview of Oracle ADF in *Understanding Oracle Application Development Framework*.

Overview of Building an Application with Oracle ADF

You can build a Fusion web application with Oracle ADF using JDeveloper. Use the step-by-step ADF application development process that minimizes the coding effort of the developer to build an application’s infrastructure and to implement complex business logic of the application.

Oracle ADF emphasizes the use of the declarative programming paradigm throughout the development process to allow users to focus on the logic of application creation without having to get into implementation details. Using JDeveloper with Oracle ADF, you benefit from a high-productivity environment that automatically manages your application's declarative metadata for data access, validation, page control and navigation, user interface design, and data binding.

At a high level, the development process for a Fusion web application usually involves the following:

- Creating an application workspace: Using a wizard, JDeveloper automatically adds the libraries and configuration needed for the technologies you select, and structures your application into projects with packages and directories.
- Modeling the database objects: You can create an online database or offline replica of any database, and use JDeveloper editors and diagrammers to edit definitions and update schemas.
- Creating use cases: Using the UML modeler, you can create use cases for your application.
- Designing application control and navigation: You use diagrammers to visually determine the flow of application control and navigation. JDeveloper creates the underlying XML for you.
- Identifying shared resources: You use a resource library that allows you to view and use imported libraries by simply dragging and dropping them into your application.
- Creating business components to access data: From your database tables, you create entity objects using wizards or dialogs. From those entity objects, you create the view objects used by the pages in your application. You can implement validation rules and other types of business logic using editors.
- Implementing the user interface with JSF: The **Data Controls panel** in JDeveloper contains a representation of the view objects in your application. Creating a user interface is as simple as dragging an object onto a page and selecting the UI component you want to display the underlying data. For UI components that are not databound, you use the Components window to drag and drop components. JDeveloper creates the page code for you.
- Binding UI components to data using ADF Model: When you drag an object from the Data Controls panel, JDeveloper automatically creates the bindings between the page and the data model.
- Incorporating validation and error handling: Once your application is created, you use editors to add additional validation and to define error handling.

- Securing the application: You use editors to create roles and populate these with users. You then use a flat file editor to define security policies for these roles and assign them to specific resources in your application.
- Testing and debugging: JDeveloper includes an integrated application server that allows you to fully test your application without needing to package it up and deploy it. JDeveloper also includes the ADF Declarative Debugger, a tool that allows you to set breakpoints and examine the data.
- Deploying the application: You use wizards and editors to create and edit deployment descriptors, JAR files, and application server connections.

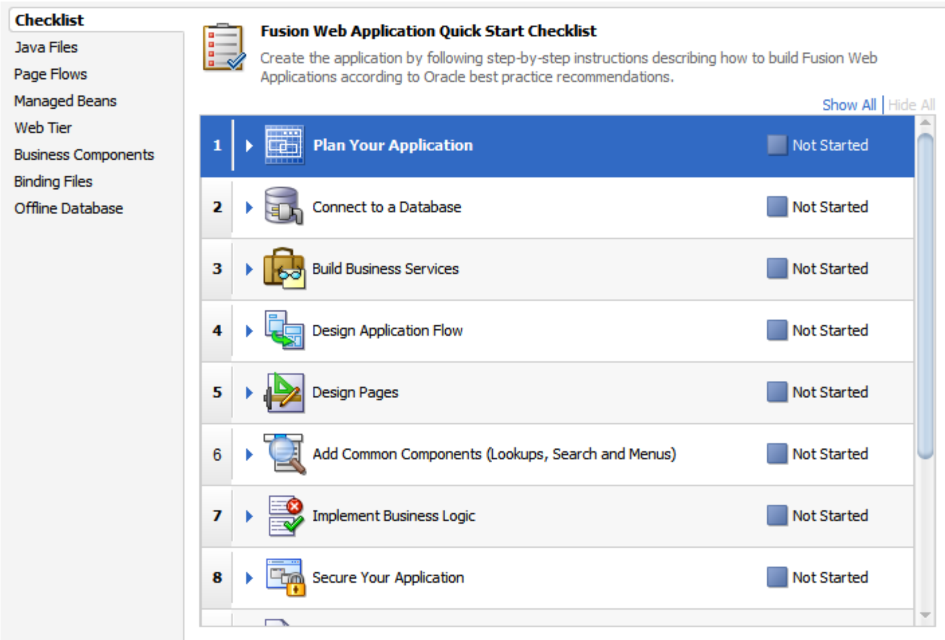
Creating an Application Workspace

The first step in building a new application is to assign it a name and to specify the directory where its source files will be saved. When you create an application using the application templates provided by JDeveloper, it organizes your workspace into projects and creates and organizes many of the configuration files required by the type of application you are creating.

One of these templates is the ADF Fusion Web Application template, which provides the correctly configured set of projects you need to create a web application that uses ADF Faces for the view, ADF Controller for the page flow, and ADF Business Components for business services. When you create an application workspace using this template, JDeveloper automatically creates the JSF and ADF configuration files needed for the application.

One part of the application overview is the Fusion Web Application Quick Start Checklist. This checklist provides you with the basic steps for creating a Fusion web application. Included are links to pertinent documentation, prerequisites, and the ability to keep track of status for each step in the checklist, as shown in Figure 1-3.

Figure 1-3 Fusion Web Application Quick Start Checklist



Fusion Web Application Quick Start Checklist

Create the application by following step-by-step instructions describing how to build Fusion Web Applications according to Oracle best practice recommendations.

1	Plan Your Application	Not Started
2	Connect to a Database	Not Started
3	Build Business Services	Not Started
4	Design Application Flow	Not Started
5	Design Pages	Not Started
6	Add Common Components (Lookups, Search and Menus)	Not Started
7	Implement Business Logic	Not Started
8	Secure Your Application	Not Started

JDeveloper also creates a project named `Model` that will contain all the source files related to the business services in your application, and a project named `ViewController` that will contain all the source files for your ADF Faces view layer and model layer, including files for the controller.

To save you having to add the associated libraries yourself, JDeveloper automatically adds the following libraries to the data model project, once you create a business component:

- ADF Model Runtime
- BC4J Oracle Domains
- BC4J Runtime
- BC4J Security
- MDS Runtime
- MDS Runtime Dependencies
- Oracle JDBC

JDeveloper also adds the following libraries to the view project:

- JSP Runtime
- JSF 2.1
- JSTL 1.2
- ADF Page Flow Runtime
- ADF Controller Runtime
- ADF Controller Schema
- ADF Faces Runtime 11
- ADF Common Runtime
- ADF Web Runtime
- MDS Runtime
- MDS Runtime Dependencies
- Commons Beanutils 1.6
- Commons Logging 1.0.4
- Commons Collections 3.1
- ADF DVT Faces Runtime
- ADF DVT Faces Databinding Runtime
- ADF DVT Faces Databinding MDS Runtime

Once you add a JSF page, JDeveloper adds the Oracle JEWT library.

You can then use JDeveloper to create additional projects, and add the packages and files needed for your application.

Note:

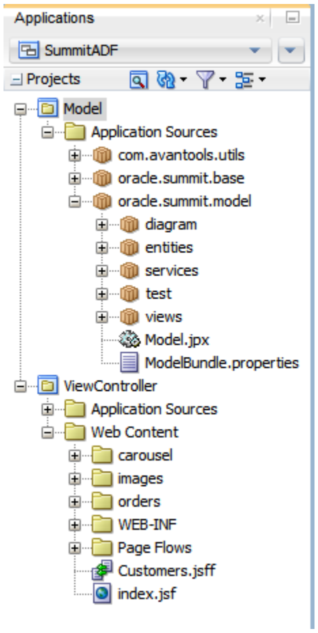
If you plan to reuse artifacts in your application (for example, task flows), then you should follow the naming guidelines presented in Reusing Application Components in order to prevent naming conflicts.

Tip:

You can edit the default values used in application templates, as well as create your own templates. To do so, choose **Application > Manage Templates**.

Figure 1-4 shows the different projects, packages, directories, and files for the Summit ADF sample application, as displayed in the Applications window.

Figure 1-4 Summit ADF Sample Application Projects, Packages, and Directories



```
Applications

    oracle.summit.base
    oracle.summit.model
      diagram
      entities
      services
      test
      views
      Model.jpx
      ModelBundle.properties
ViewController
  Application Sources
  Web Content
    carousel
    images
    orders
    WEB-INF
    Page Flows
    Customers.jsff
    index.jsf
```

For more information, see the "Managing Applications and Projects" section of *Developing Applications with Oracle JDeveloper*.

When you work with your files, you use mostly the Applications window, editor window, the Structure window, and the Properties window, as shown in Figure 1-5. The editor window allows you to view many of your files in a WYSIWYG environment, or you can view a file in an overview editor where you can declaratively make changes, or you can view the source code for the file. The Structure window shows the structure of the currently selected file. You can select objects in this window and then edit the properties for the selection in the Properties window.

Modeling with Database Object Definitions

In JDeveloper, you can work with a database that is online, or, after you create your application workspace, you can copy database objects from a database schema to an offline database or project where they become available as offline database objects, saved as `.xml` files. With either an online or offline database, you can then create and edit database object definitions within a project. You can also compare your offline database objects with other offline or live database schemas and generate SQL statements (including `CREATE`, `REPLACE`, and `ALTER`).

For example, you can drag a table from a database connection that your application defines onto a database diagram and JDeveloper will give you the choice to model the database object live or offline (to create the `.xml` file representation of the object). Modeling database definitions, such as tables and foreign keys, visually captures the essential information about a schema. You can use the diagram to drag and drop columns and keys to duplicate, move, and create foreign key relationships. Working in offline mode, whenever you model a node on a diagram, JDeveloper creates the underlying offline object and lists it in the Applications window. Working with a live schema, JDeveloper updates the live database object as you amend the diagram. You can create multiple diagrams from the same offline database objects and spread your offline database across multiple projects.

Using a database diagram like the one shown in Figure 1-6 you can visualize the following:

- Tables and their columns

- Foreign key relationships between tables
- Views
- Offline sequences and synonyms

In addition to using the diagram directly to create and edit database objects, you can work with specific database object editors. After you have finished working with the offline database objects, you can generate new and updated database definitions to online database schemas.

When you work with the database diagram you can customize the diagram to change the layout, change how objects are represented and grouped, add diagram annotations to specify dependencies or links (such as URLs), and change visual properties, such as color and font of diagram elements.

For more information about modeling database definitions with database diagrams, see the "Creating, Editing, and Dropping Database Objects" section in *Developing Applications with Oracle JDeveloper*.

Creating Use Cases

After creating an application workspace, you may decide to begin the development process by doing use case modeling to capture and communicate end-user requirements for the application to be built. Figure 1-7 shows a simple diagram for an HR administrator creating a new employee that you might design using the UML modeler in JDeveloper. Using diagram annotations, you can capture particular requirements about what end users might need to see on the screens that will implement the use case. For example, in this use case, it is noted that the user will choose to create a new employee while viewing a list of all employees.

Figure 1-7 Use Case Diagram for Viewing Order History

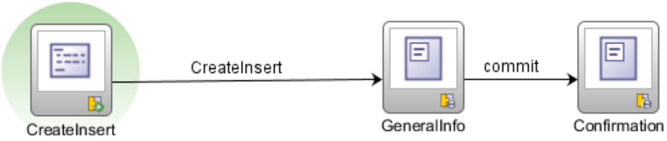
For more information about creating use case diagrams, see the "Developing Applications Using Modeling" chapter of *Developing Applications with Oracle JDeveloper*.

Designing Application Control and Navigation Using ADF Task Flows

By modeling the use cases, you begin to understand the kinds of user interface pages that will be required to implement end-user requirements. At this point, you can use these diagrams as documentation tools that will help as you begin to design the flow of your application. In a Fusion web application, you use **ADF task flows** instead of standard JSF navigation flows. Task flows provide a more modular and transaction-aware approach to navigation and application control. Like standard JSF navigation flows, task flows contain mostly viewable pages (or page fragments). Aside from navigation, task flows can also have nonvisual activities that can be chained together to affect the page flow and application behavior. For example, these nonvisual activities can call methods on managed beans, evaluate an EL expression, or call another task flow. This facilitates reuse, as business logic can be invoked independently of the page being displayed.

Figure 1-8 shows a task flow for creating an employee. In this task flow, `GeneralInfo` and `Confirmation` are view activities that represent pages, while `CreateInsert` is a method call activity. When the user enters this flow, the `CreateInsert` activity is invoked (because it is the entry point for the flow, as denoted by the green circle) and the corresponding method is called. Because this is a call to a method, and the method itself is not included in the task flow, the method can be reused elsewhere in the application. Or, the logic in the method could be changed, without affecting the metadata for the page flow. From there, the flow continues to the `GeneralInfo` page, and once the data is submitted, to the `Confirmation` page.

Figure 1-8 Task Flow to Create an Employee



ADF Controller provides a mechanism to define navigation using **control flow** rules. The control flow rule information, along with other information regarding the flow, is saved in a configuration file. Figure 1-9 shows the Structure window for the task flow. This window shows each of the items configured in the flow, such as the control flow rules. The Properties window (by default, located at the bottom right) allows you to set values for the different elements in the flow.

Aside from pages, task flows can also coordinate page fragments. Page fragments are JSF documents that are rendered as content in other JSF pages. You can create page fragments and the control between them in a **bounded task flow** as you would create pages, and then insert the entire task flow into another page as a **region**. Because it is simply another task flow, the region can independently execute methods, evaluate expressions, and display content, while the remaining content on the containing page stays the same.

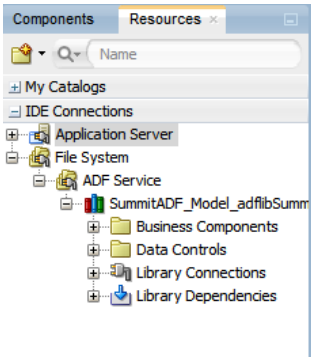
Regions also facilitate reuse. You can create a task flow as a region, determine the pieces of information required by a task and the pieces of information it might return, define those as parameters and return values of the region, then drop the region on any page in an application. Depending on the value of the parameter, a different view can display.

The chapters in Creating ADF Task Flows contain information about using task flows. For general information about task flows and creating them, see Getting Started with ADF Task Flows . For information about task flow activities, see Working with Task Flow Activities . If you need to pass parameters into or out of task flows, see Using Parameters in Task Flows. For more information about regions, see Using Task Flows as Regions . For information about advanced functionality that task flows can provide, such as transactional capabilities and creating mandatory sequences of pages (known as **trains**), see Creating Complex Task Flows . For information about using task flows to create dialogs, see Using Dialogs in Your Application.

Identifying Shared Resources

When designing the application, you may find that some aspects of your application can be reused throughout the application. For example, you might have one developer that creates the business components, and another that creates the web interface. The business component developer can then save the project and package it as a library. The library can be sent to other developers who can add it to their resource catalog, from which they can drag and drop it onto any page where it's needed. Figure 1-10 shows a resources catalog in the Resources window of JDeveloper.

Figure 1-10 Resources Window in JDeveloper



Be sure to note all the tasks that can possibly become candidates for reuse. Reusing Application Components provides more information about the ADF artifacts that can be packaged and reused as an ADF library, along with procedures both for creating and using the libraries.

Creating a Data Model to Access Data with ADF Business Components

Typically, when you implement business logic as **ADF Business Components**, you do the following:

- Create **entity objects** to represent tables that you expect your application to perform a transaction against. The entity objects can actually be created from an existing database schema. Add validation and business rules as needed.
- Create **view object**s that work with the entity objects to query the database. These view objects will be used to make the data available for display at your view layer. You can also create read-only view objects, which you might use to

display static lists. Like entity objects, view objects can be created from an existing database schema.

- Create the **application module**, which is the transactional component that UI clients use to work with application data. The application module provides the interface to the business services that a consumer of those services (such as the UI layer of your application) will use. This application module contains view object instances in its data model along with any custom methods that users will interact with through the application's web pages.
- If needed, publish your services as web services for remote invocation.

The chapters contained in Building Your Business Services provide information on creating each of these artifacts. The chapters in Completing Your Application provide additional information, such as extending business objects, tuning, and state management.

Creating a Layer of Business Domain Objects for Tables

Once you have an understanding of the data that will be presented and manipulated in your application, if you haven't already done so, you can build your database (for more information, see the "Designing Databases Within Oracle JDeveloper" chapter of *Developing Applications with Oracle JDeveloper*). Once the database tables are in place, you can create a set of entity objects that represents them and simplifies modifying the data they contain. When you use entity objects to encapsulate data access and validation related to the tables, any pages you build today or in the future that work with these tables are consistently validated. Any relationships between the tables will be reflected as associations between the corresponding entity objects.

Once the entity objects are created, you can define control and attribute hints that simplify the display of the entities in the UI, and you can also add behaviors to the objects. For more information, see Creating a Business Domain Layer Using Entity Objects.

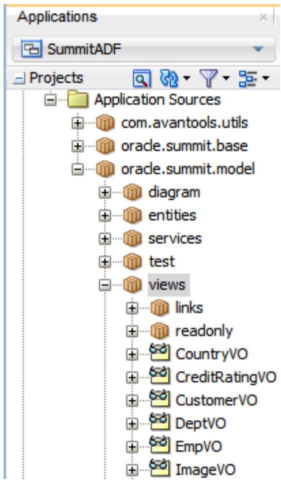
Building the Business Services

Once the reusable layer of business objects is created, you can implement the application module's data model and service methods with which a UI client can work.

The application module's data model is composed of instances of the view object components you create that encapsulate the necessary queries. View objects can join, project, filter, sort, and aggregate data into the shape required by the end-user task being represented in the user interface. When the end user needs to update the data, your view objects reference entity objects in your reusable business domain layer. View objects are reusable and can be used in multiple application modules. For more information, see Defining SQL Queries Using View Objects.

Figure 1-11 shows the `oracle.summit.model.view` package, which contains many of the queries needed by the application.

Figure 1-11   View Objects in the Summit ADF Sample Application



Additionally, you may find that you need to expose functionality to external applications. You can do this by exposing this functionality through a service interface. For example, the `ServiceAppModule` application module is exposed as a web service. This web service exposes the `CustomersView` and OrdersView view instances, as shown in Figure 1-12. For more information, see Creating SOAP Web Services with Application Modules.

Remote Service Definition File: ServiceAppModuleService.wsdl
Remote Server Class: ServiceAppModuleServiceImpl.java

Testing and Debugging Business Services with the Oracle ADF Model Tester

While you develop your application, you can iteratively test your business services using the Oracle ADF Model Tester. The tester allows you to test the queries, business logic, and validation of your business services without having to use or create a user interface or other client to test your services. Using the tester allows you to test out the latest queries or business rules you've added, and can save you time when you're trying to diagnose problems. For more information about developing and testing application modules, see Implementing Business Services with Application Modules.

The tester also interacts with the ADF Declarative Debugger to allow debug your business services. You can set breakpoints on any custom methods you create. For more information, see Using the Oracle ADF Model Tester for Testing and Debugging.

Implementing the User Interface with JSF

From the page flows you created during the planning stages, you can double-click the page icons to create the actual JSF files. When you create a JSF page for an ADF Faces application, by default, you create a Facelets XHTML file that uses the `.jsf` extension. Facelets is a JSF-centric XML view definition technology that provides an alternative to using the JSP engine.

> **Tip:**
>
> While Facelet pages can use any well formed XML file, when you create a Facelet page in JDeveloper, it is created as an XHTML file.

ADF Faces provides a number of components that you can use to define the overall layout of the page. JDeveloper contains predefined quick start layouts that use these components to provide you with an efficient way to correctly determine the layout of your pages. You can choose from one-, two-, or three-column layouts, and then determine how you want the columns to behave. You can also choose to apply themes to the layouts, which adds color to some of the components for you. For more information see the "Using Quick Start Layouts" section of *Developing Web User Interfaces with Oracle ADF Faces*.

Oracle ADF also allows you to create and use your own page templates. When creating templates, you can determine the layout of the page (either using one of the quick layout templates or creating the layout manually), provide static content that must appear on all pages, and create placeholder attributes that can be replaced with valid values for each page. Each time the template is changed, for example if the layout changes, any page that uses the template will reflect the update.

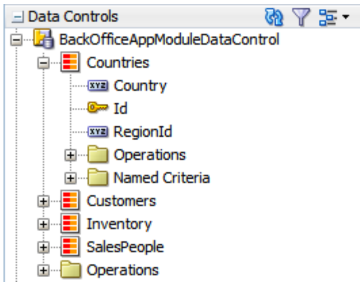
The chapters in Creating a Databound Web User Interface provide information on creating different types of UI functionality, from basic forms to more complex search capabilities.

Data Binding with ADF Model

In a typical JSF application, you bind the UI component attributes to properties or methods on managed beans. The JSF runtime manages instantiating these beans on demand when any EL expression references them for the first time. However, in an application that uses ADF Model, JDeveloper automatically binds the UI component attributes to ADF Model, which uses XML configuration files that drive generic data binding features. It implements concepts that enable decoupling the user interface technology from the business service implementation: **data controls** and **declarative bindings**.

Data controls use XML configuration files to describe a service. At design time, visual tools like JDeveloper can leverage that metadata to allow you to declaratively bind UI components to any data control operation or data collection, creating bindings. For example, Figure 1-13 shows the `BackOfficeAppModuleDataControl` data control as it appears in the Data Controls panel of JDeveloper.

Figure 1-13 BackOfficeAppModuleDataControl

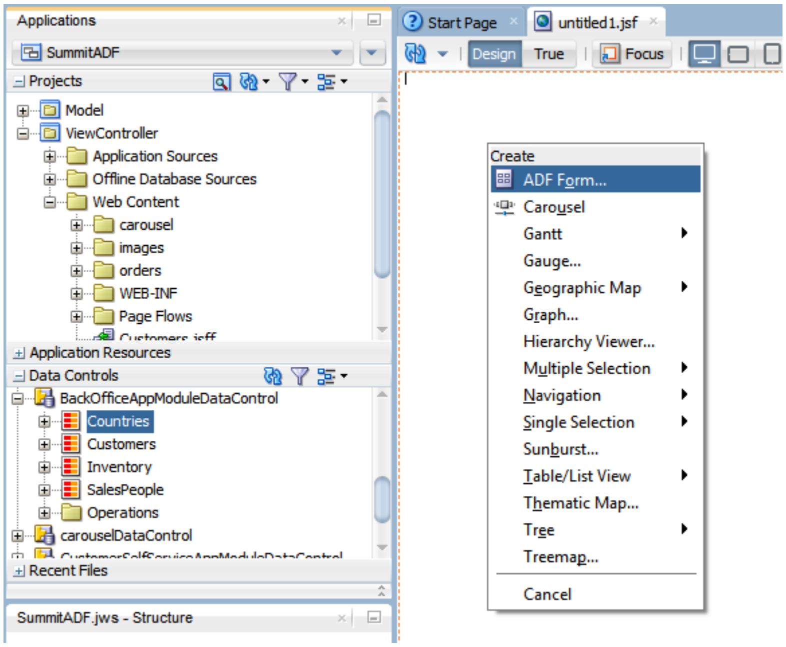


Note that the collections that display in the panel represent the set of rows returned by the query in each view object instance contained in the `BackOfficeAppModuleDataControl` application module. For example, the `Countries` data collection in the Data Controls panel represents the `Countries` view object instance in the `BackOfficeAppModuleDataControl's` data model. The attributes available in each row of the respective data collections appear as child nodes. The data collection level Operations node contains the built-in operations that ADF Model supports on data collections, such as `previous`, `next`, `first`, `last`, and so on.

> **Note:**
>
> If you create other kinds of data controls for working with web services, XML data retrieved from a URL, JavaBeans, or EJBs, these would also appear in the Data Controls panel with an appropriate display. When you create one of these data controls in a project, JDeveloper creates metadata files that contain configuration information. These additional files do not need to be explicitly created when you are working with Oracle ADF application modules, because application modules are already metadata-driven components, and so contain all the information necessary to be exposed automatically as ADF Model data controls.

Using the Data Controls panel, you can drag and drop a data collection onto a page in the visual editor, and JDeveloper creates the necessary bindings for you. Figure 1-14 shows the `Countries` collection being dragged from the Data Controls panel, and dropped as a form onto a JSF page.

Figure 1-14   Declaratively Creating a Form Using the Data Controls Panel



The first time you drop a databound component from the Data Controls panel on a page, JDeveloper creates an associated **page definition file**. This XML file describes the group of bindings supporting the UI components on a page. ADF Model uses this file at runtime to instantiate the page's bindings. These bindings are held in a request-scoped map called the **binding container**. Each time you add components to the page using the Data Controls panel, JDeveloper adds appropriate binding entries into this page definition file. Additionally, as you perform drag and drop data binding operations, JDeveloper creates the required tags representing the JSF UI components on the JSF page. For more information about using the Data Controls panel, see Using ADF Model in a Fusion Web Application.

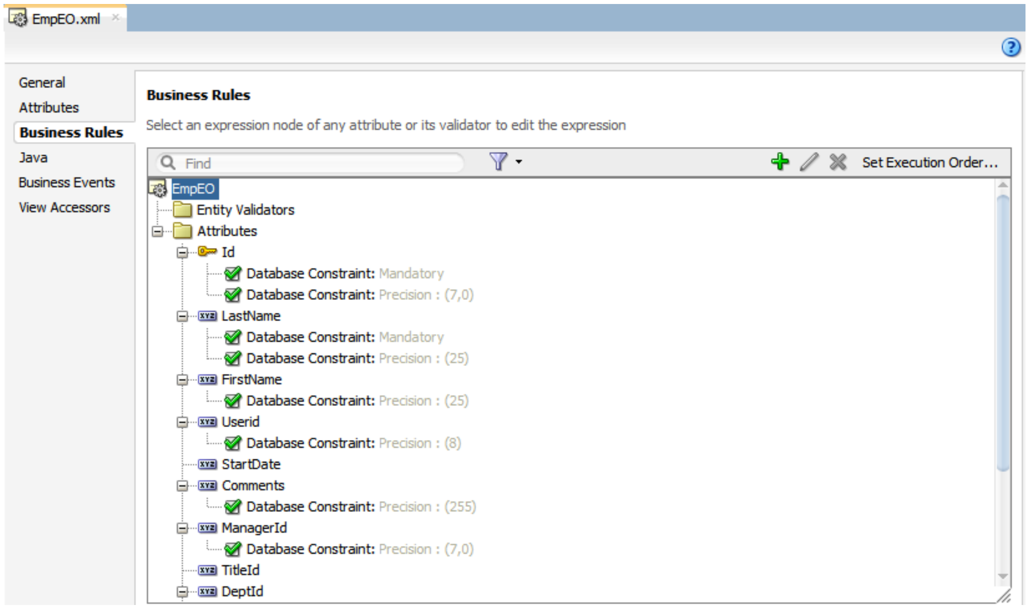
Aside from forms and tables that display or update data, you can also create search forms, and databound charts and graphs. For more information about using data controls to create different types of pages, see the chapters contained in Creating a Databound Web User Interface . For more information about the Data Controls panel and how to use it to create any UI data bound component, see Using ADF Model in a Fusion Web Application. For detailed information about ADF Model, see About ADF Model in *Developing Applications with Oracle ADF Data Controls*.

Validation and Error Handling

You can add validation to your business objects declaratively using the overview editors for entity and view objects. In the case of entities, the business rules always reflect the data type constraints defined on the attributes.

Figure 1-15 shows the Business Rules page of the overview editor for the EmpEO entity object.

Figure 1-15   Setting Validation in the Overview Editor



Business Rules

Select an expression node of any attribute or its validator to edit the expression

```
EmpEO
  Entity Validators
  Attributes
    Id
      Database Constraint: Mandatory
      Database Constraint: Precision : (7,0)
    LastName
      Database Constraint: Mandatory
      Database Constraint: Precision : (25)
    FirstName
      Database Constraint: Precision : (25)
    Userid
      Database Constraint: Precision : (8)
    StartDate
    Comments
      Database Constraint: Precision : (255)
    ManagerId
      Database Constraint: Precision : (7,0)
    TitleId
    DeptId
```

Along with providing the validation rules, you also set the error messages to display when validation fails. To supplement this declarative validation, you can also use Groovy-scripted expressions. For more information about creating validation at the service level, see Defining Validation and Business Rules Declaratively.

Additionally, ADF Faces input components have built-in validation capabilities. You set one or more validators on a component either by setting the `required` attribute or by using the prebuilt ADF Faces validators. You can also create your own custom validators to suit your business needs. For more information, see the "Validating and Converting Input" chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

You can create a custom error handler to report errors that occur during execution of an application. Once you create the error handler, you only need to register the handler in one of the application's configuration files.

Adding Security

Oracle ADF provides a security implementation that is based on Java Authentication and Authorization Service (JAAS). It enables applications to authenticate users and enforce authorization. The Oracle ADF implementation of JAAS is permission-based. You define these permissions and then grant them on application roles that you associate with users of the application. For more information about securing your application, see Enabling ADF Security in a Fusion Web Application.

Testing and Debugging the Web Client Application

Testing an Oracle ADF web application is similar to testing and debugging any other Java EE application. Most errors result from simple and easy-to-fix problems in the declarative information that the application defines or in the EL expressions that access the runtime objects of the page's ADF binding container. In many cases, examination of the declarative files and EL expressions resolve most problems.

For errors not caused by the declarative files or EL expressions, you can use the ADF Logger, which captures runtime trace messages from ADF Model API. The trace includes runtime messages that may help you to quickly identify the origin of an application error. You can also search the log output for specific errors.

JDeveloper also includes the ADF Declarative Debugger, a tool that allows you to set breakpoints on declarative aspects of Oracle ADF, such as the binding layer, taskflows and more. When a breakpoint is reached, the execution of the application is paused and you can examine the data that the ADF binding container has to work with, and compare it to what you expect the data to be. Testing and Debugging ADF Components contains useful information and tips on how to successfully debug a Fusion web application.

For testing purposes, JDeveloper provides integration with JUnit. You use a wizard to generate regression test cases. For more information, see Regression Testing with JUnit.

Refactoring Application Artifacts

Using JDeveloper, you can easily rename or move the different components in your application. When you use JDeveloper to refactor the business components of your data model project, you can rename components or move them to a different package and JDeveloper will find and update all references to the refactored component. Whenever possible, you should use JDeveloper's refactoring actions to avoid error-prone manual editing of the project. For more information, see Refactoring a Fusion Web Application .

Deploying a Fusion Web Application

You can deploy a Fusion web application to either the integrated WebLogic server within JDeveloper or to a supported standalone instance. For more information about deployment, see Deploying Fusion Web Applications.

Integrating a Fusion Web Application

You can build your Fusion web application so that it can easily integrate with other applications. You can publish your application modules as services. You can also create events that can be used for example, to initiate business processes. See Creating SOAP Web Services with Application Modules. Your application modules can also call other web services directly. See Calling a Web Service from an Application Module. You can also integrate your application using task flows. For example, a task flow can be used to initiate a business process flow.

Working Productively in Teams

Working effectively in a team is crucial for application development. It requires effective communication, collaboration, and time management between the developers working on developing different parts of an ADF application.

Often, applications are built in a team development environment. While a team-based development process follows the development cycle outlined in Overview of Building an Application with Oracle ADF ,many times developers are creating the different parts of the application simultaneously. Working productively means team members divide the work, understand how to enforce standards, and manage source files with a source control system, in order to ensure efficient application development.

Before beginning development on any large application, a design phase is typically required to assess use cases, plan task flows and screens, and identify resources that can be shared.

The following list shows how the work for a typical Fusion web application might be broken up once an initial design is in place:

- Infrastructure

  An administrator creates Ant scripts (or other script files) for building and deploying the finished application. SQL scripts are developed to create the database schema used by the application.

- Entity objects

  In a large development environment, it may be that a separate development group builds all entity objects for the application. Because the rest of the application depends on these objects, entity objects should be one of the first steps completed in development of the application or part of the application.

  Once the entity objects are finished, they can be shared with other teams using Oracle ADF libraries (see Packaging a Reusable ADF Component into an ADF Library for more information). The other teams then access the objects by adding to them to a catalog in the Resources window. In your own application development process, you may choose not to divide the work this way. In many applications, entity objects and view objects might be developed by the same team (or even one person) and would be stored within one project.

- View objects

  After the entity objects are created and provided either in a library or within the project itself, view objects can be created as needed to display data (in the case of building the UI) or supply service data objects (when data is needed by other applications in a SOA infrastructure).

  During development, you may find that two or more view objects are providing the same functionality. In some cases, these view objects can be easily combined by altering the query in one of the objects so that it meets the needs of each developer's page or service. **View criteria**, in particular, enable developers to easily adapt a query to distinct usages.

  Once the view objects are in place, you can create the application module, data controls, and add any needed custom methods. The process of creating view objects, reviewing for redundancy, and then adding them to the application module can be an iterative one.

- User interface (UI) creation

  With a UI design in place, the view objects in place and the data controls created, the UI can be built either by the team that created the view objects (as described in the previous bullet point) or by a separate team. You can also develop using a UI-first strategy, which would allow UI designers to create pages before the data controls are in place. Oracle ADF provides placeholder data controls that UI designers can use early in the development cycle. See Designing a Page Using Placeholder Data Controls .

Enforcing Standards

Because numerous individuals divided into separate teams will be developing the application, you should enforce a number of standards before development begins to ensure that all components of the application will work together efficiently. The following are areas within an application where it is important to have standardization in place when working in a team environment:

- Code layout style

  So that more than one person can work efficiently in the code, it helps to follow specific code styles. JDeveloper allows you to choose how the built-in code editor behaves. While many of the settings affect how the user interacts with the code editor (such as display settings), others affect how the code is formatted. For example, you can select a code style that determines things like the placement of opening brackets and the size of indents. You can also import any existing code styles you may have, or you can create your own and export them for use by the team. For more information, see the "How to Set Preferences for the Source Editor" section in *Developing Applications with Oracle JDeveloper*.

- Package naming conventions

  You should determine not only how packages should be named, but also the granularity of how many and what kinds of objects will go into each package.

- Pages

  You can create templates to be used by all developers working on the UI, as described in Implementing the User Interface with JSF. This not only ensures that all pages will have the same look and feel, but also allows you to make a change in the template and have the change appear on all pages that use it. For more information, see Using Page Templates.

  Aside from using templates, you should also devise a naming standard for pages. For example, you may want to have names reflect where the page is used in the application. To achieve this goal, you can create subdirectories to provide a further layer of organization.

- Connection names: Unlike most JDeveloper and Oracle ADF objects that are created only once per project and by definition have the same name regardless of who sees or uses them, database connection names might be created by individual team members, even though they map to the same connection details. Naming discrepancies may cause unnecessary conflicts. Team members should agree in advance on common, case-sensitive connection names that should be used by every member of the team.

Using a Source Control System

When working in a team environment, you will need to use a source control system. By default, JDeveloper provides support for the Subversion source control system, and others (such as CVS) are available through extensions. You can also create an extension that allows you to work with another system in JDeveloper. For information about using these systems within JDeveloper, see the "Versioning Applications with Source Control" chapter of *Developing Applications with Oracle JDeveloper*.

Following are suggestions for using source control with a Fusion web application:

- Checking out files

Using JDeveloper, you can create a connection to the source control server and use the source control window to check out the source. When you work locally in the files, the pending changes window notifies you of any changed files. You can create a script using Apache Ant (which is integrated into JDeveloper). You can then use the script to build all application workspaces locally. This can ensure that the source files compile before you check the changed files into the source control repository. To find out how to use Apache Ant to create scripts, see the "Building with Apache Ant" section of *Developing Applications with Oracle JDeveloper*.

- Automating builds

  Consider running a continuous integration tool. Once files are checked into the source server, the tool can be used to recognize either that files have changed or to check for changed files at determined intervals. At that point, the tool can run an Ant script on the server that copies the full source (note that this should be a copy, and not a checkout), compiles those files, and if the compilation is successful, creates a zip file for consumers (not developers) of the application to use. The script should then clean up the source directory. Running a continuous integration tool will improve confidence in the quality of the code in the repository, encourage developers to update more often, and lead to smaller updates and fewer conflicts. Hudson (`http://hudson-ci.org/`) is one example of a continuous integration tool.

- Updating and committing files

  When working with Subversion, updates and commits should be done at the Working Copy level, not on individual files. If you attempt to commit and update an individual file, there is a chance you will miss a supporting metadata file and thereby corrupt the committed copy of the application.

- Resolving merge conflicts

  When you add or remove business components in a data model project with ADF Business Components, JDeveloper reflects it in the project file (`.jpr`). When you create (or refactor) a component into a new package, JDeveloper reflects that in the project file and in the ADF Business Components project configuration file (`.jpx`). Although the XML format of these project control files has been optimized to reduce occurrences of merge conflicts, merge conflicts may still arise and you will need to resolve them in JDeveloper using the **Resolve Conflicts** option on the context menu of each affected file.

  After resolving merge conflicts in any ADF Business Components XML component descriptor files, the project file (`.jpr`) for a data model project, or the corresponding ADF Business Components project configuration file (`.jpx`), close and reopen the project to ensure that you're working with latest version of the component definitions. To do this, select the project in the Applications window, choose **File** > **Close** from the JDeveloper main menu, and then expand the project again in the Applications window.

Generation of Complete Web Tier Using Oracle JHeadstart

Oracle JHeadstart application generator is an additional extension for JDeveloper that offers additional productive advantage in creating web-based, JEE business applications. Using Oracle ADF's built-in features, Oracle JHeadstart adds an additional capability to iteratively generate a fully-working web tier using ADF Faces as View layer and ADF Task Flows as Controller layer.

As you'll learn throughout the rest of this guide, JDeveloper and Oracle ADF give you a productive, visual environment for building richly functional, database-centric

Java EE applications with a maximally declarative development experience. However, if you are used to working with tools like Oracle Designer that offer *complete* user interface generation based on a higher-level application structure definition, you may be looking for a similar facility for your Java EE development. If so, then the Oracle JHeadstart application generator may be of interest to you. It is an additional extension for JDeveloper that uses Oracle ADF's built-in features to offer complete web-tier generation for your application modules. Starting with the data model you've designed for your ADF business service, you use the integrated editors that JHeadstart adds to the JDeveloper environment to iteratively refine a higher-level application structure definition. These editors control the functionality and organization of the view objects' information in your generated web user interface. By checking boxes and choosing various options from **dropdown lists**, you describe a logical hierarchy of pages that can include multiple styles of search regions, list of values (LOVs) with validation, shuttle controls, nested tables, and other features. These declarative choices use terminology familiar to Oracle Forms and Designer users, further simplifying web development. Based on the application structure definition, you generate a complete web application that automatically implements the best practices described in this guide, easily leveraging the most sophisticated features that Oracle ADF and JSF have to offer.

Whenever you run the JHeadstart application generator, rather than generating *code*, it creates (or regenerates) all of the declarative view and controller layer artifacts of your Oracle ADF-based web application. These artifacts use ADF Model and work with your ADF application module as their business service. The generated files are the same kinds you produce when using the JDeveloper built-in visual editors. The key difference is that JHeadstart creates them in bulk, based on a higher-level definition that you can iteratively refine until the generated pages match your end users' requirements as closely as possible. The generated files include:

- JSF pages with databound ADF Faces UI components
- ADF Model page definition XML files describing each page's data bindings
- JSF navigation rules to handle page flow
- Resource files containing localizable UI strings

Once you've generated a maximal amount of your application's web user interface, you can spend your time using the productive environment of JDeveloper to tailor the results or to concentrate your effort on additional showcase pages that need special attention. Once you've modified a generated page, you can adjust a setting to avoid regenerating that page on subsequent runs of the application generator. Of course, since both the generated pages and your custom designed ones leverage the same ADF Faces UI components, all of your pages automatically inherit a consistent look and feel. For more information on how to get a fully functional trial of JHeadstart for evaluation, including details on pricing, support, and additional services, see the JHeadstart page on the Oracle Technology Network at`http://www.oracle.com/technetwork/developer-tools/jheadstart/ overview/index.html`

Other Resources for Learning Oracle ADF

To learn how to best use Oracle ADF in applications, you can take the help of many other resources in addition to the developers guide. Some of these resources are step-by-step tutorials, technical papers, pre-recorded sessions, books, trainings, certifications, and so forth.

In addition to this developers guide, Oracle also offers the following resources to help you learn how you can best use Oracle ADF in your applications:

- Tutorials: JDeveloper cue cards provide step-by-step support for the application development process using Oracle ADF. They are designed to be used either with the included examples and a sample schema, or with your own data. The tutorials also include topics that provide more detailed background information, viewlets that demonstrate how to complete the steps in the card, and code samples. Tutorials provide a fast, easy way to become familiar with the basic features of Oracle ADF, and to work through a simple end-to-end task.
- Technical papers, samples, and more on Oracle Technology Network, including ADF Insider, recorded sessions that will help you get up to speed with Oracle ADF.
- Oracle Press and Packt Publishing offer a number of books on JDeveloper and Oracle ADF. See `http://www.oracle.com/technetwork/developer-tools/adf/learnmore/index.html`
- Oracle University offers training and certification for Oracle ADF. See `http://education.oracle.com`.
- Other developer guides for supporting Oracle ADF technology: Oracle provides developer guides for data controls (other than for ADF Business Components), ADF Faces, and **ADF Desktop Integration** to name a few. For information about related guides, see Related Documents, in this book's Preface.

2

Introduction to the ADF Sample Application

This chapter describes how to run the Summit sample applications for Oracle ADF. These samples exist to demonstrate the use of the Fusion web application technology stack to create transaction-based web applications. Details about the schema and features that implement the Summit sample applications for Oracle ADF are also provided.
Before examining the individual components and their source code in depth, you may find it helpful to install and become familiar with the functionality of the Summit sample applications for Oracle ADF. The demonstration application is used as an example throughout this guide to illustrate points and provide code samples.

This chapter includes the following sections:

- About the Summit Sample Applications for Oracle ADF
- Setting Up the Summit Sample Applications for Oracle ADF
- Running the Core Summit ADF Sample Application in the SummitADF Workspace
- Running the Standalone Samples from the SummitADF_Examples Workspace
- Running the Sample Application in the SummitADF_TaskFlows Workspace
- Running the Standalone Samples in the SummitADF_DVT Workspace

About the Summit Sample Applications for Oracle ADF

Summit sample applications are a collection of end-to-end application samples developed by Fusion Middleware Product Management. The Summit samples demonstrate various capabilities of Oracle ADF.

The Summit sample applications for Oracle ADF are a set of applications developed with the purpose of demonstrating common use cases in Fusion web applications, including the integration between the components of the Oracle ADF technology stack (**ADF Business Components**, **ADF Faces**, ADF Data Visualization Tools (DVT), **ADF Controller**, and **ADF Desktop Integration**).

The sample applications are organized into several JDeveloper application workspaces that focus on particular features of the ADF component functionality. Each of the application workspaces uses the same underlying database schema. This approach makes it very easy to access the source code, and also to experience the runtime behavior of the samples in its workspace. Collectively, these sample applications cover the breadth of Oracle ADF functionality for Fusion web applications and are referred to as *Summit sample applications for Oracle ADF*. Chapters of this guide describe sample code drawn from these sample applications.

The core Summit ADF sample application, supported by the underlying Summit ADF schema, serves as a good introduction to Oracle ADF. It provides a runnable application based on a fictional customer management website and demonstrates many user interface design and database transaction features of Oracle ADF. For a detailed description of the core Summit ADF sample application and the features that it implements, see Taking a Look at the Sample Application in the SummitADF Workspace.

A more comprehensive introduction to Oracle ADF functionality is provided by the remaining Summit ADF sample applications, some of which are small standalone samples, while others are extensions of the core sample application. For a list of the Summit ADF sample application workspaces and a description of what functionality each sample provides, see Table 2-1.

In order to view and run any of the samples from its application workspace, you need to install Oracle JDeveloper Studio. You then need to download the ZIP archive files containing the Summit ADF schema and sample applications for this demonstration. Instructions to complete these tasks appear in this chapter. To begin, see Setting Up the Summit Sample Applications for Oracle ADF.

Setting Up the Summit Sample Applications for Oracle ADF

The Summit sample ADF applications contains the database scripts needed to install the summit schema.To set up the Summit sample applications for Oracle ADF, download and extract the sample applications ZIP archive files from Oracle Technology Network (OTN) web site. You will need an Oracle database and JDeveloper, utilizing a shared “summit_adf” schema, which must be installed before any of the samples can be run.

The Summit sample applications for Oracle ADF run using an Oracle database and JDeveloper. The platforms supported are the same as those supported by JDeveloper.

To prepare the environment and run the sample applications, you must download the required application resources. Included among those resources are ZIP archive files that contain the Summit ADF sample application workspaces.

Table 2-1 identifies the sample application archive files that are available for download on the Oracle Technology Network (OTN) website. You may choose to download all of the sample applications in a single archive file; or, when you want to focus on particular Oracle ADF technologies, you may select among the archive files to download just the desired samples.

Table 2-1 The Summit Sample Application Downloadable ZIP Archive Files

Downloadable Samples	ZIP Archive Description
`SummitADF1221.zip`	Contains all the Summit sample applications for Oracle ADF in one convenient download file. It also contains the build file that you will need to install the Summit ADF schema on your database. **Note:** When this ZIP file is expanded, you will have a separate application workspace for each of the sample applications listed below.
`SummitADF_Schema1221.zip`	Contains an application workspace that includes the build file needed to install the Summit ADF schema on your database. The Summit ADF schema is required to run any Summit ADF sample application. For complete details about installing the schema, see How to Install the Summit ADF Schema.

Table 2-1 (Cont.) The Summit Sample Application Downloadable ZIP Archive Files

Downloadable Samples	ZIP Archive Description
`SummitADF_Core1221.zip`	Contains an application workspace that includes the core Summit ADF sample application. This basic application consists of a web user interface and business service layer to demonstrate Oracle ADF technology in Fusion web applications. For a detailed description of this application, see Taking a Look at the Sample Application in the SummitADF Workspace.
`SummitADF_TaskFlows1221.zip`	Contains an application workspace that includes the *Summit sample application for ADF task flows*. This application builds on the core Summit ADF sample application by more fully utilizing **ADF task flows** to demonstrate ADF Security, contextual events, and task flows in Fusion web applications.
`SummitADF_DVT1221.zip`	Contains an application workspace that includes the *Summit sample application for ADF DVT components*. This application workspace consists of a set of standalone sample pages that demonstrate creation and configuration of ADF DVT components.
`SummitADF_Examples1221.zip`	Contains an application workspace that includes the *Summit standalone sample applications for Oracle ADF*. This application workspace consists of small sample applications that allow you to investigate Oracle ADF functionality that does not appear in any of the other sample applications.
`SummitADF_DI1221.zip`	Contains an application workspace that includes the *Summit sample application for ADF Desktop Integration*. This sample application builds on the core Summit sample application by more fully utilizing ADF Desktop Integration functionality. **Note:** This sample is not described in this guide. For complete details about the Summit sample for ADF Desktop Integration, see "Introduction to the ADF Desktop Integration Sample Application" in *Developing Applications with Oracle ADF Desktop Integration*.

How to Download the Application Resources

The Summit sample applications for Oracle ADF require an existing Oracle database for its data. You run the sample applications using JDeveloper.

Do the following before installing the sample applications:

To download the application resources to prepare your environment:

1. Install Oracle JDeveloper Release 12*c*, as described in Installing Oracle JDeveloper Studio in *Installing Oracle JDeveloper*.

   You will need to install the Studio configuration of Oracle JDeveloper Release 12*c* to view the application's projects and run the application in Integrated WebLogic Server. You can download JDeveloper from:

`http://www.oracle.com/technetwork/developer-tools/jdev/overview/index.html`

> **Note:**
>
> When you download and install JDeveloper, ensure that it is the Studio configuration, not the Java configuration. You can verify these details in JDeveloper from the **Help** > **About** menu option.

2. Download the ZIP archive files for the desired Summit ADF sample application workspaces, as identified in Table 2-1. When you want to install all available samples, you can download the single archive file `SummitADF1221.zip`.

   Download the desired Summit ADF sample application archive files from the following web page on the Oracle Technology Network website.

   `http://www.oracle.com/pls/topic/lookup?ctx=E26099_01&id=jdevcodesamples`

3. Install an Oracle database.

   The SQL scripts were written for an Oracle database, so you will need some version of an Oracle RDBMS, such as 11*g*, or Oracle Database Express Edition (Oracle Database XE). The scripts will not install into Oracle Database Lite. If you wish to use Oracle Database Lite or some other database, then you will need to modify the database scripts accordingly. You can download an Oracle database from:

   `http://www.oracle.com/technetwork/database/enterprise-edition/downloads/index.html`

   Specifically, the small footprint of Oracle Database XE is ideally suited for setting up the database on your local machine. You can download it from:

   `http://www.oracle.com/technetwork/database/database-technologies/express-edition/downloads/index.html`

How to Install the Summit ADF Schema

To install the Summit ADF schema, extract the schema files, configure the database connection, and execute the `build_summit_schema.sql` script in JDeveloper.

Before you begin:

It may be helpful to have an understanding of the schema that the Summit sample applications for Oracle ADF use. For more information, see What Happens When You Install the Summit ADF Schema.

You will need to complete these tasks:

- Install Oracle JDeveloper Studio and meet the installation prerequisites. The Summit sample applications for Oracle ADF require an existing Oracle database. For details, see How to Download the Application Resources.
- Download the Summit ADF archive file containing the Summit ADF schema application workspace from the Oracle Technology Network to a local directory. For details, see How to Download the Application Resources.

To install the Summit ADF schema to your database:

1. Navigate to the location where you downloaded the Summit ADF schema archive file and unzip it.
2. Start JDeveloper and in the main menu, choose **File** and then **Open**.
3. In the Open dialog, navigate to where you expanded the ZIP file for the `SummitADF_Schema` directory, select the `Summit_Schema.jws` application workspace and click **Open**.

> **Note:**
>
> If you downloaded the single archive file `SummitADF1221.zip`, the `Summit_Schema.jws` file is in the `Schema` folder. Double-click the `Schema` folder. Select `Summit_Schema.jws` and click Open.

4. In the Applications window, expand the Application Resources panel.
5. Right-click **Connections** and choose **New Connection** and then **Database**.
6. In the Create Database Connection dialog, modify the properties shown in Table 2-2 for your environment. For help with the dialog, press F1 or click **Help.**

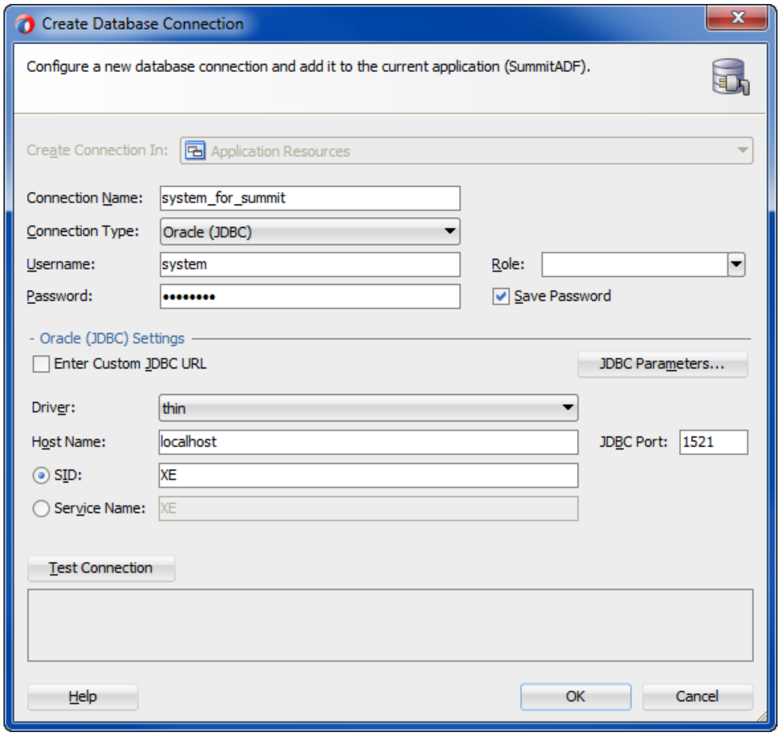
Table 2-2 Properties Required to Install a Summit ADF Sample Application

Property	Description
Connection Name	Descriptive name for the connection. This name must be a valid Java identifier, such as `system_for_summit`.
User Name	The system user for your database. For example: `system`
Password	The password for the system user.
Driver	The JDBC driver for the database. Select a value from the dropdown menu. The default is thin, which is also the default value to specify for Oracle Database XE and any other Oracle database that is not using Oracle Call Interface (OCI).
Host Name	The name of the server running the Oracle database. Use an IP address or a host name that can be resolved by TCP/IP. The default value is `localhost`.
SID	The unique system identifier (SID) of an Oracle Database instance. The default is `XE`, which is also the default value to specify if your database server is running Oracle Database XE. If your server is running another Oracle database, the SID is typically `ORCL`.
JDBC Port	The port of your database. The default value is 1521.

> **Note:**
>
> If your server resides on a remote machine, you may also need to modify the script that builds the schema. To open the script, right-click `build_summit_schema.sql` and choose **Open**.

Figure 2-1 shows the completed Create Database Connection dialog. In this example, the connection is made to an Oracle Database XE instance residing on a local machine.

Figure 2-1 Create Database Connection Dialog for Summit ADF Schema



Create Database Connection

Configure a new database connection and add it to the current application (SummitADF).

Create Connection In: Application Resources

Connection Name: system_for_summit

Connection Type: Oracle (JDBC)

Username: system

Role:

Password: ••••••••

☑ Save Password

Oracle (JDBC) Settings

□ Enter Custom JDBC URL

Driver: thin

Host Name: localhost

JDBC Port: 1521

● SID: XE

○ Service Name: XE

7. Click **Test Connection** to verify that you have a working connection.
8. Click **OK** to create the connection and exit the dialog.
9. In the Applications window, in the Projects panel, expand Database and then Resources.
10. Right-click `build_summit_schema.sql` and choose **Run in Sql*Plus >** *connection name*.

    The connection name displayed is the one you configured in Step 6.
11. In the SQL*Plus Connection dialog, verify that the information matches the configuration you specified in Step 6 and click **OK**.
12. In the SQL*Plus Location dialog, click **Browse** and locate the `sqlplus.exe` executable for your database.

    Typically, the executable is installed in the `BIN` directory under `$ORACLE_HOME`, where `$ORACLE_HOME` represents the path to your Oracle database installation.

13. Click **Open** to select the `sqlplus.exe` executable and then **OK** to exit the dialog.
14. In the SQL*Plus window, enter the password for the system user you specified in Step 6.

    Once you enter the password, the Ant build script creates the Summit ADF sample application users and populates the tables in the Summit ADF schema. In the Messages - Log window, you will see a series of SQL scripts and finally:

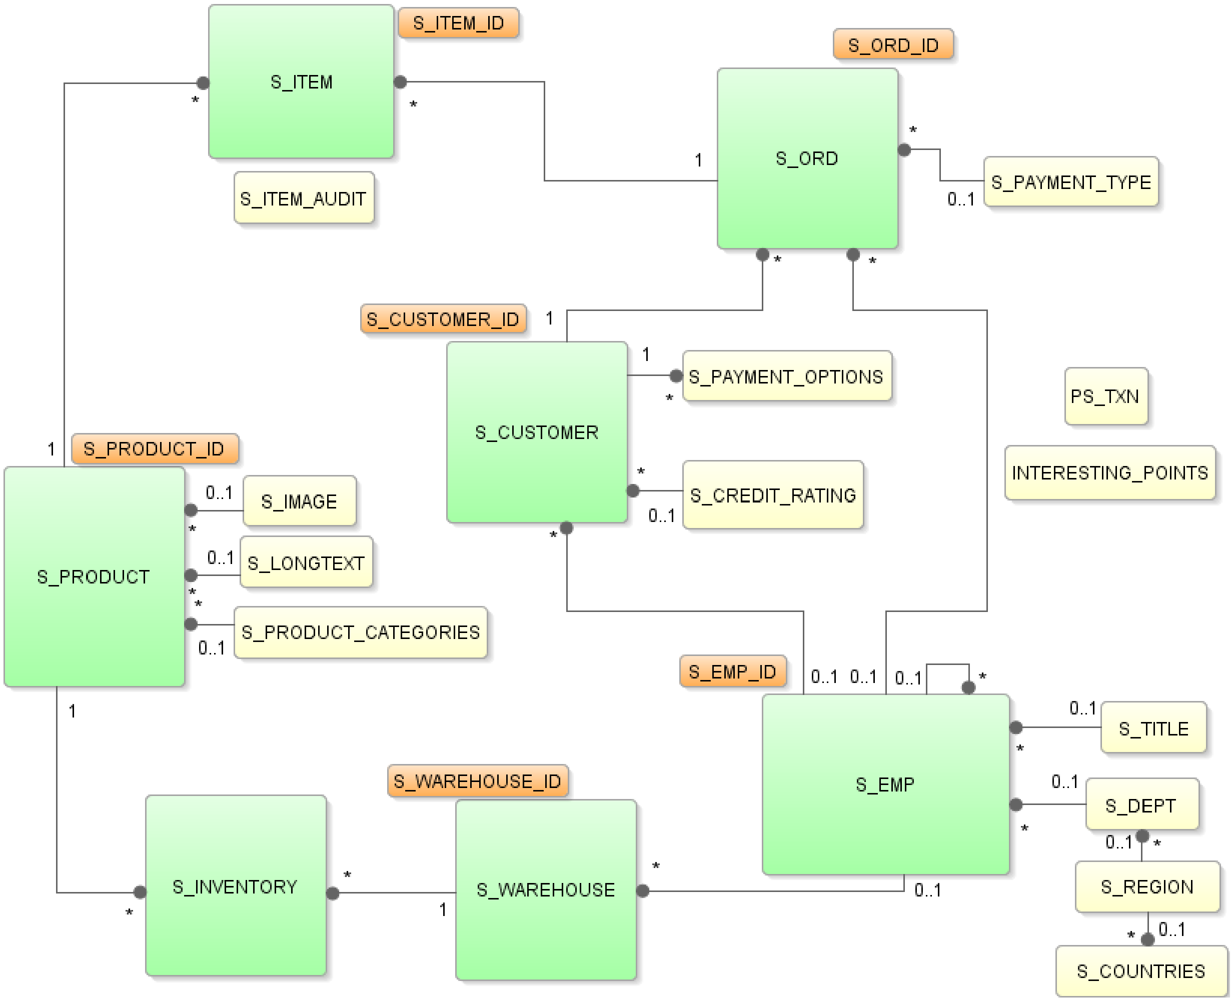
    ```
    Commit complete.

    Commit complete.
    SQL>
    ```
15. At the SQL prompt, enter `quit` to exit the SQL*Plus window.
16. In JDeveloper, in the main menu, choose **Application** and then **Close** to close the Summit ADF schema application.

What Happens When You Install the Summit ADF Schema

Figure 2-2 shows a simplified representation of the schema for the Summit sample applications for Oracle ADF. The green shapes in the diagram represent the seven core tables. The other tables are shown as yellow shapes. Some of the tables use sequences, but only those used by the core tables are shown. To minimize the number of crossed lines, the schema is displayed in a bottom-to-top hierarchy.

Figure 2-2 Schema Diagram for the Summit Sample Applications for Oracle ADF



The core tables represented by the green diagram elements include:

- S_ITEM: For each order, there may be many order items recorded. This table stores the unit price and quantity of each order item. The order line item and its order ID uniquely identify each order item.
- S_ORD: This table represents activity by specific customers. When an order is created, the date of the order, the total amount of the order, the ID of the customer who created it, and the name of the sales representative is recorded. After the order is fulfilled, the order status and order shipped date are updated. All orders are uniquely identified by a sequence-assigned ID.
- S_CUSTOMER: This table stores the name and address of all Summit customers. Each customer is uniquely identified by a sequence-assigned ID. The table also includes a foreign key that associates each customer with a Summit sales representative.
- S_EMP: This table stores all the employees who interact with the system. The first name, last name, email address, and address details of each user is stored. A user is uniquely identified by an ID. Other IDs provide foreign keys to tables with

title and department information, and, in the case of the employee's manager, a self-referential association.

- S_PRODUCT: This table stores all of the products available in the store. For each product, the name and suggested wholesale price are recorded. All products are uniquely identified by a sequence-assigned ID. The image of the product and its description are stored in separate tables, which each reference the product ID.
- S_WAREHOUSE: This table stores the location and manager of each warehouse that carries stock for the Summit products. For each warehouse, the location and manager are recorded. The warehouses are uniquely identified by a sequence-assigned ID.
- S_INVENTORY: This table stores inventory data for the Summit products. For each product, the amount in stock, reorder point, and maximum stock levels are recorded for each warehouse that carries the product.

The sequences that the core tables use include:

- S_ITEM_ID: Populates the ID for each new order item.
- S_ORD_ID: Populates the ID for each new order.
- S_CUSTOMER_ID: Populates the ID for each new customer.
- S_EMP_ID: Populates the ID for each new employee.
- S_PRODUCT_ID: Populates the ID for each new product.

How to Create the Database Connection for Summit Sample Applications for Oracle ADF

The Summit sample applications for Oracle ADF require a connection to the Summit database for data access. By default, each application is configured to use a local connection to an Oracle database that you must verify and modify as needed for your environment. The steps to modify a database connection for any of the Summit sample applications for Oracle ADF are the same for all workspaces and are performed after you have opened the application in JDeveloper.

Before you begin:

It may be helpful to have an understanding of the Summit ADF schema. For more information, see What Happens When You Install the Summit ADF Schema.

You will need to complete these tasks:

- Complete all steps to download the application resources to prepare your environment. For details, see How to Download the Application Resources.
- Install the Summit ADF schema. For details, see How to Install the Summit ADF Schema.
- Open the sample application to which you are connecting using the instructions for the application:
  - How to Run the Core Summit ADF Sample Application
  - How to Run the Summit ADF Standalone Sample Applications
  - How to Run the Summit Sample Application for ADF Task Flows
  - How to Run the Summit ADF DVT Sample Application Pages

To create the database connection for Summit sample applications for Oracle ADF:

1. In the Applications window, expand the Application Resources panel.
2. In the Application Resources panel, expand **Connection** and then **Database**.

   The existing database connection is displayed. For the core Summit ADF application, the database connection is **summit_adf**.
3. Right-click the database connection and choose **Properties**.

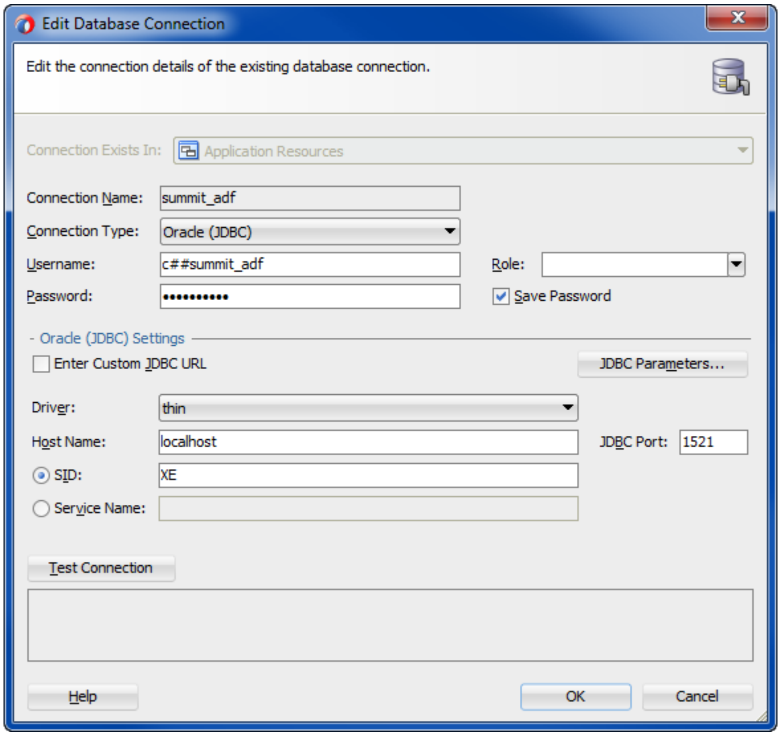
   For example, right-click **summit_adf** and choose **Properties**.
4. In the Edit Database Connection dialog, modify the properties shown in Table 2-3 for your environment. For help with the dialog, press F1 or click **Help**.

Table 2-3 Properties to Create a Database Connection for a Summit ADF Sample Application

Property	Description
User Name	The user name for the Summit ADF sample database. You must use `c##summit_adf` for this property. Note that Oracle Database 12c requires the user name to begin with `c##`.
Password	The password for the Summit ADF sample database. You must use `summit_adf` for this value.
Driver	The JDBC driver for the database. Select a value from the dropdown menu. The default is `thin`, which is also the default value to specify for Oracle Database XE instances and any other Oracle database that is not using Oracle Call Interface (OCI).
Host Name	The host name for your database. For example: `localhost`
JDBC Port	The port for your database. For example: `1521`
SID	The unique system identifier (SID) of an Oracle Database instance. The default is `XE`, which is also the default value to specify if your database server is running Oracle Database XE. If your server is running another Oracle database, the SID is typically `ORCL`.

Figure 2-3 shows the completed Edit Database Connection dialog. In this example, the connection is made to an Oracle Database XE instance residing on a local machine.

Figure 2-3   Edit Database Connection Dialog for a Summit ADF Sample Application



Edit Database Connection

Edit the connection details of the existing database connection.

Connection Exists In: Application Resources

Connection Name: summit_adf

Connection Type: Oracle (JDBC)

Username: c##summit_adf

Role:

Password: ••••••••••

☑ Save Password

Oracle (JDBC) Settings

□ Enter Custom JDBC URL

Driver: thin

Host Name: localhost

JDBC Port: 1521

● SID: XE

○ Service Name:

5. Click **Test Connection** to verify that you have a working connection.
6. Click **OK** to create the connection and exit the dialog.
7. In the Applications window, in the Projects panel, right-click **Model** and choose **Rebuild Model.jpr**.

Running the Core Summit ADF Sample Application in the SummitADF Workspace

The core Summit ADF sample application demonstrates various capabilities of Oracle ADF using a fictional scenario called Summit Sporting Goods. The purpose of the core Summit sample application is to demonstrate common use cases in Fusion web applications.

In the core Summit ADF sample application, sporting goods equipment is sold to international customers by a fictional sporting goods supplier called Summit Management. Employees of Summit Management can visit the website, and manage customer orders by fulfilling orders for products while monitoring the status of product inventory. The functionality in this core sample application has been intentionally restricted to demonstrate a limited number of potential Fusion web application use cases that are suitable for anyone new to Oracle ADF technology.

The core Summit ADF sample application consists of a web user interface and a business service layer. Specifically, the following projects are part of the core Summit ADF sample application:

- `Model`: Provides access to the customer management data and provides transaction support to update data for customer information and orders.

- ViewController: Provides the JSF web page and JSFF page fragments that the Summit user interacts with to browse the customers list, place orders, view order details, check order status, and inspect product inventory.

How to Run the Core Summit ADF Sample Application

You run the core Summit ADF sample application in JDeveloper by running the index.jspx page in the ViewController project. The ViewController project uses JavaServer Faces (JSF) as the view technology, and relies on the **ADF Model** layer to interact with ADF Business Components in the Model project. To learn more about the core Summit ADF sample application and to understand its implementation details, see Taking a Look at the Sample Application in the SummitADF Workspace.

Before you begin:

It may be helpful to have an understanding of the Summit ADF schema. For more information, see What Happens When You Install the Summit ADF Schema.

You will need to complete these tasks:

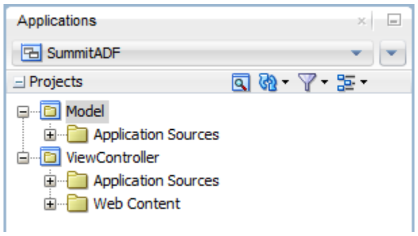
- Install Oracle JDeveloper Studio and meet the installation prerequisites. The core Summit ADF sample application requires an existing Oracle database. For details, see How to Download the Application Resources.
- Download the Summit ADF archive file from the Oracle Technology Network to a local directory and unzip the core Summit ADF sample application. For details, see How to Download the Application Resources.
- Install the Summit ADF schema. For details, see How to Install the Summit ADF Schema.

To run the sample application in the SummitADF application workspace:

1. Open the application in JDeveloper:
   a. In the main menu, choose **File** and then **Open**.
   b. Navigate to the location where you expanded the ZIP file for the SummitADF directory, select the SummitADF.jws application workspace and click **Open**.

      Figure 2-4 shows the Applications window after you open the file for the SummitADF.jws application workspace file in JDeveloper. For a description of each of the projects in the workspace, see Taking a Look at the Sample Application in the SummitADF Workspace.

Figure 2-4 Projects in the SummitADF Application Workspace



2. Create a connection to the Summit database. For details, see How to Create the Database Connection for Summit Sample Applications for Oracle ADF.

3. In the Applications window, expand **ViewController**, right-click `index.jsf` and choose **Run**.

   The Create Default Domain dialog appears the first time you run the application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

   The `index.jspx` page within the `ViewController` project is the run target. When you run the page, JDeveloper will launch the browser and display the Summit Management web page of the core Summit ADF sample application.

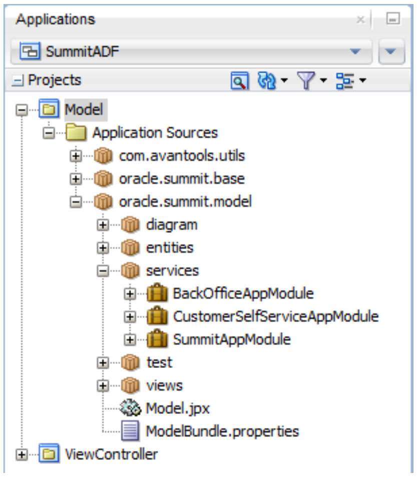
Once the Summit Management web page appears, you can browse the website. Note that the core Summit ADF sample application does not implement security for the Oracle ADF application resources and login is not required.

Taking a Look at the Sample Application in the SummitADF Workspace

Once you have opened the projects in JDeveloper, you can then begin to review the artifacts within each project. The development environment for the core Summit ADF sample application is divided into two projects: the `Model` project and the `ViewController` project.

The `Model` project contains the classes associated with the data model that allow the product data to be displayed in the web application. Figure 2-5 shows the `Model` project and its associated directories.

Figure 2-5 The Data Model Project of the SummitADF Workspace

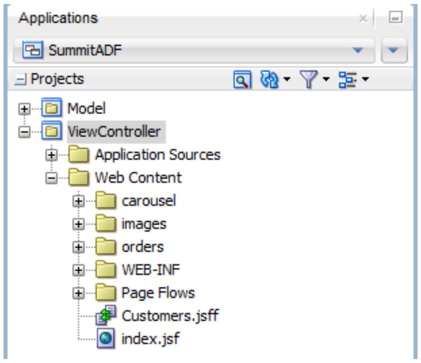


The `ViewController` project contains the following folders associated with the user interface:

- `Application Sources`: Contains the files used to access the product data. Included are the metadata files used by Oracle ADF to bind the data to the view.
- `META-INF`: Contains a file used in deployment.

The ViewController project contains the files for the web interface, including the backing beans, deployment files, and JSF and JSFF files. Figure 2-6 shows the ViewController project and its associated folders.

Figure 2-6 The ViewController Project of the SummitADF Workspace



The ViewController project contains the following directories:

- Application Sources: Contains the code used by the web client, including the managed and backing beans, property files used for internationalization, and the metadata used by Oracle ADF to display bound data.
- Web Content: Contains the web files, including the JSP files, images, skin files, deployment descriptors, and libraries.

Browsing the Application

Start the core Summit ADF sample application by running the index.jspx page in the ViewController project. For details about running the application using the default target, index.jsf, see Running the Core Summit ADF Sample Application in the SummitADF Workspace.

The index.jsf page is organized by an **ADF page** template which provides the structure for the page and uses an af:panelTabbed component to identify the page fragments to display in each of the tab panels.

When you enter the Summit ADF website, the site opens on the index page with three tabs displayed: Welcome, Summit Management, and Inventory Control. Click on each tab to view the separate page fragments referenced as regions by the index page.

The Summit Management region is the main **region** where you can browse the list of customers and their orders. This region is defined by the customers.jsff page fragment and is itself organized by ADF Faces components that provide tabbed panels. The Browse and Search panels are one af:panelTabbed component and the Customer, Order, and Order Dashboard panels belong to another af:panelTabbed component.

Figure 2-7 shows the index page with an order displayed in the Summit Management region.

Figure 2-7 Index Page with Multiple Regions

Where to Find Implementation Details

Following are the sections of *Developing Fusion Web Applications with Oracle Application Development Framework* that describe how to create a databound web page:

- Providing the structure for the web page

  The index page separates features of the application into regions that are implemented using a combination of ADF Faces templates and JavaServer Faces (JSF) page fragments. ADF Faces templates and the fragments allow you to add ADF databound components. For information about the steps you perform before adding databound user interface components to a web page, see About Developing a Web Application with ADF Faces.

- Designing the user interface using a variety of components

  JDeveloper allows you to create databound components declaratively for your JSF pages, meaning you can design most aspects of your pages without needing to look at the code. By dragging and dropping items from the **Data Controls panel**, JDeveloper declaratively binds ADF Faces UI components and ADF Data Visualization graph components to attributes on a **data control** using an **ADF binding**. For information about creating databound web pages with ADF Faces components, see About Creating a Basic Databound Page.

- Managing entry points to the application

  The page fragments of the index page are supported by individual **ADF task flows**. In general, the Fusion web application relies on this ADF Controller feature to define entry points to the application. When your application uses more than one page, you define an **unbounded task flow** to control the entry point of the application. JDeveloper helps you to create task flows with visual design elements that you drag and drop from the Components window. For more information about specifying the entry points to the application using an **ADF unbounded task flows**, see About ADF Task Flows.

Browsing the Customers List

To view the list of customers, click the **Browse** tab and in the Customers tree, expand a country node to view the list of customers for that country. The customers list is layed out with collapsing nodes organized by an ADF Faces `af:tree` component. The dropdown menu on the tree component lets you choose to organize the branches by country or by sale representative. The nodes of the tree display data from the database corresponding to the name and ID of each customer.

Figure 2-8 shows the tree expanded with a customer node selection.

Figure 2-8   Databound Tree Component Displays Customer Names and ID

Where to Find Implementation Details

Following is the section of *Developing Fusion Web Applications with Oracle Application Development Framework* that describes how to develop the components used to support browsing product details:

- Displaying data in a web page

  To display data from the data model, user interface components in the web page are bound to ADF Model layer binding objects using JSF Expression Language (EL) expressions. For example, when the user expands a country node in the Customers tree to display the list of customers for that country, the JSF runtime evaluates the EL expression for the UI component and pulls the value from the

ADF Model layer. At design time, when you work with the Data Controls panel to drag an attribute for an item of a data collection into your web page, and then choose an ADF Faces component to display the value, JDeveloper creates all the necessary JSF tag and binding code needed to display and update the associated data. For more information about the Data Controls panel and the declarative binding experience, see About Using ADF Model in a Fusion Web Application.

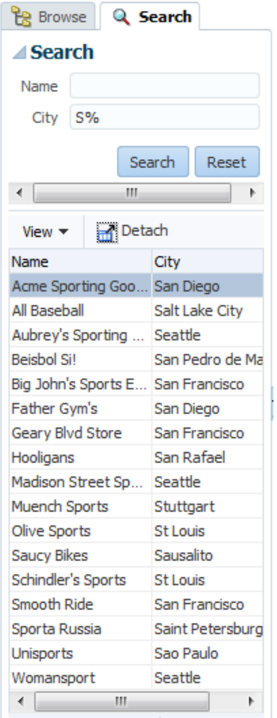
Searching for Customers

To search the customer list, click the Search tab in the Summit Management region. When you click the tab, the Browse panel changes to allow you to enter a search criteria in the query search form and view the search results in the table below. The layout of the search panel is defined by an ADF Faces `af:query` component.

You use the input fields on the Search form to perform a simple keyword search against the attributes common to all customers, such as customer names or cities. For example, you might query the database for the list of customers that begin with a particular letter.

Figure 2-9 shows the search results returned for the customers residing in a city that begins with "S".

Figure 2-9 Query Search Component Filters Customer List



Name

City S%

Name	City
Acme Sporting Goo...	San Diego
All Baseball	Salt Lake City
Aubrey's Sporting ...	Seattle
Beisbol Si!	San Pedro de Ma
Big John's Sports E...	San Francisco
Father Gym's	San Diego
Geary Blvd Store	San Francisco
Hooligans	San Rafael
Madison Street Sp...	Seattle
Muench Sports	Stuttgart
Olive Sports	St Louis
Saucy Bikes	Sausalito
Schindler's Sports	St Louis
Smooth Ride	San Francisco
Sporta Russia	Saint Petersburg
Unisports	Sao Paulo
Womansport	Seattle

Where to Find Implementation Details

Following are the sections of *Developing Fusion Web Applications with Oracle Application Development Framework* that describe how to define queries and create query search forms:

- Defining the query for the search form to display

  A query is associated with an ADF Business Components **view object** that you create for the data model project to define a particular query against the database. In particular, a query component is the visual representation of the **view criteria** defined on that view object. If there are multiple view criteria defined, each of the view criteria can be selected from the **Saved Search** dropdown list. These saved searches are created at design time by the developer. When the query associated with that view object is executed, both view criteria are available for selection. For more information, see About Creating Search Forms.

- Creating a search form

  You create a query search form by dropping a named view criteria item from the Data Controls panel onto a page. You have a choice of dropping only a search panel, dropping a search panel with a results table, or dropping a search panel with a tree table. For more information, see Creating Query Search Forms.

- Displaying the results of a query search

  Normally, you would drop a query search panel with the results table or tree table. JDeveloper will automatically wire up the results table or tree table with the query panel. If you drop a query panel by itself and want a separate results component, you can set the query component's `resultComponentId` attribute to the relative expression of the results component. For more information, see How to Create a Query Search Form and Add a Results Component Later.

Viewing Customer Details

To begin browsing the orders for a customer, click the **Summit Management** tab and make a selection in the expanded Customers tree from the Browse tab or Search tab. This action changes the details displayed in the Summit Customer Management tab to display details about the selected customer.

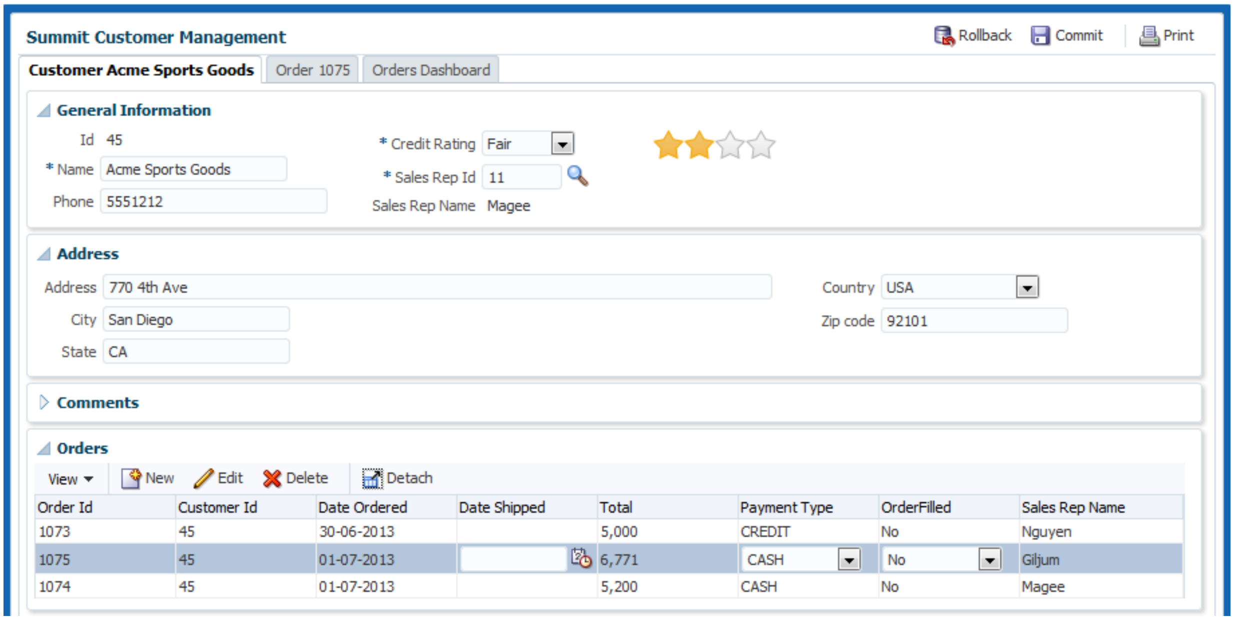
In the Customer details tab you can collapse and expand the panels to view various details of the selected customer. The first three panels display input forms consisting of individual input fields corresponding to the customer details. The customer you select also has one or more orders displayed in the Orders panel as a table, where each row comprises a single order and its details.

This relationship between a customer and their orders represents a business object relationship known as master and detail. In this case, the master, or parent object, can have many detail rows, or child objects. In turn the business objects in the core Summit ADF sample application, correspond to the `S_CUSTOMER` and `S_ORD` tables in the database.

The table of orders is defined by an ADF Faces `af:table` component. You can sort the table rows by clicking the sort buttons in any cell of the table header.

Figure 2-10 shows the customers page fragment with the details of the customer displayed in the top portion and the list of orders specific to the customer in the bottom portion.

Figure 2-10 Customers Page Fragment with Orders List



Id 45
* Name Acme Sports Goods

1075	45	01-07-2013		6,771	CASH	No	Giljum
1074	45	01-07-2013		5,200	CASH	No	Magee

Where to Find Implementation Details

Following are the sections of *Developing Fusion Web Applications with Oracle Application Development Framework* that describe how to use tables and forms to display master-detail related objects:

- Dragging and dropping master and detail components

  You can create pages that display master-detail data using the Data Controls panel. The Data Controls panel displays master-detail related objects in a hierarchy that mirrors the one you defined in the data model for the ADF **application module**, where the detail objects are children of the master objects. All you have to do is drop the collections on the page and choose the type of component you want to use. For example, in the core Summit ADF sample application, the page fragment `customers.jsff` displays the master list of customer categories in an `af:tree` component and displays the detail list of orders in an `af:table` component. For more information about the data model, see Exposing Application Modules with ADF Data Controls. For more information about various types of pages that display master-detail related data, see About Displaying Master-Detail Data.

- Sorting data that displays in tables

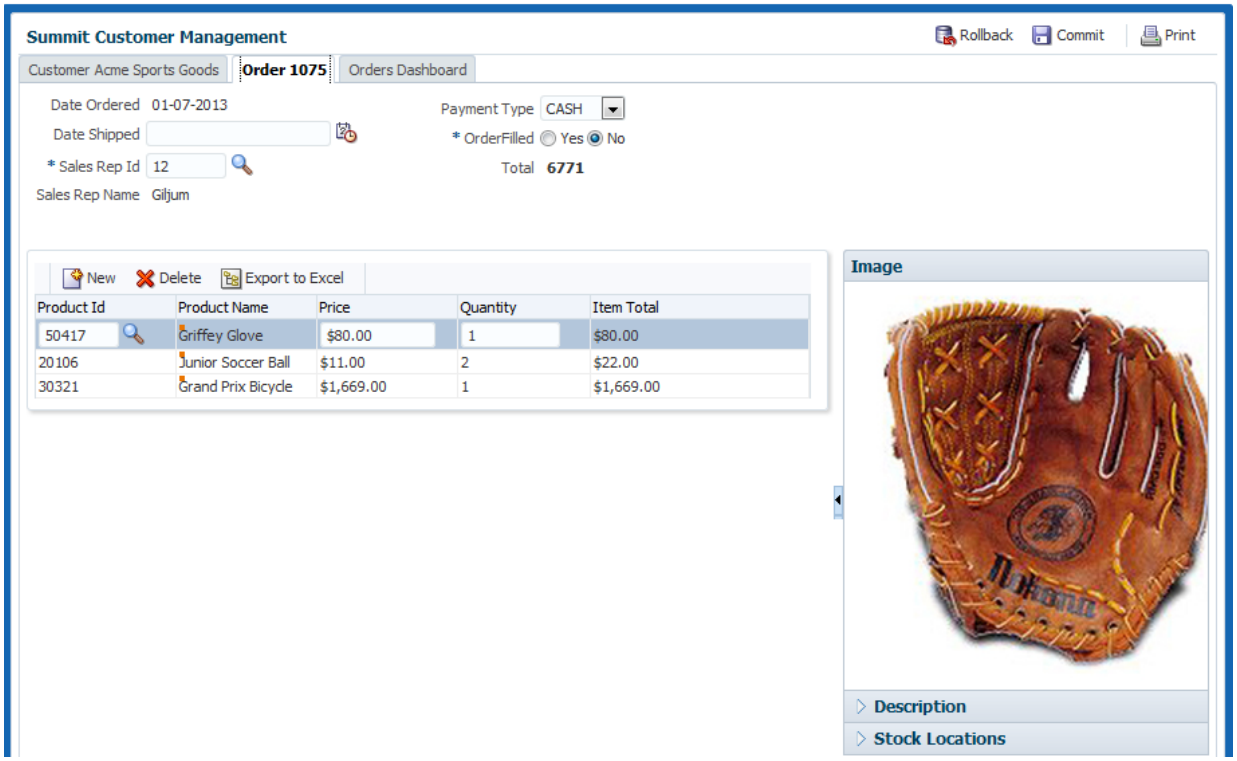
  When you create an ADF Faces table component you bind the table to the complete collection or to a range of data objects from the collection. The specific components that display the data in the columns are then bound to the attributes of the collection. The **iterator binding** handles displaying the correct data for each object, while the table component handles displaying each object in a row. You can set the **Sort** property for any column when you want the iterator to perform an order-by query to determine the order. You can also specify an `ORDER BY` clause for the query that the view object in the data model project defines. For more information about binding table components to a collection, see About Creating ADF Databound Tables. For more information about creating queries that sort data in the data model, see Populating View Object Rows from a Single Database Table.

Viewing Order Details

To update the details of an existing order, select an order from the Orders table displayed in the Customer tab and click the **Order** tab. The Order tab displays the same data that appeared in the row you selected, but organized as an edit form with fields that you can update. To change the order status, for example, you can select a choice from the **OrderFilled** radio button. The selection you make on the ADF Faces `af:selectOneRadio` component updates the corresponding `S_ORD` table column.

Figure 2-11 shows the Order page fragment with Order 1075 selected in the Customer details tab. Data for Order 1075 in both the order form and the Customer details tab are coordinated by the application to reflect changes in the database. Change the status of **OrderFilled** to **Yes**, and return to the Customer details tab to verify that the status is consistent.

Figure 2-11 Orders Page Fragment Displays Order Details

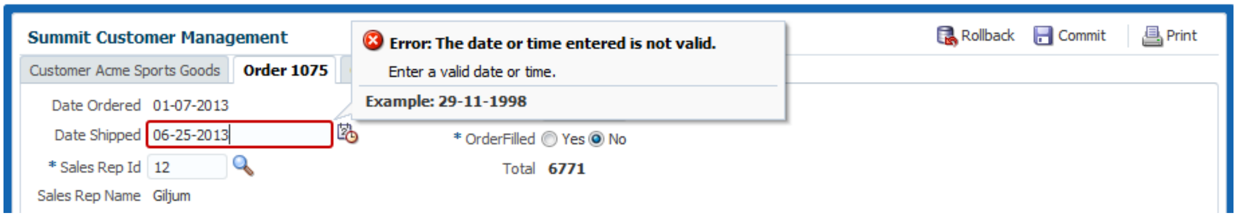


Date Ordered	01-07-2013
Date Shipped	
* Sales Rep Id	12
Sales Rep Name	Giljum
Payment Type	CASH
* OrderFilled	○ Yes ● No
Total	6771

Product Id	Product Name	Price	Quantity	Item Total
50417	Griffey Glove	$80.00	1	$80.00
20106	Junior Soccer Ball	$11.00	2	$22.00
30321	Grand Prix Bicycle	$1,669.00	1	$1,669.00

Other types of data, such as dates and currency, can be displayed using ADF Faces components to handle formatting of the values. Figure 2-12 shows the Order page fragment with a system error that enforces date formats that have been defined on the attribute underlying the **Date Shipped** field.

Figure 2-12 Orders Page Fragment Displays Format Mask Error



Error: The date or time entered is not valid.

Enter a valid date or time.

Example: 29-11-1998

Date Ordered 01-07-2013

Date Shipped 06-25-2013

* Sales Rep Id 12

Sales Rep Name Giljum

* OrderFilled ○ Yes ● No

Total 6771

Validation rules based on Groovy calculated expressions can be defined on data updates. Figure 2-13 shows the Order page fragment with a validation error that calculates the customer's credit score before allowing a **Payment Type** of **CREDIT** to be selected.

50417	Griffey Glove	$80.00
20106	Junior Soccer Ball	$11.00
30321	Grand Prix Bicycle	$1,669.00

Where to Find Implementation Details

Following are the sections of *Developing Fusion Web Applications with Oracle Application Development Framework* that describe how to create edit forms:

- Creating a databound edit form

  When you want to create a basic form that collects values from the user, instead of having to drop individual attributes, JDeveloper allows you to drop all attributes for an object at once as an input form. You can create forms that display values, forms that allow users to edit values, and forms that collect values. For example, in the core Summit ADF sample application, the page fragment `Orders.jsff` displays a form to display order information. For more information, see Creating a Form to Edit an Existing Record.

- Requiring values to complete a form

  The input form displays attributes of a data collection that you drop from the Data Controls panel. You can set the `required` property of individual components in the form to control whether an attribute value is mandatory. For details about how to customize the `required` property, see Creating Text Fields Using Data Control Attributes. Alternatively, you can set a display **control hint** property directly on the attribute where it is defined by an ADF Business Components **entity object**. The entity object is a data model component that represents a row from a specific table in the database and that simplifies modifying its associated attributes. For details about using control hints to make an attribute mandatory, see Setting Attribute Properties.

- Defining a list of values for selection lists

  Input forms displayed in the user interface can utilize databound ADF Faces selection components to display a **list of values (LOV)** for individual attributes of the data collection. To facilitate this common design task, ADF Business Components provides declarative support to specify the LOV usage for attributes in the data model project. For example, in the core Summit ADF sample application, the `af:selectOneChoice` component for the payment type field displayed in the page fragment `Orders.jsff` is bound to an LOV-enabled attribute configured for the `OrdVO` view object. For more information about configuring attributes for LOV usage, see Working with List of Values (LOV) in View Object Attributes.

- Defining format masks for forms

  Format masks help ensure the user supplies attribute values in the required format. To facilitate this task, ADF Business Components provides declarative support known as **control hints** for attributes in the data model project. For example, in the core Summit ADF sample application, the attribute for the `OrdVO` view object used to specify the date shipped is configured with a format mask hint and enforced in the page fragment `Orders.jsff`. For information on defining format masks for input form components, see Defining UI Hints for View Objects.

- Defining validation rules for data updates

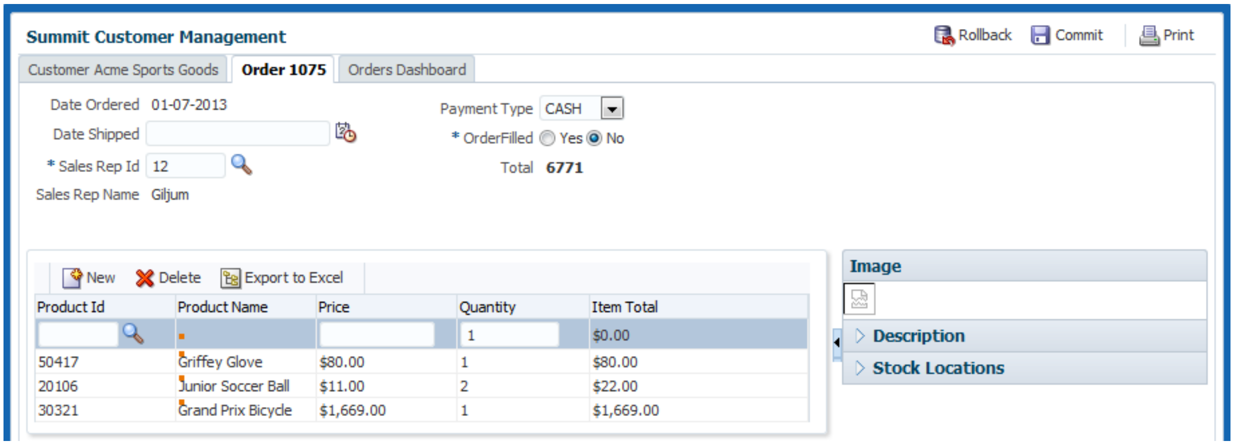
  Validation rules help ensure the user supplies attribute values that meet particular business needs. To facilitate this task, ADF Business Components provides declarative validation for attributes in the data model project. For example, in the core Summit ADF sample application, the attribute for the `OrdEO` entity object used to specify the payment type is configured with a validation rule and enforced in the page fragment `Orders.jsff`. For information on defining validation rules for attributes of entity objects and view objects, see Defining Validation and Business Rules Declaratively.

The Ordering Process

Creating a new customer order requires a database transaction that involves updating the records of the customer's order while decreasing the quantity of products remaining in the Summit inventory. When you click **New** on Customer page above the list of orders, the application creates a new order form with only the date displayed.

Figure 2-14 shows the new order form with no products added.

Figure 2-14 Order Page Fragment Displays New Empty Order



Date Ordered 01-07-2013

Date Shipped

* Sales Rep Id 12

Sales Rep Name Giljum

Payment Type CASH

* OrderFilled ○ Yes ● No

Total 6771

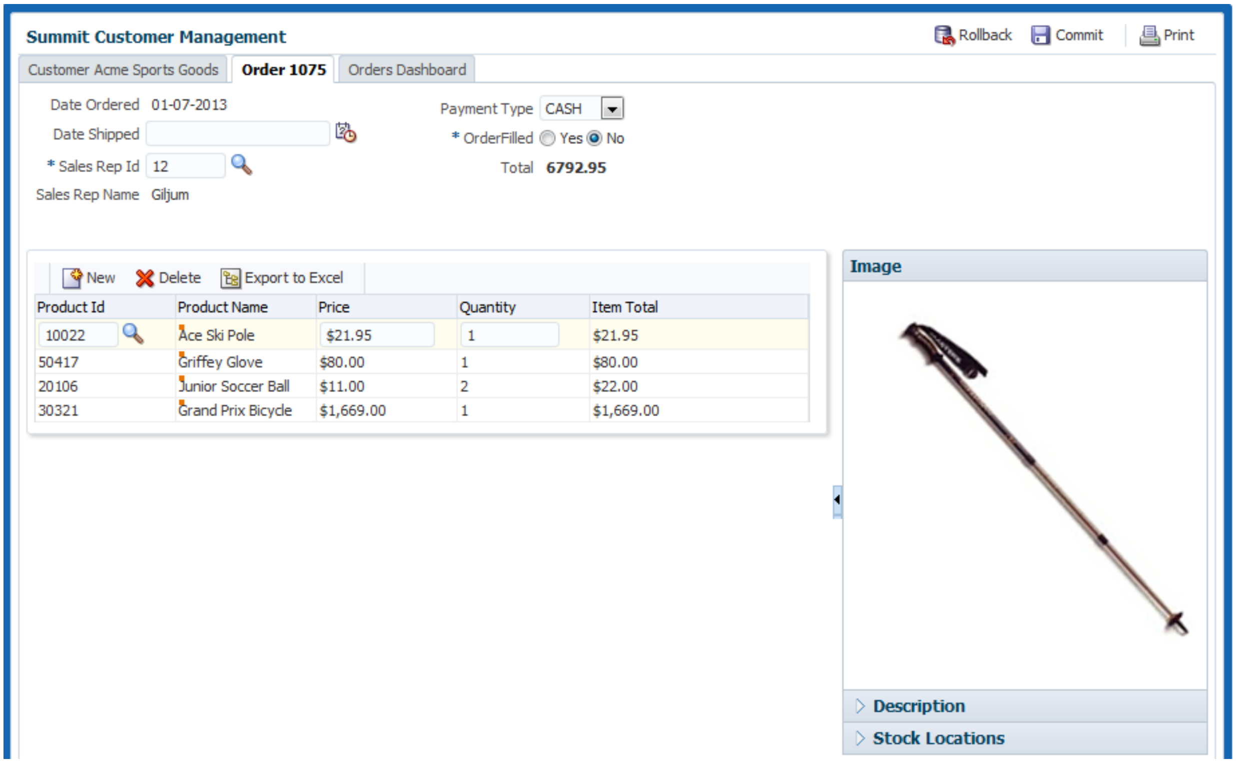
Product Id	Product Name	Price	Quantity	Item Total
			1	$0.00
50417	Griffey Glove	$80.00	1	$80.00
20106	Junior Soccer Ball	$11.00	2	$22.00
30321	Grand Prix Bicycle	$1,669.00	1	$1,669.00

To create the order, click **New** above the empty list of products. Then, next to the **ProductId** field, click the Search icon. The `af:inputListOfValues` component launches the popup window that you can use to search the database for the product. To make searching easier, the popup window displays a limited number of fields from the `S_PRODUCT` table, including product ID and product Name. This type of filtering for display at runtime is performed by the ADF binding that backs the databound `af:inputListOfValues` component.

Select a product in the popup window and click **OK**. The Order tab updates to display the selection in the product table.

Figure 2-15 shows the Order tab with an order comprising the product order.

Figure 2-15   Order Page Fragment Displays Order Entry



Date Ordered 01-07-2013
Date Shipped
* Sales Rep Id 12
Sales Rep Name Giljum

Payment Type CASH
* OrderFilled ○ Yes ● No
Total **6792.95**

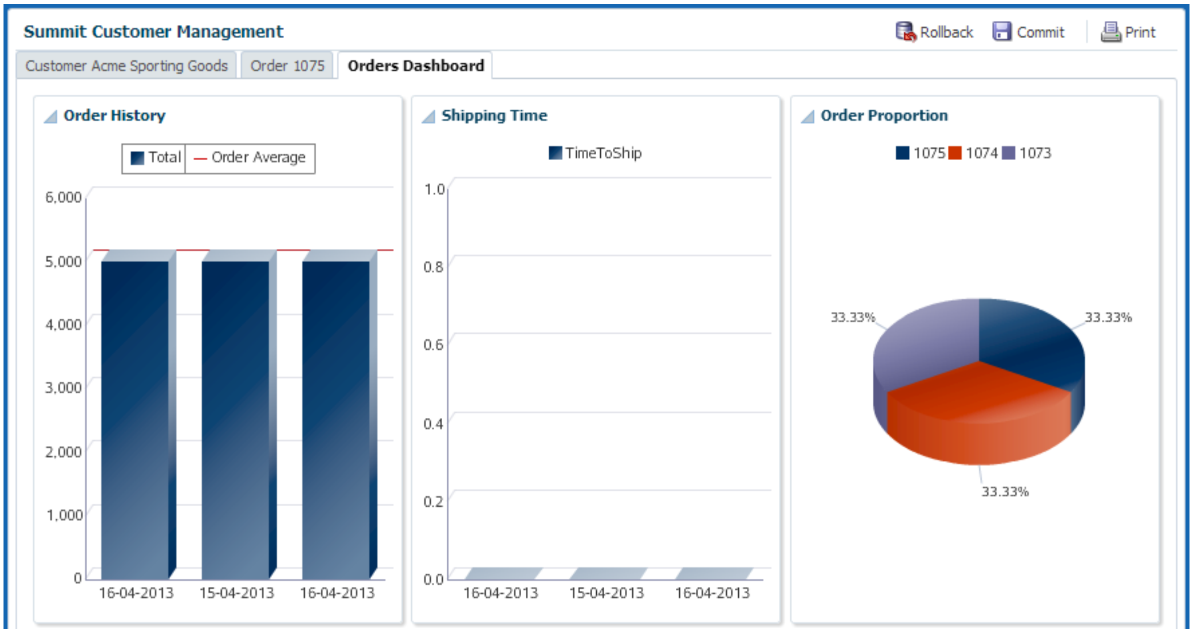
Product Id	Product Name	Price	Quantity	Item Total
10022	Ace Ski Pole	$21.95	1	$21.95
50417	Griffey Glove	$80.00	1	$80.00
20106	Junior Soccer Ball	$11.00	2	$22.00
30321	Grand Prix Bicycle	$1,669.00	1	$1,669.00

To complete the order, enter the ID of a sales representative and then click the **Commit** button in the top right corner of the Summit Customer Management page. This updates the database with the new order detail and reduced product inventory.

To visualize the customer's order history, click the Orders Dashboard tab. The dashboard displays various graphs using ADF Faces DVT components. The **Shipping Time** graph is an `dvt:barChart` component. This component relies on information that is calculated only when the order ship date is updated; the data to display is not obtained from a database table since it must be determined at runtime. To display the **Shipping Time** data the bar chart relies on an ADF Business Components method call to return the number of days for shipping for each order.

Figure 2-16 shows dashboard information for three orders made by the Acme Sporting Goods company.

Figure 2-16   Order Page Fragment Displays Dashboard Details



To visualize how orders affect the product inventory, click the Inventory Control tab, next to the Summit Management tab. The Inventory Control page displays only those products that are below the reorder threshold. The low stock is displayed both visually with the `af:carousel` component and in table format with the `af:table` component. Select an item from the low stock carousel and notice that the table updates to make the selected item the current row. The current row in a table is the one that is highlighted. These two components are synchronized through the ADF Model layer with a Java method call that is executed when the carousel selection is made.

Figure 2-17 shows the inventory status of item 13 out of 26. The current row selection in the low stock table reflects the selection displayed in the inventory carousel.

Figure 2-17 Inventory Control Page Fragment Displays Low Stock Items

Where to Find Implementation Details

Following are the sections of *Developing Fusion Web Applications with Oracle Application Development Framework* that describe how to develop database forms like the ones used to update the database in the Orders and Inventory Control page fragments:

- Triggering data updates with command components

  To support data updating, the Orders page fragment of the Summit Management region uses command components represented as `af:button` components to allow users to execute specific ADF data control operations in the declarative ADF **page definition file**. The built operations of the ADF data control enable you to declaratively handle common form functions such as navigating between records and committing changes to a database. Most operations are available for individual data collections in a data control. The Commit and Rollback operations are available on the whole data control. By dragging and dropping an operation from the Data Controls panel, you are prompted to choose what kind of command component to create, such as a button or a link. For information about triggering built-in operations, see Creating Command Components Using Data Control Operations.

- Triggering backing bean method calls with command components

  To support operations that may require custom logic to handle an interaction with the database, the `InventoryControl` page fragment of the Summit Management region uses the `carouselSpinListener` on the `af:carousel` components to trigger a custom method `handleCarouselSpin()` defined on the backing bean `InventoryControl.java`. When you select an item in the carousel, the action listener triggers the backing bean method which updates the current row for the af:table component iterator binding. For details about executing Java code in backing beans, see How to Create a Databound Carousel Component.

- Keeping track of transient session information and triggering business component method calls

  When you create a data model project that maps attributes to columns in an underlying table, your ADF view objects can include transient attributes that display calculated values (for example, using Java or Groovy expressions) or that are value holders. For example, in the core Summit ADF sample application, the Orders Dashboard tab on the page fragment Orders.jsff displays the value of the TimeToShip attribute calculated by the expression defined on the OrdVO view object. The calculateTimeToShip expression invokes a method on the OrdVORowImpl.java client interface for the view row. For more information about defining transient attributes in the data model project, see Adding Transient and Calculated Attributes to an Entity Object. For more information about implementing custom Java methods in view objects, see How to Generate Client Interfaces for View Objects and View Rows.

Running the Standalone Samples from the SummitADF_Examples Workspace

The standalone sample applications in theSummitADF_Examples application workspace use programmatic test clients to demonstrate concepts related to the ADF Business Components framework. These applications allow you to look into the ADF functionalities that does not appear in the SummitADF workspace.

The Summit standalone sample applications for Oracle ADF include a set of sample packages that allow you to investigate Oracle ADF functionality that does not appear in the SummitADF workspace. Collectively, these sample packages are referred to as Summit ADF standalone sample applications. The standalone applications appear in the Model project of the SummitADF_Examples application workspace, located in the SummitADF_Examples folder where you extracted the Summit ADF standalone sample applications ZIP file.

In general, the standalone applications demonstrate concepts of ADF Business Components and data model projects. References to these standalone applications appear throughout the chapters contained in Building Your Business Services of this developer's guide. As you read sections this guide, you may want to run the corresponding standalone applications to investigate the concepts further. For a brief description of each standalone application and links to the documentation, refer to the table in Overview of the Summit ADF Standalone Sample Applications.

How to Run the Summit ADF Standalone Sample Applications

The approach you use in JDeveloper to run a standalone application depends on the individual package. Some packages are set up to use the interactive testing tool JDeveloper provides for the ADF Business Components data model project (this tool is known as the Oracle ADF Model Tester). Other applications provide Java test clients (with file names like TestClientAaa.java) that use the ADF Business Components API to execute queries and display results. In the case of the Oracle ADF Model Tester, you work entirely within the tool, which essentially provides a convenient user interface for interacting with business components. In the case of the Java clients, the program files output their results and print statements to the JDeveloper Log window.

Running the Standalone Sample Applications From a Java Test Client

When the standalone application has a test client to programmatically exercise the ADF Business Components API, you will use the test client to run the applications.

Before you begin:

It may be helpful to have an understanding of individual Summit ADF standalone sample applications. For more information, see Overview of the Summit ADF Standalone Sample Applications.

You will need to complete these tasks:

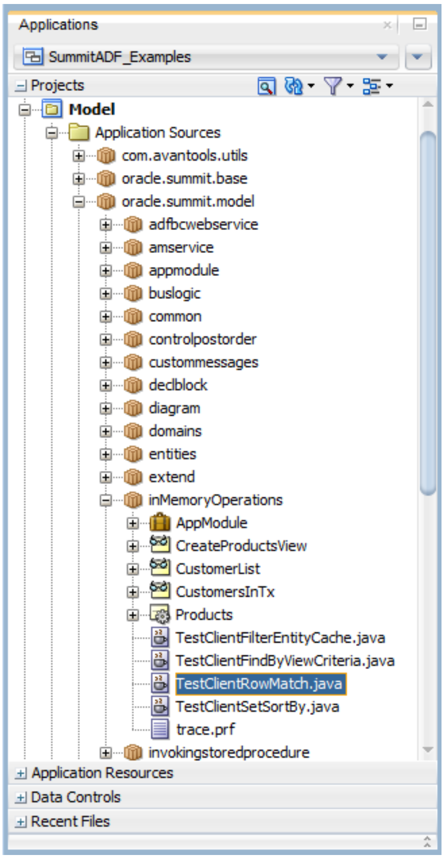
- Install Oracle JDeveloper Studio and meet the installation prerequisites. The standalone applications require an existing Oracle database. For details, see How to Download the Application Resources.
- Download the Summit ADF archive file from the Oracle Technology Network to a local directory and unzip the Summit ADF standalone sample applications. For details, see Setting Up the Summit Sample Applications for Oracle ADF.
- Install the Summit ADF schema. For details, see How to Install the Summit ADF Schema.

To run a standalone application from its provided test client:

1. Open the application in JDeveloper:
   a. In the main menu, choose **File** and then **Open**.
   b. Navigate to the location where you expanded the ZIP file for the **SummitADF_Examples** directory, select the **SummitADF_Examples.jws** application workspace and then click **Open**.
2. Create a database connection for the standalone applications. For details, see How to Create the Database Connection for Summit Sample Applications for Oracle ADF.
3. Run the SQL script in JDeveloper for standalone samples that require it. Some of the standalone applications work with a modified version of the Summit ADF schema. For standalone applications that require schema changes, the application's project contains a SQL script that you must run in JDeveloper. Once you are through running a standalone application, you can use the script to back out the schema changes
4. In the Applications window, expand the project node and locate the test client (`.java`) file node. In some cases, the test client is added to a package located under the **Application Sources** node. In other cases, the **Resources** node contains the test client.

   For example, Figure 2-18 shows the expanded **inMemoryOperations** node with the Java file node **TestClientRowMatch.java** selected.

Figure 2-18 Test Client Selected in Applications Window



5. Right-click the test client and choose **Run**.

   For the names and location of the test clients provided with the standalone applications, see the table in Overview of the Summit ADF Standalone Sample Applications.

   The Create Default Domain dialog appears the first time you run an executable and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter must be eight characters or more and have a numeric character.

6. Examine the JDeveloper Log window for the test client's output.

   Refer to the referenced documentation for details about the expected results.

Running the Standalone Applications Without a Test Client

When the standalone application does not provide a test client to programmatically exercise the ADF Business Components API, you will use the interactive testing tool, known as the Oracle ADF Model Tester.

Before you begin:

It may be helpful to have an understanding of individual Summit ADF standalone sample applications. For more information, see Overview of the Summit ADF Standalone Sample Applications.

It also may be helpful to have an understanding of the Oracle ADF Model Tester. For more information, see Testing View Object Instances Using the Oracle ADF Model Tester.

You will need to complete these tasks:

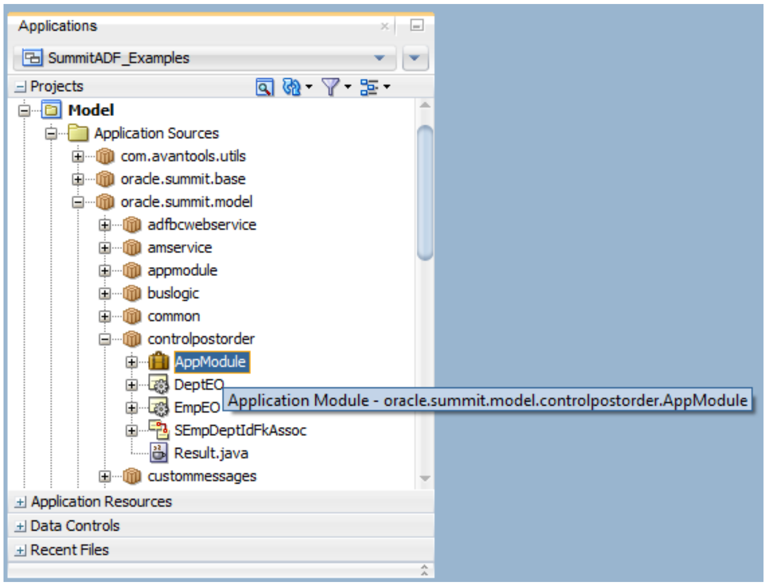
- Install Oracle JDeveloper Studio and meet the installation prerequisites. The standalone applications require an existing Oracle database. For details, see How to Download the Application Resources.
- Download the Summit ADF archive file from the Oracle Technology Network to a local directory and unzip the Summit ADF standalone sample applications. For details, see How to Download the Application Resources.
- Install the Summit ADF schema. For details, see How to Install the Summit ADF Schema.

To run a standalone application in the Oracle ADF Model Tester:

1. Open the application in JDeveloper:
   a. In the main menu, choose **File** and then **Open**.
   b. Navigate to the location where you expanded the ZIP file for the `SummitADF_Examples` directory, select the `SummitADF_Examples.jws` application workspace file and then click **Open**.
2. Create a database connection for the standalone applications. For details, see How to Create the Database Connection for Summit Sample Applications for Oracle ADF.
3. Run the SQL script in JDeveloper for standalone samples that require it. Some of the standalone applications work with a modified version of the Summit ADF schema. For standalone applications that require schema changes, the application's project contains a SQL script that you must run in JDeveloper. Once you are through running a standalone application, you can use the script to back out the schema changes
4. In the Applications window, expand the project node and locate the application module in a package under the **Application Sources** node.

   For example, Figure 2-19 shows the expanded **controlpostorder** project with the application module **AppModule** selected and a tooltip for the node displayed.

Figure 2-19 Application Module Node Selected in Applications Window



5. Right-click the application module node and choose **Run**.

   For the names of the runnable application modules, see the table in Overview of the Summit ADF Standalone Sample Applications.

   The Create Default Domain dialog displays the first time you run an executable and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter must be eight characters or more and have a numeric character.

6. Use the Oracle ADF Model Tester to interact with the view instances of the standalone application.

   Refer to the referenced documentation for details about the application. For details about using the tester to interact with the data model, see Testing View Object Instances Using the Oracle ADF Model Tester.

Overview of the Summit ADF Standalone Sample Applications

Some of the standalone applications in the `SummitADF_Examples` application workspace use programmatic test clients to demonstrate concepts related to the ADF Business Components framework. Others demonstrate framework functionality when you run the application in the Oracle ADF Model Tester.

Figure 2-20 shows the Applications window after you open the `SummitADF_Examples` application workspace.

Note that the test clients for the standalone applications provide a good starting point for understanding how to exercise methods of the ADF Business Components API. They also make good samples for test clients that you may want to create to test business component queries in a data model project. For background on working with test clients, see Testing View Object Instances Programmatically.

Note:

The ADF Business Components API is available when you need to generate custom classes to augment the default runtime behavior of the business components. For background about the ADF Business Components framework, see Getting Started with ADF Business Components.

Table 2-4 describes the standalone applications in the `SummitADF_Examples` application workspace. Examples from these applications appear throughout the chapters contained in Building Your Business Services of this guide.

Table 2-4 Standalone Applications in the SummitADF_Examples Application Workspace

Package Name	Runnable Class or Project Target	Documentation
`amservice`	Run **ServiceAppModule** using the Oracle ADF Model Tester.	For information about the application module service interface, see Publishing Service-Enabled Application Modules.
`appmodule`	Run **TestAM.java** under the **service** node. Run **TestCustomEntity.java** under the **service** node. These test clients exercise custom methods of application module's client interface and print to the JDeveloper Log window to indicate the results.	For details about the test client, see How to Work Programmatically with an Application Module's Client Interface. For details about the methods of the client interface, see the examples in Working Programmatically with Entity Objects and Associations.
`buslogic`	Run **AppModule** using the Oracle ADF Model Tester.	For information about business logic units and groups, see Defining Business Logic Groups.
`controlpostorder`	Run **AppModule** using the Oracle ADF Model Tester.	For information about controlling the posting order resulting from DML operations to save changes to a number of related entity objects, see How to Control Entity Posting Order to Prevent Constraint Violations.
`custommessages`	Run **AppModule** using the Oracle ADF Model Tester.	For information about how to provide an alternative message string for the builtin error codes in a custom message bundle, see Customizing Business Components Error Messages.
`declblock`	Run **AppModule** using the Oracle ADF Model Tester.	For information about how to use custom metadata properties to control insert, update, or delete on a view object, see Declaratively Preventing Insert, Update, and Delete.
`domains`	Run **AppModule** using the Oracle ADF Model Tester.	For information about creating custom data types, see Creating Custom, Validated Data Types Using Domains.
`extend`	Run **TestClient.java**. This client casts the results of the `productByName.first()` method to the `ProductViewRow` interface so that it can make method calls, and prints to the JDeveloper Log window to display the results.	For information about how to extend business components to create a customized versions of the original, see Creating Extended Components Using Inheritance. For information about iterating over a collection using the view row accessor attribute, see Exposing View Row Accessors to Clients.

Table 2-4 (Cont.) Standalone Applications in the SummitADF_Examples Application Workspace

Package Name	Runnable Class or Project Target	Documentation
`inMemoryOperations`	Run the test clients: - **TestClientFilterEntityCache.java** - **TestClientFindByViewCriteria.java** - **TestClientRowMatch.java** - **TestClientSetSortBy.java** These test clients illustrate how to use the in-memory sorting and filtering functionality from the client side using methods on the interfaces in the `oracle.jbo` package, and print to the JDeveloper Log window to display the results.	For information about how to use view objects to perform in-memory searches and sorting to avoid unnecessary trips to the database, see Performing In-Memory Sorting and Filtering of Row Sets.
`invokingstoredprocedure`	Run the **ExampleSQLPackage.sql** script against the `summit_adf` database connection to set up the additional database objects required for the example. Run **TestClient.java**. The test client exercises custom methods of application module's client interface to invoke database stored procedures and functions, and prints to the JDeveloper Log window to indicate the results.	For information about how to code custom Java classes for business components that invoke database stored procedures and functions, see Invoking Stored Procedures and Functions.
`multieoupdate`	Run **AppModule** using the Oracle ADF Model Tester.	For information about creating a view object with multiple updatable entities to support creating new rows, see Creating a View Object with Multiple Updatable Entities.
`multinamedviewcriteria`	Run **MultiNamedViewCriteriaTestClient.java**. The test client exercises custom methods on the view object interface and prints to the JDeveloper Log window to display the results.	For information about how to programmatically filter query results, see Working Programmatically with Multiple Named View Criteria.
`polymorphic`	Run **PolymorphicAppModule** (under the **service** node) using the Oracle ADF Model Tester and display the subtype view instances for US customers (`CountryId=4`). Subtype view usages display the subtype attribute `State`.. This sample demonstrates entity-based polymorphic view objects.	For details about creating an entity object inheritance hierarchy, see Using Inheritance in Your Business Domain Layer and for details about creating view usages for those entity objects, see Working with Polymorphic Entity Usages.

Table 2-4 (Cont.) Standalone Applications in the SummitADF_Examples Application Workspace

Package Name	Runnable Class or Project Target	Documentation
`polymorphicvo`	Run **AppModule** (under the **service** node) using the Oracle ADF Model Tester and display subtype view rows for Sales department employees (`TitleId=2`). Subtype view rows display the subtype attribute `CommissionPct`. This sample demonstrates view row-based polymorphic view objects.	For details about creating a view row subtypes, see Working with Polymorphic View Rows.
`PolymorphicVO_WSClient` (This is a client project of the `polymorphicvo` package.)	First run **AppModuleServiceImpl.java** in the **polymorphicvo** package of the Model project, then run the web service client **AppModuleServiceSoapHttpPortClient** (under the **com.oracle.xmlns.apps.hr.service.types** node). The client file creates a new salesman subtype and prints to the JDeveloper Log. This sample demonstrates how to work with polymorphic collections in SOAP web service clients.	For details about working with subtype view objects in web services, see Accessing Polymorphic Collections in the Consuming Application.
`processChange`	Run **processChangeTestClient.java**. The test client exercises custom methods on the view object interface and prints to the JDeveloper Log window to display the results.	For information about invoking database change notifications, see What You May Need to Know About Programmatically Invoking Database Change Notifications. For details about the test client, see How to Work Programmatically with an Application Module's Client Interface.
`readandwritexml`	Run **TestClientReadXML.java** under the **client** node, then run **TestClientWriteXML.java**.	For details about how to produce XML from queried data, see Reading and Writing XML.
`rest_WS`	This package is reserved for future use.	For details about creating RESTful web services from view instances of an application module, see Creating ADF RESTful Web Services with Application Modules.

Table 2-4 (Cont.) Standalone Applications in the SummitADF_Examples Application Workspace

Package Name	Runnable Class or Project Target	Documentation
`rowfinder`	Run **TestClient.java** to programmatically exercise the row finder `EmpByTitleId` defined on `EmpView`. Row finders may be invoked programmatically within a test client or from the methods of exposed service data object (SDO) operations on a SOAP web service. Alternatively, expand the **serviceinterface** folder of the **EmpService** application module node and run `EmpServiceServiceImpl.java` to test the row finder in the HTTP Analyzer. In the HTTP Analyzer, select the `updateEmpView1` operation and enter `1` for the `TrTitleId` and then enter any First Name to update the Employee record based on a person with the Title Id of "`1`". Row finders may be defined on view objects to support record lookups using any attribute without requiring the view object's key attribute.	For information about defining a row finder and programmatically invoking it, see Working with Row Finders. For information about using row finder operations in SOAP web services, see What You May Need to Know About Row Finders and the ADF Web Service Operations.
`sdo`	This package implements service data objects (SDO) for use with SOAP web services that are based on the `DeptView1` and `EmpView1` view instances of the `HRAppModule` application module. This package exposes a find operation on the `EmpView1` SDO. See `SDO_Client` and `SDO_WSClient` for instruction about running the client projects to test the exposed find operation.	For information about how to create SDO from an application module, see Creating SOAP Web Services with Application Modules.
`SDO_Client`	Run **SDOClientServlet.java** SOAP web service servlet. The test client exercises the `findEmpView1()` method implemented as a SOAP web service view criteria find operation in the services package of the Model project. The servlet `testFindEmps()` method creates a dynamic view criteria passed to `findEmpView1()` that filters employees by a named department and verifies the test result. This is the servlet version of the `SDO_WSClient` project.	For more information about exposing find operations, see How to Expose a Custom Find Method Filtered By a Required Bind Variable.

Table 2-4 (Cont.) Standalone Applications in the SummitADF_Examples Application Workspace

Package Name	Runnable Class or Project Target	Documentation
`SDO_WSClient`	Run **HRAppModuleServiceSoapHttpPortClient.java** SOAP web service HTTP port client. The test client exercises the `findEmpView1()` method implemented as a SOAP web service view criteria find operation in the services package of the Model project. The servlet `testFindEmps()` method creates a dynamic view criteria passed to `findEmpView1()` that filters employees by a named department and verifies the test result. This the web service client version of the `SDO_Client` project.	For more information about exposing find operations in ADF service data objects, see How to Expose a Custom Find Method Filtered By a Required Bind Variable.
`TaskFlowProducer`	Run **RemoteViewer.jsf** page in the **Web Content** folder of this view controller project. The page displays a remote invocable task flow that can be consumed by a consumer application.	For information about creating remote task flows, see How to Configure an Application to Render Remote Regions. Once you deploy this sample application, you can consume the remote invocable task flow, as described in Creating Remote Regions in a Fusion Web Application.
`validation`	Run **AppModule** using the Oracle ADF Model Tester. Click `OrdersView1` and edit the `Data Ordered` field to see an example of attribute level validation using a programmatic validation method.	For information about how to create programmatic validators, see Implementing Validation and Business Rules Programmatically.
`viewobjectonrefcursor`	Run the **CreateRefCursorPackage.sql** script against the `summit_adf` database connection to set up the additional database objects required for the example. Run **AppModule** using the Oracle ADF Model Tester.	For details about how to use PL/SQL to open a cursor to iterate through the results of a query, see How to Create a View Object on a REF CURSOR.
`viewobjects`	Run **TestClient.java**. Programmatically iterates over the customers view instance using methods of the Business Components API `RowIterator` interface and prints to the JDeveloper Log window.	For details about iterating over a collection, see How to Count the Number of Rows in a Row Set. For details about how to create test clients, see Testing View Object Instances Programmatically.
	Run **TestClient2.java**. Programmatically iterates over the customers view instance, accesses the detail collection of orders using a **view link accessor** attribute, and prints to the JDeveloper Log window.	For details about iterating over a detail collection, see How to Access the Detail Collection Using the View Link Accessor. For more details about the test client, see How to Access a Detail Collection Using the View Link Accessor.

Table 2-4 (Cont.) Standalone Applications in the SummitADF_Examples Application Workspace

Package Name	Runnable Class or Project Target	Documentation
	Run **TestClient3.java**. Finds and updates a foreign key value and prints to the JDeveloper Log window.	For details, see How to Find a Row and Update a Foreign Key Value.
	Run **TestClient4.java**. Finds a view instance, creates a new row, inserts it into the row set, and prints to the JDeveloper Log window.	For details, see How to Create a New Row for a View Object Instance.
	Run **TestClient5.java**. Finds a view instance, accesses the row set, iterates over the rows to display the key, and prints to the JDeveloper Log window.	For details, see How to Retrieve the Row Key Identifying a Row.
`wrapplsql`	Run **AppModule** using the Oracle ADF Model Tester.	For details about overriding the default DML processing event for an entity object to invoke methods in a PL/SQL API package that encapsulates insert, update, and delete access to an underlying table, see Basing an Entity Object on a PL/SQL Package API.

Running the Sample Application in the SummitADF_TaskFlows Workspace

The sample Summit application for task flows describes how to use activities in the ADF task flows that you create in your Fusion web application.

The Summit sample application for ADF task flows demonstrates how you can implement security, contextual events, and task flows in your Fusion web application.

How to Run the Summit Sample Application for ADF Task Flows

The easiest way to run the Summit ADF task flow sample application is to expand the ViewController project and run the `index.jsf` page from within this project.

Before you begin:

It may be helpful to have an understanding of the schema that the Summit ADF task flow sample application uses. For more information, see What Happens When You Install the Summit ADF Schema.

You will need to complete these tasks:

- Install Oracle JDeveloper Studio and meet the installation prerequisites. The Summit ADF task flow sample application requires an existing Oracle database. For details, see How to Download the Application Resources.

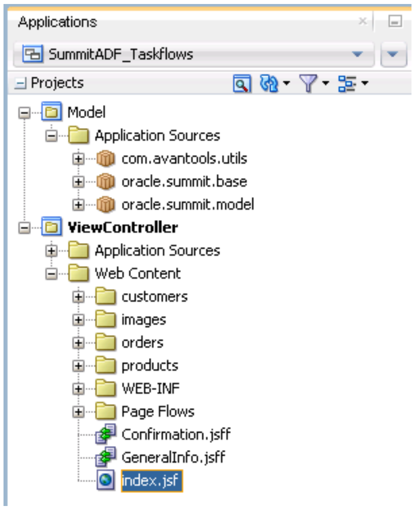
- Download the Summit ADF archive file from the Oracle Technology Network to a local directory and unzip the Summit sample application for ADF task flows. For details, see How to Download the Application Resources.
- Install the Summit ADF schema. For details, see How to Install the Summit ADF Schema.

To run the Summit sample application for ADF task flows:

1. Open the application in JDeveloper:
   a. In the main menu, choose **File** and then **Open**.
   b. Navigate to the location where you expanded the ZIP file for the `SummitADF_Taskflows` directory, select the `SummitADF_Taskflows.jws` application workspace and click **Open**.

      Figure 2-21 shows the Applications window after you open the `SummitADF_Taskflows.jws` application workspace file and expand a number of the nodes. For a description of each of the task flows in the workspace, see Overview of the Summit Sample Application for ADF Task Flows.

      Figure 2-21 Projects in the Summit ADF TaskFlows Application Workspace



2. Create a database connection for the Summit ADF task flow sample application. For details, see How to Create the Database Connection for Summit Sample Applications for Oracle ADF.
3. In the Applications window, expand the **ViewController** and **Web Content** nodes, then right-click `index.jsf` and choose **Run**.

   The Create Default Domain dialog appears the first time you run an application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.
4. Once the `index.jsf` page renders in your browser, you can log in using one of the user accounts listed in Table 2-5 to view the functionality that is configured for an employee or a customer in the application.

Table 2-5 Supplied Users in the Summit ADF Task Flow Sample Application

Username	Password	Application Role	Notes
cmagee	welcome1	Application Employee Role	This is the only user who is preregistered as an employee in the Summit ADF task flow sample application.
214	welcome1	Application Customer Role	This is the only user who is preregistered as a customer in the Summit ADF task flow sample application. The user ID of the customer, Ojibway Retail, serves as the username.

Overview of the Summit Sample Application for ADF Task Flows

The application in the SummitADF_Taskflows workspace demonstrates how you can implement security, contextual events and task flows in your Fusion web application.

The following list shows the filenames of the task flows in the SummitADF_Taskflows workspace. Expand the **Page Flows** node under the ViewController project in the Applications window to view these task flows.

```
|   adfc-config.xml
|
\---flows
    |   customers-task-flow-definition.xml
    |   edit-customer-task-flow-definition.xml
    |   emp-reg-task-flow-definition.xml
    |   product-inventory-task-flow-definition.xml
    |   show-products-task-flow-definition.xml
    |
    \---orders
            create-edit-orders-task-flow-definition.xml
            orders-select-many-items.xml
```

Table 2-6 briefly describes these task flows and provides references to the sections in this guide that use these task flows to demonstrate concepts related to security, contextual events, data rendering and data input.

Apart from these task flows, the SummitADF_Taskflows workspace also contains a jazn-data.xml file where JDeveloper saves all policy store and identity store changes for the application. For more information about this file and its use, see ADF Security Process Overview.

Table 2-6 Task Flows in the Summit ADF Task Flow Sample Application

Task Flow Name	Documentation
adfc-config.xml	Every Fusion web application contains this file. It is the source file for the unbounded task flow that JDeveloper creates by default when you create a Fusion web application. In the Summit ADF task flow sample application, this task flow contains the index view activity that renders the index.jsf page end users see at runtime. This task flow also registers the managed bean (oracle.summit.bean.LoginBean) that handles authentication of users who want to access resources that require authentication. For more information, see How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication.
customers-task-flow-definition.xml	This task flow contains a router, a view and a method call activity to navigate an authenticated customer to the row that the customer selects within the Customer.jsff page fragment. For more information, see Working with Task Flow Activities . ADF Security secures this task flow so that only authenticated customers can access the functionality it configures or the web pages it exposes. For more information, see About ADF Security.
edit-customer-task-flow-definition.xml	This task flow renders a number of page fragments in an ADF region that provide controls to authenticated users to edit data. For more information, see Task Flows and ADF Region Use Cases and Examples.
emp-reg-task-flow-definition.xml	The Summit ADF task flow sample application renders this task flow in an ADF dynamic region when an end user clicks the **Register as Employee** link that appears in the index.jsf page at runtime. For more information, see Creating ADF Dynamic Regions. Unlike other task flows (for example, customers-task-flow-definition.xml) users do not have to be authenticated to access this task flow. For this reason, the security policy for this task flow grants view privileges to the builtin anonymous-role application role, as described in What Happens When You Define the Security Policy.
product-inventory-task-flow-definition.xml	This task flow renders the showInventory.jsff page fragment that appears in the Inventory Control tab. This tab is enabled when you log in as an employee. The application uses contextual events to determine what data to display in the showInventory.jsff page fragment in response to the end user selecting data in another ADF region. For more information about this task flow's use of contextual events, see Using Contextual Events.
show-products-task-flow-definition.xml	This task flow renders the showProducts.jsff page fragment that renders an ADF Faces table component containing data about products. At runtime, an end-user's selection of a product broadcasts a contextual event that the product-inventory-task-flow-definition.xml task flow consumes so that it can display the inventory for the product. For more information about this task flow's use of contextual events, see Using Contextual Events.
create-edit-orders-task-flow-definition.xml	This task flow renders the Orders.jsff page fragment where an end user can add a new product to an order. It also calls another task flow (orders-select-many-items), as described in How to Call a Bounded Task Flow Using a Task Flow Call Activity.
orders-select-many-items.xml	This task flow renders a modal dialog, as described in Running a Bounded Task Flow in a Modal Dialog.

Running the Standalone Samples in the SummitADF_DVT Workspace

The standalone Summit sample application for ADF DVT components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data.

The Summit sample application for ADF DVT components includes a set of standalone sample pages that demonstrate creation and configuration of ADF DVT components using ADF Business Components and data binding.

References to these standalone pages appear throughout the following chapters:

- Creating Databound Chart and Gauge Components
- Creating Databound Pivot Table and Pivot Filter Bar Components
- Creating Databound Geographic and Thematic Map Components
- Creating Databound Gantt Chart and Timeline Components
- Creating Databound Hierarchy Viewer, Treemap, and Sunburst Components

Overview of the Summit ADF DVT Standalone Samples

Each of the standalone pages in the Summit ADF DVT sample application uses the Summit ADF schema to demonstrate creation and configuration of a databound Oracle ADF Data Visualization component.

Figure 2-22 shows the Applications window after you open the `SummitADF_DVT` application workspace.

Figure 2-22 Runnable Pages in the Summit ADF DVT Application Workspace

`sunburstDemo.jsf`	Demonstrates creation of a sunburst using data controls	How to Create Treemaps and Sunbursts Using ADF Data Controls
`thematicMapDemo.jsf`	Demonstrates creation of a thematic map using data controls	How to Create a Thematic Map Using ADF Data Controls
`timelineDemo.jsf`	Demonstrates creation of a timeline component using data controls	How to Create a Timeline Using ADF Data Controls
`treemapDemo.jsf`	Demonstrates creation of a treemap using data controls	How to Create Treemaps and Sunbursts Using ADF Data Controls

How to Run the Summit ADF DVT Sample Application Pages

To run the Summit ADF DVT sample application JSF pages, open the application, expand the View Controller project and run any of the *sample*`.jsf` files.

Before you begin:

It may be helpful to have an understanding of the schema that the Summit ADF DVT sample application uses. For more information, see What Happens When You Install the Summit ADF Schema.

You will need to complete these tasks:

- Install Oracle JDeveloper Studio and meet the installation prerequisites. The Oracle ADF DVT sample application requires an existing Oracle database. For details, see How to Download the Application Resources.
- Download the Summit ADF archive file from the Oracle Technology Network to a local directory and unzip the Summit sample application for ADF DVT. For details, see How to Download the Application Resources.
- Install the Summit ADF schema. For details, see How to Install the Summit ADF Schema.

To run the Summit ADF DVT sample application pages:

1. Open the application in JDeveloper:
   a. In the main menu, choose **File** and then **Open**.
   b. Navigate to the location where you expanded the ZIP file for the `SummitADF_DVT` directory, select the `SummitADF_DVT.jws` application workspace and click **Open**.
2. Create a database connection for the Summit ADF DVT sample application. For details, see How to Create the Database Connection for Summit Sample Applications for Oracle ADF.
3. In the Applications window, expand the **ViewController** and **Web Content** nodes.

   Figure 2-22 shows the Applications window after you open the `SummitADF_DVT.jws` application workspace file for the Summit ADF DVT sample application and expand the **View Controller** and **Web Content** nodes. For a description of each page in the application, see Table 2-7.
4. To run a page, right-click the desired .jsf page and choose **Run**.

   The Create Default Domain dialog appears the first time you run an application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

Part II
Building Your Business Services

This part describes the tasks developers can perform when creating the business components of the Fusion web application.

Part II contains the following chapters:

3

Getting Started with ADF Business Components

This chapter describes getting started with the ADF Business Components in Oracle ADF applications. It describes key features such as the design-time wizards, overview editors, and ADF Model Tester. It also provides an overview of the process that you follow when creating business components in the data model project.

This chapter includes the following sections:

About ADF Business Components

ADF Business Components is a framework that supports creating the Business Service layer of a Fusion web application in JDeveloper with a minimum of coding. In the Fusion web application, the **business service layer** handles connecting to the database, retrieving data, locking database records, and managing transactions. Consider the following three simple examples of business service layer functionality:

- New data appears in relevant displays without requerying

  A person logs into a customer management application and displays a customer and their existing orders. Then if the person creates a new order, when he views the inventory for the ordered product, the amount of product in stock is updated without the need to requery the database.

- Changes caused by business domain logic automatically reflected

  A back office application causes an update to the order status. Business logic encapsulated in the `Orders` **entity object** in the business domain layer contains a simple rule that updates the last update date whenever the order status attribute is changed. The user interface updates to automatically reflect the last update date that was changed by the logic in the business domain layer.

- Invocation of a business service method by the ADF Model layer binding requeries data and sets current rows

  In a tree display, the end user clicks on a specific node in a tree. This action declaratively invokes a business service method by the ADF tree binding on your **application module** that requeries master-detail information and sets the current rows to an appropriate row in the row set. The display updates to reflect the new master-detail data and current row displayed.

Developers save time building business services using **ADF Business Components** since the JDeveloper design time makes typical development tasks entirely declarative. In particular, JDeveloper supports declarative development with ADF Business Components to:

- Author and test business logic in components which automatically integrate with databases
- Reuse business logic through multiple SQL-based views of data, supporting different application tasks
- Access and update the views from browser, desktop, mobile, and web service clients
- Customize application functionality in layers without requiring modification of the delivered application

ADF Business Components supports the business service layer through the following set of cooperating business components:

- Entity object

  An **entity object** represents a row in a database table and simplifies modifying its data by handling all data manipulation language (DML) operations for you. It can encapsulate business logic for the row to ensure that your business rules are consistently enforced. You associate an entity object with others to reflect relationships in the underlying database schema to create a layer of business domain objects to reuse in multiple applications.

- View object

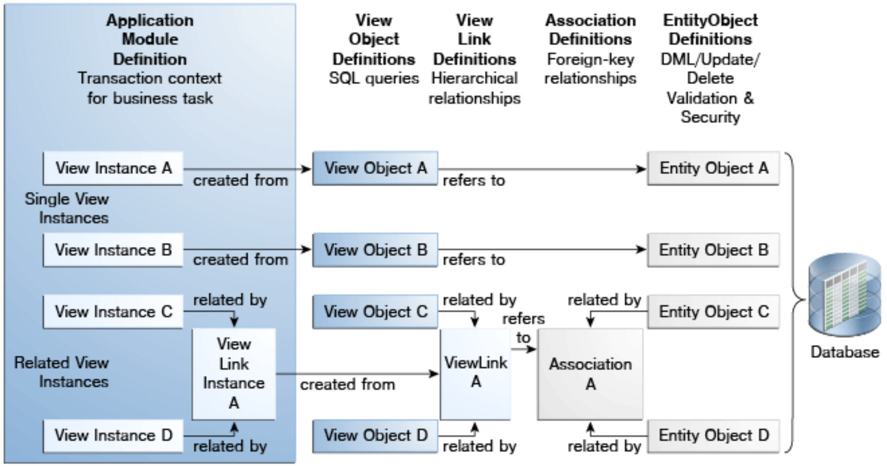
  A **view object** represents a SQL query. You use the full power of the familiar SQL language to join, filter, sort, and aggregate data into exactly the shape required by the end-user task. This includes the ability to link a view object with others to create master-detail hierarchies of any complexity. When end users modify data in the user interface, your view objects collaborate with entity objects to consistently validate and save the changes.

- Application module

  An **application module** is the transactional component that UI clients use to work with application data. It defines an updatable data model and top-level procedures and functions (called **service methods**) related to a logical unit of work related to an end-user task.

Figure 3-1 shows the overall components of the ADF Business Components and their relationships.

Figure 3-1 Overview of ADF Business Components



ADF Business Components Use Cases and Examples

ADF Business Components provides a foundation of Java classes that allow the business service layer of the Fusion web application to leverage the functionality depicted in the following examples:

Simplify Data Access

- Design a data model for client displays, including only necessary data
- Include master-detail hierarchies of any complexity as part of the data model
- Implement end-user Query-by-Example data filtering without code
- Automatically coordinate data model changes with the **business services layer**
- Automatically validate and save any changes to the database

Enforce Business Domain Validation and Business Logic

- Declaratively enforce required fields, primary key uniqueness, data precision-scale, and foreign key references
- Easily capture and enforce both simple and complex business rules, programmatically or declaratively, with multilevel validation support
- Navigate relationships between business domain objects and enforce constraints related to compound components

Support User Interfaces with Multipage Units of Work

- Automatically reflect changes made by business service application logic in the user interface
- Retrieve reference information from related tables, and automatically maintain the information when the end user changes foreign-key values
- Simplify multistep web-based business transactions with automatic web-tier state management

- Handle images, video, sound, and documents without having to use code
- Synchronize pending data changes across multiple views of data
- Consistently apply prompts, tooltips, format masks, and error messages in any application
- Define custom metadata for any business components to support metadata-driven user interface or application functionality
- Add dynamic attributes at runtime to simplify per-row state management

Implement a Service-Oriented Architecture

- Support highly functional web service interfaces for business integration without writing code
- Enforce best-practice interface-based programming style
- Simplify application security with automatic JAAS integration and audit maintenance
- "Write once, run anywhere": use the same business service as plain Java class or web service

Support Application Customization

- Extend component functionality after delivery without modifying source code
- Globally substitute delivered components with extended ones without modifying the application
- Deliver application upgrades without losing or having to reapply downstream customizations manually

Additional Functionality for ADF Business Components

You may find it helpful to understand related **Oracle ADF** features before you start working with ADF Business Components. Following are links to other functionality that may be of interest.

- For details about the Java EE design patterns that ADF Business Components implements, see ADF Business Components Java EE Design Pattern Catalog.
- For details about method calls of the ADF Business Components interfaces and classes, see Most Commonly Used ADF Business Components Methods.
- For details about common Oracle Forms tasks are implemented in Oracle ADF, see Performing Common Oracle Forms Tasks in Oracle ADF.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Creating the ADF Business Components Data Model Project

JDeveloper allows you to create the data model project using ADF view objects and encapsulate them in an ADF Application Module.
JDeveloper includes comprehensive design time support for ADF Business Components. Collectively, these facilities let you create, edit, diagram, test, and refactor the business components.

How to Create a Data Model Project for ADF Business Components

JDeveloper provides an application template that aids in creating databound web applications with Oracle ADF. When you use the **ADF Fusion Web Application** template, your application will consist of one project for the data model (with ADF Business Components) and another project for the view and controller components (**ADF Faces** and **ADF task flows**).

Before you begin:

It may be helpful to have an understanding of the Fusion web application. See Introduction to Building Fusion Web Applications with Oracle ADF.

You may also find it helpful to understand ADF Business Components preferences that can be specified globally across data model projects. For more information, see How to Customize ADF Business Components Preferences.

You may also find it helpful to understand more about the tools and features that JDeveloper provides to create and manage applications. See Getting Started with Developing Applications with Oracle JDeveloperin *Developing Applications with Oracle JDeveloper*.

To create a data model project with the ADF Fusion Web Application template:

1. In the main menu, choose **File** and then **Application > New**.
2. In the New Gallery, in the **Items** list, double-click **ADF Fusion Web Application**.
3. In the Create ADF Fusion Web Application wizard, enter application details like the name and directory. For help with the wizard, press F1.

   The Project 1 Name page of the wizard shows the list of features needed to complete the data model project. The project feature **ADF Business Components** should appear in the list.
4. Click **Finish**.

How to Create a Data Model Project for ADF REST Web Applications

JDeveloper provides an application template that aids in creating databound web applications with Oracle ADF. When you use the **ADF REST Web Application** template, your application will consist of one project for the web components (REST Web Project) and another project for the data model (ADF Business Components).

Before you begin:

It may be helpful to have an understanding of the REST web application. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand ADF Business Components preferences that can be specified globally across data model projects. For more information, see How to Customize ADF Business Components Preferences.

You may also find it helpful to understand more about the tools and features that JDeveloper provides to create and manage applications. For more information, see the Getting Started with Developing Applications with Oracle JDeveloper chapter in *Developing Applications with Oracle JDeveloper*.

To create a data model project with the ADF REST Web Application template:

1. In the main menu, choose **File** and then **Application > New**.
2. In the New Gallery, in the **Items** list, double-click **ADF REST Web Application**.
3. In the Create ADF REST Web Application wizard, enter application details like the name and directory. For help with the wizard, press F1.
4. The Version page of the wizard shows the new version release name and internal name created during the application creation process. Click **Next**.
5. The Project Name page of the wizard shows the list of features needed to complete the data model project. The project feature **ADF Business Components** should appear in the list. Click **Next**.
6. In the Project Java Settings page, enter the package name, the directory of the Java source code in your project, and output directory where output class files will be placed, and click **Finish**.

   > **Note:**
   >
   > REST Web Service project is named by default as `RESTWebService` and contains the `web.xml` file. You cannot edit this project name during the new application setup.

7. You may proceed to create ADF REST resources using the Create Business Components from Tables wizard. For details, see How to Create ADF REST Resources Using the Create Business Components from Tables Wizard.

How to Add an ADF Business Components Data Model Project to an Existing Application

Applications that you create without using a predefined technology template, may be constructed by adding project folders from the New Gallery. When you add a project for ADF Business Components, you will select **ADF Model Project** from the list in the New Gallery. This creates a project that defines a data model for an ADF web application that relies on ADF Business Components.

Before you begin:

It may be helpful to have an understanding of the Fusion web application. For more information, see Introduction to Building Fusion Web Applications with Oracle ADF.

You may also find it helpful to understand more about the tools and features that JDeveloper provides to create and manage applications. See Getting Started with Developing Applications with Oracle JDeveloper in *Developing Applications with Oracle JDeveloper*.

To add a data model project to your application:

1. In the Applications window, select any existing project and in the main menu, choose **File** and then **New > Project**.
2. In the New Gallery, in the **Items** list, double-click **ADF Model Project**.
3. In the Create ADF Model Project wizard, enter project details like the name and directory. For help with the wizard, press F1.

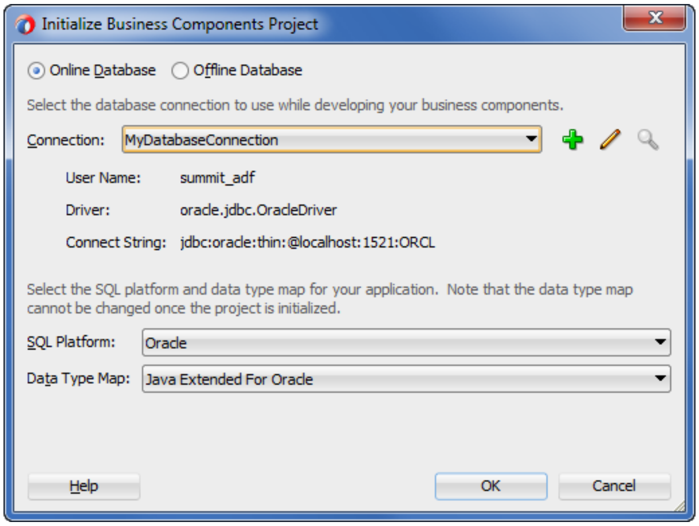
The Project Name page of the wizard shows the list of features needed to complete the model project. The project feature **ADF Business Components** should appear in the list.

4. Click **Finish**.

How to Initialize the Data Model Project With a Database Connection

The first time you create a business component in your ADF Business Components model project, you'll see the Initialize Business Components Project dialog shown in Figure 3-2. You use this dialog to select a design time application resource connection to use while working on your business components in this data model project or to create a new application resource connection by copying an existing IDE-level connection. You can specify whether the database that JDeveloper will use to create business components will be online or offline. The dialog default specifies an online database, for more details about working with an offline database, see How to Change the Data Model Project to Work With Offline Database Objects.

Figure 3-2 Initialize Business Components Project Dialog



● Online Database ○ Offline Database

Select the database connection to use while developing your business components.

Connection: MyDatabaseConnection

User Name: summit_adf

Driver: oracle.jdbc.OracleDriver

Connect String: jdbc:oracle:thin:@localhost:1521:ORCL

Select the SQL platform and data type map for your application. Note that the data type map cannot be changed once the project is initialized.

SQL Platform: Oracle

Data Type Map: Java Extended For Oracle

Since this dialog appears before you create your first business component, you also use it to globally control the SQL platform that the view objects will use to formulate SQL statements. SQL platforms that you can choose include:

- Oracle SQL platform for an Oracle database connection (the default)
- OLite for the Oracle Lite database
- SQLServer for a Microsoft SQLServer database
- DB2 for an IBM DB2 database
- SQL92 for any other supported SQL92- compliant database

> **Note:**
>
> If you plan to have your application run against both Oracle and non-Oracle databases, you should select the **SQL92** SQL platform when you begin building your application, not later. While this sacrifices some of the Oracle-specific optimizations that are inherent in using the Oracle SQL platform, it makes the application portable to both Oracle and non-Oracle databases. Additionally, it is important to understand that support for running ADF applications with multiple SQL platforms chosen at design time is not supported by the ADF runtime. Therefore, you must ensure that ADF applications that you plan to deploy to the same managed server all use a single value for their chosen SQL platform. In the scenario where you will run against both Oracle and non-Oracle databases, you must therefore ensure that all applications have SQL92 chosen as their SQL platform. If this requirement is not observed, SQL validation errors may result at runtime.

Additionally, the dialog lets you determine which set of data types that you want the data model project to use. JDeveloper uses the data type selection to define the data types of attributes when you create entity object and view objects in the data model project. It is therefore important that you make the appropriate selection before you save the settings in the Initialize Business Components Project dialog. The dialog provides these options:

- **Java Extended for Oracle** type map is selected by default if JDeveloper detects you are using an Oracle database driver. The **Java Extended for Oracle** type map uses standard Java types and the optimized types in the `oracle.jbo.domain` package for common data types.

  > **Tip:**
  >
  > New Fusion web applications should use the default **Java Extended for Oracle** type.

- **Java** type map is provided to support applications that will run on a non-Oracle database and that you create using SQL92-compliance. In this case, you should set the data type map to **Java** to globally use only the basic Java data types.
- **Oracle Domains** type map is provided for backward compatibility and for ADF applications that do not use ADF Faces as the view layer technology, as explained in What You May Need to Know About Displaying Numeric Values. Please note that when you migrate an application developed with JDeveloper version 11.1.1.4.0 or earlier, your application will continue to use the **Oracle Domains** type map and will not change to the current default type map **Java Extended for Oracle**

Once you save project selections in the Initialize Business Components Project dialog, the project is considered initialized. You will not be able to change the data type map of the initialized project and it is not recommended to change the SQL platform after you have created business components.

Before you begin:

It may be helpful to have an understanding about database connections as resources in JDeveloper. See Connecting to and Working with Databases in *Developing Applications with Oracle JDeveloper*.

You will need to complete these tasks:

- Create the data model project for ADF Business Components, as described in How to Create a Data Model Project for ADF Business Components.
- Obtain the connection credentials for the database that you will use as a data source for the business components you will create.

To initialize the data model project:

1. In the Application window, right-click the model project in which you want to create business components and choose **New > Business Components from Tables**.

   You can select any other ADF Business Components option, but the option to create business components from tables is particularly useful for generating the first pass of business components that you anticipate needing. If you do not see ADF Business Components options in the context menu, make sure that a model project created for ADF Business Components appears selected in the Applications window.

2. In the Initialize Business Components Project dialog, leave **Online Database** selected and either choose an existing database resource from the dropdown list or click the **Create a New Database Connection** icon.

   If you are creating a database connection, enter the connection information into the Create Database Connection dialog. For help with the dialog, press F1. You can begin working with offline database objects at any time, as described in How to Change the Data Model Project to Work With Offline Database Objects.

3. Select the SQL platform that your business components will use.

   You can select the SQL platform in this dialog only when you first initialize your data model project. After you initialize the project, you can override the SQL platform in the Business Components page of the overview editor for the `adf-config.xml` file, but you must do this before you add business components to the project. You can locate the file in the Application Resources panel by expanding the **Descriptors** and **ADF META-INF** nodes. Specifying the database type in the `adf-config.xml` file supports generating SQL statements during runtime that can require the actual database type of the deployed Fusion web application.

4. Select the data type map that your business components will use. Note that you cannot change the data type map after you have initialized the data model project for ADF Business Components.

   For an application running against an Oracle database, you can usually accept the default **Java Extended for Oracle** which uses standard Java types wherever possible and provides custom Oracle domain types for common data types like numbers and dates. Other supported data type maps include **Oracle Domains** (provided for backward compatibility) and **Java** (select for use with SQL92-compliant applications that will run on a non-Oracle database).

5. Click **OK**.

How to Change the Data Model Project to Work With Offline Database Objects

ADF Business Components supports using offline database as its database object provider. After you have initialized the data model project to specify a database, you can switch to working with the database in offline mode. Working with an offline database to create business components in the model project lets you work in a disconnected fashion and pick up database changes when are ready. This also keeps your project independent of schema changes that might force you to make changes to the business objects.

When you create or select an existing offline database, you still need an online connection; this will be used for testing (using the Oracle ADF Model Tester) and deployment. During design time, the offline database will be used. You can also update an offline database to synchronize with the source database. A database object compare feature lets you obtain a visual mapping that you can use to accept or reject each difference.

Before you begin:

It may be helpful to have an understanding about offline databases in JDeveloper. For more information, see Connecting to and Working with Databases in *Developing Applications with Oracle JDeveloper*.

You will need to complete these tasks:

- Create the data model project for ADF Business Components, as described in How to Create a Data Model Project for ADF Business Components.
- Create the database connection for use when testing business components, as described in How to Initialize the Data Model Project With a Database Connection.

To change the data model project to work with an offline database:

1. In the Application window, right-click the data model project in which you want to create the offline database and choose **Project Properties**.
2. In the Project Properties dialog, select **ADF Business Components**.
3. On the ADF Business Components page, select **Offline Database** and click the **Create a New Offline Database** icon.
4. In the Create Offline Database dialog, enter the database and schema names that you want the data model project to display, select other options to complete the dialog, and then click **OK**.

   The data model project is updated with a new Offline Database Sources folder and contains an empty folder with the name of the offline database.
5. In the **Connection** list, choose the online database that you will connect to when testing business components in the data model project.

   The online database and offline database that you select must have the same schema to ensure database object names and enable testing. For more information about testing business components, see How to Use the Oracle ADF Model Tester.
6. Click **OK**.

To create offline database definitions in the data model project:

1. In the Application window, right-click the folder in which you want to create the offline database and choose **New > Offline Database Objects from Source Database**.
2. In the Reverse Engineer Database Objects wizard, on the Database page, verify that your online database connection is displayed as the **Source Database** and click **Next**.
3. On the Select Objects page, click **Query** and select one or more desired methods from the **Available** list and click the **Add** button to shuttle them into the **Selected** list.
4. Click **Finish**.

What You May Need to Know About Application Server or Database Independence

Applications built using ADF Business Components can be deployed to and run on any application server that Oracle certifies for ADF applications (such as Oracle WebLogic Server or GlassFish). Because business components are implemented using plain Java classes and XML files, you can use them in any runtime environment where a Java Virtual Machine is present. This means that services built using ADF Business Components are easy to use both inside a Java EE server — known as the "container" of your application at runtime — and outside. For more information about deploying ADF applications and the supported application servers, see Deploying Fusion Web Applications.

Customers routinely use application modules in such diverse configurations as command-line batch programs, web services, custom servlets, and JSP pages.

You can also build applications that work with non-Oracle databases, as described in How to Initialize the Data Model Project With a Database Connection. However, applications that target Oracle databases will find numerous optimizations built into ADF Business Components.

> **Note:**
>
> Support for using multiple SQL flavors across ADF applications running on same server is not implemented nor supported by ADF. ADF application developers must therefore ensure that ADF applications they plan to run in the same managed server all use a single value for their SQL flavor. At design time, the SQL flavor can be set either at the project level using the Initialize Business Components dialog or globally in the `adf-config.xml` file. Regardless of the approach used to set the SQLBuilder property, in practice, the value must be the same for all ADF applications running on the same managed server. Failure to implement this requirement can result in runtime conflicts in the binding style that ADF will use to process query statements and this in turn will cause SQL validation errors for the applications. Additionally, it is important to note in the scenario where an ADF application needs to run against both Oracle and non-Oracle databases, all applications on the same managed server must have SQL92 chosen as their SQL flavor.

What You May Need to Know About ADF Business Components Data Types

ADF Business Components is compatible with the built-in data types the Java language provides, including strings, dates, and numeric data. In addition to these Java data types, the `oracle.jbo.domain` packages of ADF Business Components provides types that are optimized for the Oracle database. Table 3-2 shows the ADF Business Components-specific types that you may use in addition to the built-in types provided by the Java language.

Table 3-1 Basic Data Types in the oracle.jbo.domain Packages

Data Type	Package	Represents
`DBSequence`	`oracle.jbo.domain`	Sequential integer assigned by a database trigger
`RowID`	`oracle.jbo.domain`	Oracle database ROWID
`BFileDomain`	`oracle.jbo.domain`	Binary File (BFILE) object
`BlobDomain`	`oracle.jbo.domain`	Binary Large Object (BLOB)
`ClobDomain`	`oracle.jbo.domain`	Character Large Object (CLOB)
`Struct`	`oracle.jbo.domain`	User-defined object type
`Array`	`oracle.jbo.domain`	User-defined collection type (e.g. VARRAY)

For backward compatibility, ADF Business Components still provides the option to select a set of data types in the `oracle.jbo.domain` packages that were available before Java types became the standard. Table 3-2 shows the types that you may use when backward compatibility is desired.

Table 3-2 Backward Compatible Data Types in the oracle.jbo.domain Packages

Data Type	Package	Represents
`Number` (not used by default)	`oracle.jbo.domain`	Any numerical data. If you receive compiler or runtime errors related to "Number is an abstract class" it means you are using `java.lang.Number` instead of `oracle.jbo.domain.Number`. Adding the following line at the top of your class, after the `package` line, prevents these kinds of errors: `import oracle.jbo.domain.Number;`
`Date`	`oracle.jbo.domain`	Date with optional time
`Timestamp`	`oracle.jbo.domain`	Timestamp value
`TimestampTZ`	`oracle.jbo.domain`	Timestamp value with time zone information

Table 3-2 (Cont.) Backward Compatible Data Types in the oracle.jbo.domain Packages

Data Type	Package	Represents
`TimestampLTZ`	`oracle.jbo.domain`	Timestamp value with local time zone information retrieved from JavaVM or from the ADF Context when configured in the application's `adf-config.xml` with an EL expression: `<user-time-zone-config xmlns= "http://xmlns.oracle.com/adf/usertimezone/config"> <user-timezone expression= "EL exp" /> </user-time-zone-config>` The EL expression will be evaluated to determine the time zone of the current end user; otherwise, the value defaults to the time zone of the JavaVM.

What You May Need to Know About Displaying Numeric Values

The **Java Extended for Oracle** type map and the **Oracle Domains** type map handle numeric data differently. When you create a new application the default type map **Java Extended for Oracle** maps numeric data to the `java.math.BigDecimal` class, which inherits from `java.math.Number`. The `java.math.BigDecimal` default matches the way the Fusion web application view layer, consisting of ADF Faces components, preserves alignment of numeric data (such as numeric values displayed by ADF Faces input fields in a web page). Whereas the **Oracle Domains** type map, which maps numeric data to the `oracle.jbo.domain.Number` class, may not display the data with the alignment expected by certain ADF Faces components. Aside from this alignment issue, the **Oracle Domains** type map remains a valid choice and applications without ADF Faces components will function without issue.

How to Customize Model Project Properties for ADF Business Components

Before you begin creating business components, it is a good idea to familiarize yourself with the many project properties that are available to configure ADF Business Components. Selections that you make in the Project Properties dialog will apply to the data model project you are editing. You can specify a variety of properties including suffix naming conventions for generated business components and subpackage names for the data model project.

Before you begin:

It may be helpful to have an understanding about managing projects in JDeveloper. See Getting Started with Developing Applications with Oracle JDeveloper in *Developing Applications with Oracle JDeveloper*.

You may also find it helpful to understand preferences that can be specified globally across data model projects. See How to Customize ADF Business Components Preferences.

You will need to complete this task:

Create the data model project for ADF Business Components, as described in How to Create a Data Model Project for ADF Business Components.

To customize data model project properties:

1. In the Application window, right-click the project in which you want to create the shared application module and choose **Project Properties**.
2. In the Project Properties dialog, expand **ADF Business Components** and select the desired node in the tree. For help with any of the pages of the dialog, press F1.

How to Customize ADF Business Components Preferences

Many design time and runtime options that you can configure for ADF Business Components are specified at the level of JDeveloper preferences. It is a good idea to familiarize yourself with these preferences for ADF Business Components. Selections that you make in the Preferences dialog will apply to each data model project you create.

Certain preferences that you specify globally may be overridden for individual data model projects, as described in How to Customize Model Project Properties for ADF Business Components.

Before you begin:

You may also find it helpful to understand properties that can be specified for individual data model projects. For more information, see How to Customize Model Project Properties for ADF Business Components.

You will need to complete this task:

> Create the data model project for ADF Business Components, as described in How to Create a Data Model Project for ADF Business Components.

To customize ADF Business Components preferences:

1. In JDeveloper, choose **Tools > Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and select the desired node in the tree. For help with any of the pages of the dialog, press F1.

Creating and Editing Business Components

Use JDeveloper’s design time to work with the ADF Data Model to build databound pages and also create and edit ADF Business Components using dedicated wizards and overview editors.
JDeveloper includes comprehensive design time support to create and customize the business components of the data model project. These facilities let you create the components using dedicated wizards, modify their properties with overview editors, and view their definition files in source editors.

How to Create New Components Using Wizards

In the New Gallery, in the **ADF Business Components** category, JDeveloper offers a wizard to create each kind of business component. Each wizard allows you to specify the component name for the new component and to select the package into which you'd like to organize the component. If the package does not yet exist, the new component becomes the first component in that new package.

Each wizard presents a series of pages that capture the necessary information to create the component type. When you click **Finish**, JDeveloper creates the new component by saving its XML document file. And, when you change the default **Code Generation** option in the ADF Business Components - Options page of the Project Properties dialog to generate custom Java class files, JDeveloper can also create initial custom Java class files in addition to the XML document file.

The Create Business Components from Tables wizard is particularly useful in JDeveloper because it is the only wizard that combines generating the various business component types in a single end to end process. This wizard lets you create a large number of business components quickly and easily. You can create entity objects based on an online or offline database, then you can create either entity-based view objects or query-based view objects, and an application module to contain the view instances of the data model. Finally, the wizard gives you the option to generate a business components diagram to display the relationships between the collaborating business components.

After you use a wizard, you can edit any business components you create and you can add new business components later.

Before you begin:

It may be helpful to have an understanding of the various ADF business components. For more information, see About ADF Business Components.

You will need to complete this task:

Create the data model project that will contain the business components, as described in How to Create a Data Model Project for ADF Business Components.

To create collaborating business components in one pass:

1. In the Applications window, right-click the project in which you want to create the entity objects and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Business Components from Tables**, and click **OK**.

   If this is the first component you're creating in the project, the Initialize Business Components Project dialog appears to allow you to select a database connection. Complete the dialog, as described in How to Initialize the Data Model Project With a Database Connection.
3. In the Create Business Components from Tables wizard, on the Entity Objects page, filter the database schema to display available database objects and select those database objects for which you want to create entity objects. Click **Next**.

   Note that if you change a default package name, you must not use reserved words like `rest` in the package name. For details about package naming, see What You May Need to Know About Package Naming Conventions.
4. On the Entity-based View Objects page, select among the available entity objects to create updatable view object definitions for your entity object definitions. Click **Next**.

   Note that the view object definitions you create in this wizard will contain a single usage of an entity object, and will expose all the attributes in that object.
5. On the Query-based View Objects page, select among the available database objects to create read-only view object definitions. Click **Next**.
6. On the Application Module page, leave the default selections unchanged, and click **Next**.

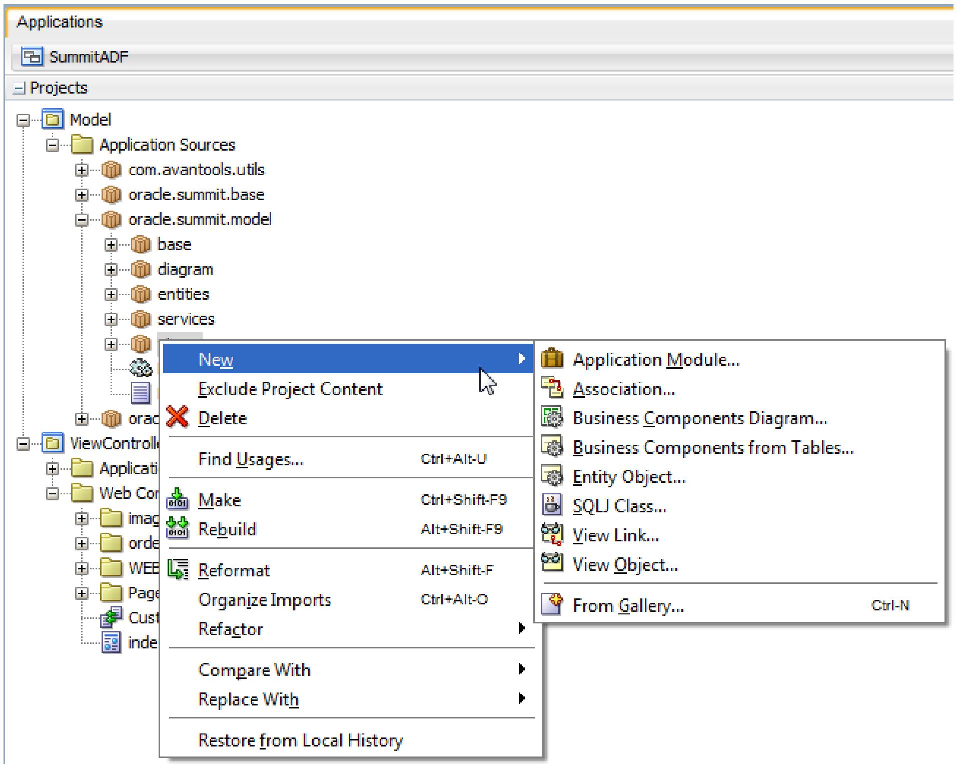
7. On the Diagram page, select **Add to Business Components Diagram**, and click **Next**.
8. On the Summary page, review the list of business components that the wizard will create, and click **Finish**

How to Create New Components Using the Context Menu

Once a package exists in the Applications window, you can quickly create additional business components of any type by selecting the component from the context menu that you display in the Applications window. To add the component, right-click the package in the data model project where you want the component to reside and select the component from the **New** menu. The components displayed in the **New** menu depend on the type of project that you have selected.

Figure 3-3 shows how the Applications window context menu displays the **New** menu after a right-click on a package in the data model project. Because the context menu is displayed on an ADF Business Components data model project, the available components are restricted to just ADF Business Components.

Figure 3-3 Context Menu Options on a Package to Create Any Kind of Business Component



The Applications window context menu displays options that are appropriate for the project that you right-click. If the context menu does not display ADF Business Components options, confirm that the project you right-clicked is an ADF Business Components model project.

Before you begin:

It may be helpful to have an understanding of the various ADF business components. For more information, see About ADF Business Components.

You will need to complete this task:

> Create the data model project that will contain the business components, as described in How to Create a Data Model Project for ADF Business Components.

To add individual business components to the data model project:

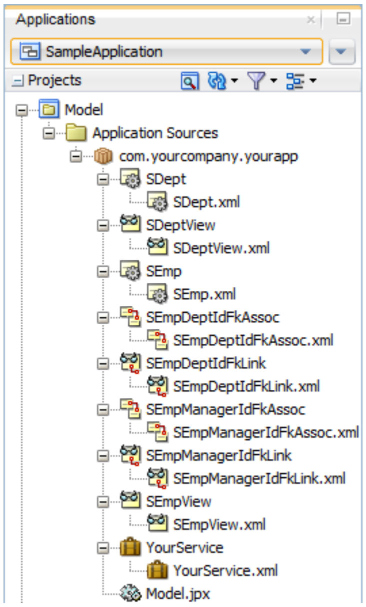
1. In the Applications window, right-click the package in the model project in which you want to create a new business component and choose **New - *business component name***.
2. In the wizard for the business component, complete the pages of the wizard and click **Finish**. For help with any of the pages of the wizard, press F1.

What Happens When You Create Business Components

Each kind of component in ADF Business Components comes with built-in runtime functionality that you control through declarative settings. These settings are stored in an XML document file with the same name as the component that it represents.

Figure 3-4 shows how the Applications window displays the XML document file for each business component in the data model project. To view XML document files in the Applications window, you can expand the node with the name assigned to the business component when it was created in JDeveloper. For example, you can expand the view object node `SDeptView` to view the associated XML document file `SDeptView.xml`. To display the overview editor for the component, you can double-click either the XML document file or its component node.

Figure 3-4   Applications Window Displays Component XML Files

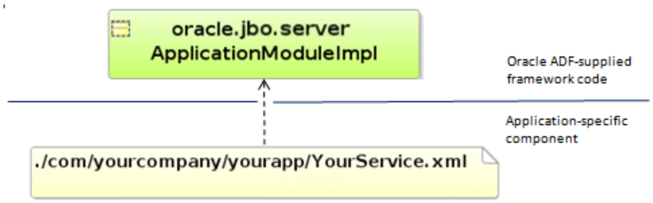


```
Applications
SampleApplication
Projects
Model
  Application Sources
    com.yourcompany.yourapp
      SDept
        SDept.xml
      SDeptView
        SDeptView.xml
      SEmp
        SEmp.xml
      SEmpDeptIdFkAssoc
        SEmpDeptIdFkAssoc.xml
      SEmpDeptIdFkLink
        SEmpDeptIdFkLink.xml
      SEmpManagerIdFkAssoc
        SEmpManagerIdFkAssoc.xml
      SEmpManagerIdFkLink
        SEmpManagerIdFkLink.xml
      SEmpView
        SEmpView.xml
      YourService
        YourService.xml
      Model.jpx
```

Figure 3-5 illustrates the XML document file for an application-specific component like an application module named *`YourService`* that you create in a package named `com.`*`yourcompany.yourapp`*. The corresponding XML document resides in a `./com/`

`yourcompany/yourapp` subdirectory of the data model project's source path root directory. That XML file records the name of the Java class it should use at runtime to provide the application module implementation. In this case, the XML records the name of the base `oracle.jbo.server.ApplicationModuleImpl` class provided by Oracle ADF.

Figure 3-5   XML Document File for an Application Module



oracle.jbo.server
ApplicationModuleImpl
Oracle ADF-supplied framework code
Application-specific component
./com/yourcompany/yourapp/YourService.xml

When used without customization, your component is completely defined by its XML document and it will be fully functional without custom Java code or even a Java class file for the component. If you have no need to extend the built-in functionality of a component in ADF Business Components, and no need to write any custom code to handle its built-in events, you can use the component in this XML-only fashion.

When you need to write custom code for a component, for example to augment the component's behavior, you can enable an optional custom Java class for the component in question, as described in How to Generate Business Component Java Subclasses.

What You May Need to Know About the Model Project Organization

Since ADF Business Components is implemented in Java, its classes and interfaces are organized into packages. Java packages are identified by dot-separated names that developers use to arrange code into a hierarchical naming structure.

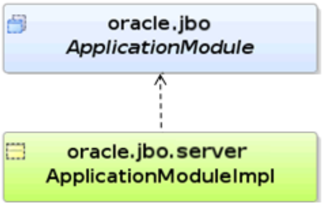
The classes and interfaces that comprise the source code provided by ADF Business Components reside in the `oracle.jbo` package and numerous subpackages. However, in day to day work with ADF Business Components, you'll work typically with classes and interfaces in these two key packages:

- The `oracle.jbo` package, which contains all of the interfaces that are designed for the business service client to work with
- The `oracle.jbo.server` package, which contains the classes that implement these interfaces

> **Note:**
>
> The term *client* here refers to any code in the model, view, or controller layers that accesses the application module component as a business service.

Figure 3-6 shows a concrete example of the application module component. The client interface for the application module is the `ApplicationModule` interface in the oracle.jbo package. This interface defines the names and signatures of methods that clients can use while working with the application module, but it does not include any specifics about the implementation of that functionality. The class that implements the base functionality of the application module component resides in the oracle.jbo.server package and is named ApplicationModuleImpl.

Figure 3-6 ADF Business Components Separate Interface and Implementation



What You May Need to Know About Package Naming Conventions

Since ADF Business Components is implemented in Java, the components of your application (including their classes, interfaces, and metadata files) will also be organized into packages.

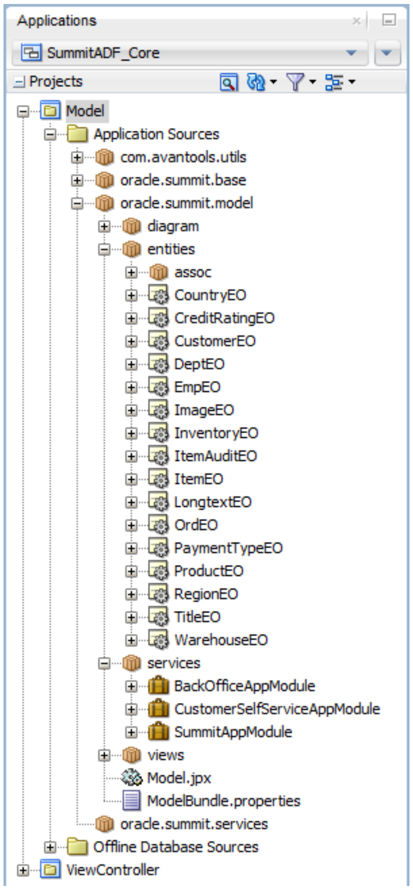
To ensure that your components won't clash with reusable components from other organizations, choose package names that begin with your organization's name or web domain name. So, for example, the Apache organization chose org.apache.tomcat for a package name related to its Tomcat web server, while Oracle picked oracle.xml.parser as a package name for its XML parser. Components you create for your own applications might reside in packages with names like com.*yourcompany*.*yourapp* and subpackages of these.

Package names that you specify must not reference the names of objects that already exist within the ADF Business Components project or include the names of certain technologies, such as rest. When you attempt to modify a default package name in an ADF Business Components wizard and use a reserved word, the wizard prevents this with an alert dialog. For example, naming a package like adf.sample.adfbc.rest is illegal in JDeveloper because rest is a reserved word.

As a specific example, the business components that make up the main business service for the Summit sample application for Oracle ADF are organized into the oracle.summit.model package and its subpackages. As shown in Figure 3-7, these components reside in the Model project in the SummitADF workspace, and are organized as follows:

- oracle.summit.model.diagram contains the business components diagram
- oracle.summit.model.entities contains the entity objects
- oracle.summit.model.services contains the SummitAppModule application module
- oracle.summit.model.views contains the view objects

Figure 3-7 Organization of ADF Business Components in the Core Summit ADF Sample Application



In your own applications, you can choose any package organization that you believe best. In particular, keep in mind that you are not constrained to organize components of the same type into a single package.

There is no optimal number of components in a package. However, the best structure should fall somewhere between the two extremes of placing all components in a single package and placing each component in its own, separate package.

One thing to consider is that the project is the unit of granularity that JDeveloper supports for reuse in other data model projects. So, you might factor this consideration into how you choose to organize components. For more information, see Packaging a Reusable ADF Component into an ADF Library.

What You May Need to Know About Renaming Components

JDeveloper supports component refactoring through specific refactoring actions that help you to incorporate changes as your application evolves. When you use JDeveloper to refactor the business components of your data model project, you can rename components or move them to a different package and JDeveloper will find and update all references to the refactored component. Whenever possible, you should use JDeveloper's refactoring actions to avoid error-prone manual editing of the project. For more information about the usages and limitations of refactoring business components in the data model project, see Refactoring a Fusion Web Application .

How to Edit Components Using the Component Overview Editor

Once a business component exists, you can edit its properties using the respective overview editor that you access either by double-clicking the component in the Applications window or by selecting it and choosing the **Open** option from the context menu.

The overview editor presents the same editing options that you see in the wizard but it may arrange them differently. The overview editor allows you to change any aspect of the component. When you make a change in the component's editor, JDeveloper updates the component's XML document file and, if necessary, any of its related custom Java files. Because the overview editor is a JDeveloper editor window, rather than a modal dialog, you can open and view the overview editor for as many components as you require.

Before you begin:

It may be helpful to have an understanding of the tools available for managing project. For more information, see the Working with Oracle JDeveloper in *Developing Applications with Oracle JDeveloper*.

You will need to complete this task:

> Create the business components in the data model project, as described in How to Create New Components Using Wizards.

To edit properties of a business component in the data model project:

1. In the Applications window, right-click the business component that you want to edit and choose **Open**.
2. In the overview editor for the business component, click the navigation tabs on the left to view and edit related groups of properties. For help with any of the pages of the overview editor, press F1.
3. In the overview editor, click the Source tab to view the changes in the XML definition source.
4. In the overview editor, click the History tab to view the revision history and compare the XML source of what appears in the current overview editor with a past revision.

   For details about managing the versions of files, see Versioning Applications with Source Control in *Developing Applications with Oracle JDeveloper*.
5. In JDeveloper, choose **File > Save** to save the property changes to the business component XML definition file.

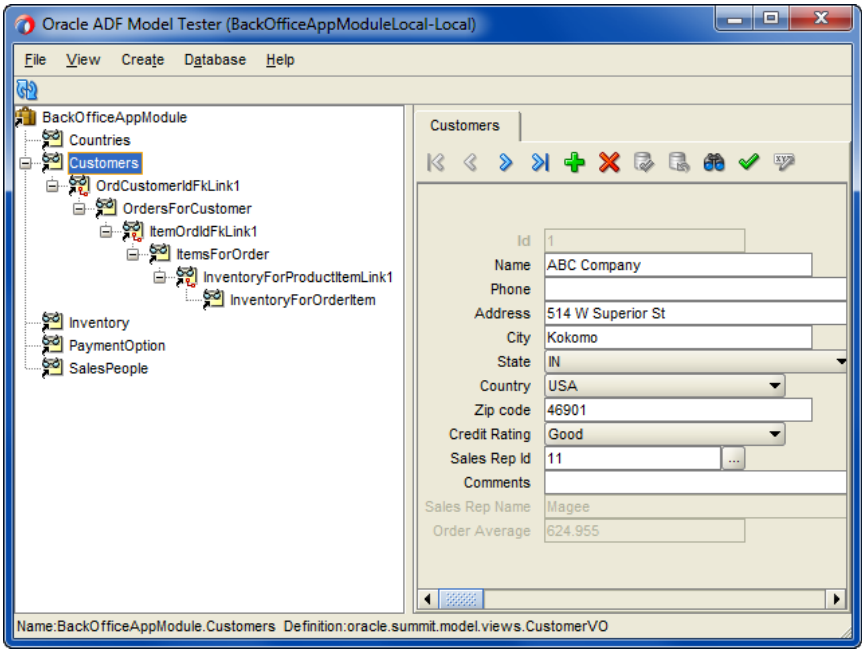
Testing, Refactoring, and Visualizing Business Components

Use the JDeveloper design time to test, refactor and visualize ADF Business Components.
JDeveloper includes comprehensive design time support to manage the growing number of business components that you create in the data model project. These facilities let you test, refactor, and visualize the business components.

How to Use the Oracle ADF Model Tester

Once you have created an application module component, you can test it interactively using the built-in Oracle ADF Model Tester. To launch the Oracle ADF Model Tester, select the application module in the Applications window or in the business components diagram and choose either **Run** or **Debug** from the context menu.

Figure 3-8   Oracle ADF Model Tester



Id: 1
Name: ABC Company
Phone:
Address: 514 W Superior St
City: Kokomo
State: IN
Country: USA
Zip code: 46901
Credit Rating: Good
Sales Rep Id: 11
Comments:
Sales Rep Name: Magee
Order Average: 624.955

Name:BackOfficeAppModule.Customers Definition:oracle.summit.model.views.CustomerVO

As shown in Figure 3-8, Oracle ADF Model Tester presents the view object instances in the application module's data model and allows you to interact with them using a dynamically generated user interface. The tool also provides a list of the application module's client interface methods that you can test interactively by double-clicking the application module node. This tool is invaluable for testing or debugging your business service both before and after you create the web page view layer.

Before you begin:

It may be helpful to have an understanding of the runtime behavior of the data model project. For more information, see Testing View Instance Queries.

You may also find it helpful to understand functionality that can be used to test Oracle ADF applications, including ADF business components. For more information, see Testing and Debugging ADF Components .

You will need to complete this task:

Create the business components in the data model project, as described in How to Create New Components Using Wizards.

To test view instances in an application module configuration:

1. In the Applications window, right-click the application module that you want to test and choose **Run**.

   Alternatively, choose **Debug** when you want to run the application in the Oracle ADF Model Tester with debugging enabled. For more information about this option, see Using the Oracle ADF Model Tester for Testing and Debugging.

2. To execute a view instance in the Oracle ADF Model Tester, expand the data model tree and double-click the desired view instance node.

3. Right-click a node in the data model tree to display the context menu for that node. For example, on a view instance node you can reexecute the query if needed, remove the view instance from the data model tree, and perform other tasks.

4. Right-click the tab of an open data viewer to display the context menu for that tab. For example, you can close the data viewer or open it in a separate window.

5. For help with the Oracle ADF Model Tester, press F1.

What You May Need to Know About Obtaining Oracle ADF Source Code

Since ADF Business Components is often used for business critical applications, it's important to understand that the full source for Oracle ADF, including ADF Business Components, is available to supported customers through Oracle Worldwide Support. The full source code for Oracle ADF can be an important tool to assist you in diagnosing problems, as described in Using the ADF Declarative Debugger. Working with the full source code for Oracle ADF also helps you understand how to correctly extend the base framework functionality to suit your needs, as described in Customizing Framework Behavior with Extension Classes.

How to Find Business Component Usages in the Data Model Project

Before you modify the names of database objects in your offline database or the names of ADF business components, you can view all objects that reference a selected item. You use the Find Usages page in the Log window to display all data model project usages of a selected item.

Before you begin:

It may be helpful to have an understanding of JDeveloper support for refactoring. See Working with Java Code in *Developing Applications with Oracle JDeveloper*.

You may also find it helpful to understand the limitations of refactoring ADF business components. For more information, see Refactoring ADF Business Component Object Attributes.

You will need to complete this task:

> Create the business components in the data model project, as described in How to Create New Components Using Wizards.

To find an item used by ADF business components:

1. In the Application window, in the data model project expand data model project and select the item for which you want to discover usages.

   To find usages of database objects, expand the Offline Database Sources folder and select the desired database object.

2. Right-click the item and choose **Find Usages**.

   To find usages of database columns, display the Structure window and right-click the column in the Structure window.

3. In the Log window, review the business components that reference the selected item.

   The Find Usages page of the Log window links the named items to editors in JDeveloper. Optionally, click an item in the list to view its details in JDeveloper.

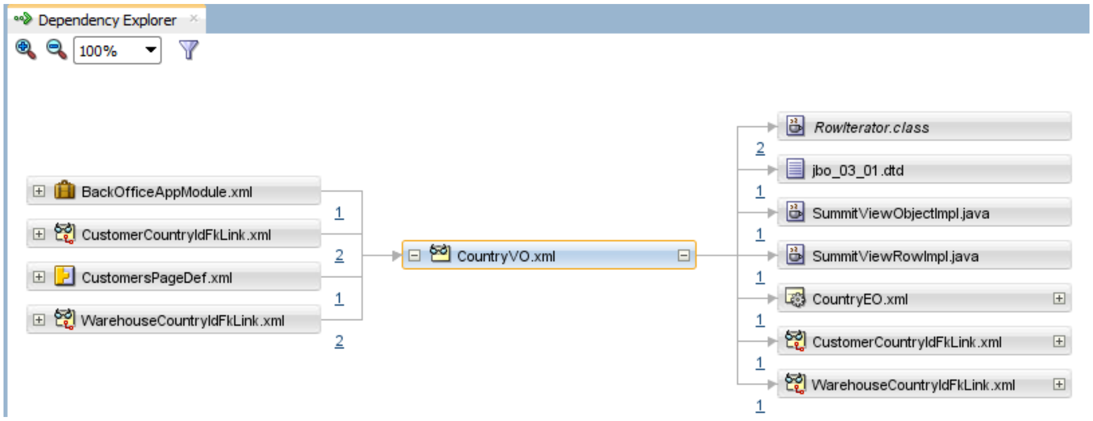
How to Explorer Business Component Dependencies in the Data Model Project

The Dependency Explorer lets you visualize the usage relationships of artifacts in the Data Model project through a diagram that you can expand. As the number of business components in your Data Model project increases, you may want to explore relationships between the business component and other project artifacts. When you expand the diagram you can display artifacts that reference the selected component and artifacts that are referenced by the selected component. In this way, the Dependency Explorer displays more complete relationship information than the usage information returned in the Find Usages log window.

Artifacts that the diagram displays for the Data Model project include the various business component XML definition files (such as, view objects, entity objects, and application module), the project configuration files (including `bc4j.xml` and `Model.jpx`), any resource bundle files (such as `ModelBundle.properties`), any Java implementation files (for example, `SummitViewObjectImpl.java` or `SummitEntityImpl.java`), and ADF Business Component framework source files (including the Oracle ADF Business Component type classes).

Figure 3-9 shows the Dependency Explorer focused on the `CountryVO.xml` file for a view object. The nodes to the left display artifacts that reference `CountryVO` and the nodes to the right are artifacts referenced by `CountryVO`. You can select **Open** from the right-click menu to open any of these artifacts in a JDeveloper source editor and view the detailed reference.

Figure 3-9 Dependency Explorer Displays ADF Business Component Artifacts



Before you begin:

It may be helpful to have an understanding of the common development tools provided by JDeveloper. For more information, see the Working with Oracle JDeveloper in *Developing Applications with Oracle JDeveloper*.

You will need to complete this task:

Create the business components in the data model project, as described in How to Create New Components Using Wizards.

To examine dependencies between ADF business components and other project artifacts:

1. In the Application window, in the data model project expand data model project and select the business component for which you want to examine dependencies.
2. Right-click the item and choose **Explore Dependencies**.
3. In the Dependency Explorer, click the plus icon on a diagram node to expand the diagram. You can expand the diagram to the left to view artifacts that reference the selected component or you can expand to the right to view artifacts referenced by the component.

   When you expand nodes to the left of the selected component you can see where the artifact is used in the application. These are the same items displayed in the Find Usages page of the Log window, when you select Find Usages on the component.
4. Click the linked numeral next to a diagram node to view the detailed list of references, and then click a reference to open the file that contains the reference.

   For more information about the Dependency Explorer, click F1.

How to Refactor Business Components in the Data Model Project

At any time, you can select a component in the Applications window and choose **Refactor > Rename** from the context menu to rename the component. The Structure window also provides a **Rename** context menu option for details of components, such as view object attributes or view instances of the **application module data model**, that do not display in the Applications window. You can also select one or more components in the Applications window by using Ctrl + click and then choosing **Refactor > Move** from the context menu to move the selected components to a new package. References to the old component names or packages in the current data model project are adjusted automatically.

Before you begin:

It may be helpful to have an understanding of JDeveloper support for refactoring. See Working with Java Code in *Developing Applications with Oracle JDeveloper*.

You may also find it helpful to understand the limitations of refactoring ADF business components. For more information, see Refactoring ADF Business Component Object Attributes.

You will need to complete this task:

Create the business components in the data model project, as described in How to Create New Components Using Wizards.

To refactor business components in the data model project:

1. In the Applications window, right-click the business component and choose **Refactor > Rename** or **Refactor > Move**.
2. To delete the object, choose **Delete**.

   If the object is used elsewhere in the application, a dialog appears with the following options:

   - **Ignore**: Unresolved usages will remain in the code as undefined references.
   - **View Usages**: Display a preview of the usages of the element in the Compiler log. You can use the log to inspect and resolve the remaining usages.

How to Refactor Offline Database Objects and Update Business Components

If you are using offline database sources with the data model project, you can rename the database, individual tables, and individual columns. JDeveloper supports refactoring of these database objects in combination with the ADF business components of the data model project, as well as the offline database itself. Changes that you make will automatically be applied to those business components whose definitions reference the database object. For example, if you change the name of a database table in the offline database, any view object queries that reference that table will be modified to use the new table name.

Before you begin:

It may be helpful to have an understanding of JDeveloper support for refactoring. For more information, see Working with Java Code in *Developing Applications with Oracle JDeveloper*.

You may also find it helpful to understand the limitations of refactoring ADF business components. See Refactoring ADF Business Component Object Attributes.

You will need to complete these tasks:

1. Create the business components in the data model project, as described in How to Create New Components Using Wizards.
2. Create the offline database in the data model project, as described in How to Change the Data Model Project to Work With Offline Database Objects.

To refactor offline database table names for ADF business components:

1. In the Application window, in the data model project expand the Offline Database Sources folder and select the database object that you want to edit.
2. In the main menu, choose **Refactor** > **Rename**.

   You can also right-click the database object and choose **Refactor** > **Rename.**
3. In the Rename dialog, enter the new name and click **Preview**.
4. In the Log window, review the business components that reference the database object name.

   The Rename page of the Log window links the named items to editors in JDeveloper. Optionally, click an item in the list to view its details in JDeveloper.
5. Click **Refactor** to apply the new names shown in the Log window.

To refactor offline database column names for ADF business components:

1. In the Application window, in the data model project expand the Offline Database Sources folder and select the database table that contains the column that you want to edit.
2. In the Structure window, double-click the column name.

   You can also right-click the database object and choose **Go to Declaration**.
3. In the overview editor for the offline database table, edit the column name and press Enter.
4. In the Log window, review the business components that reference the column name.

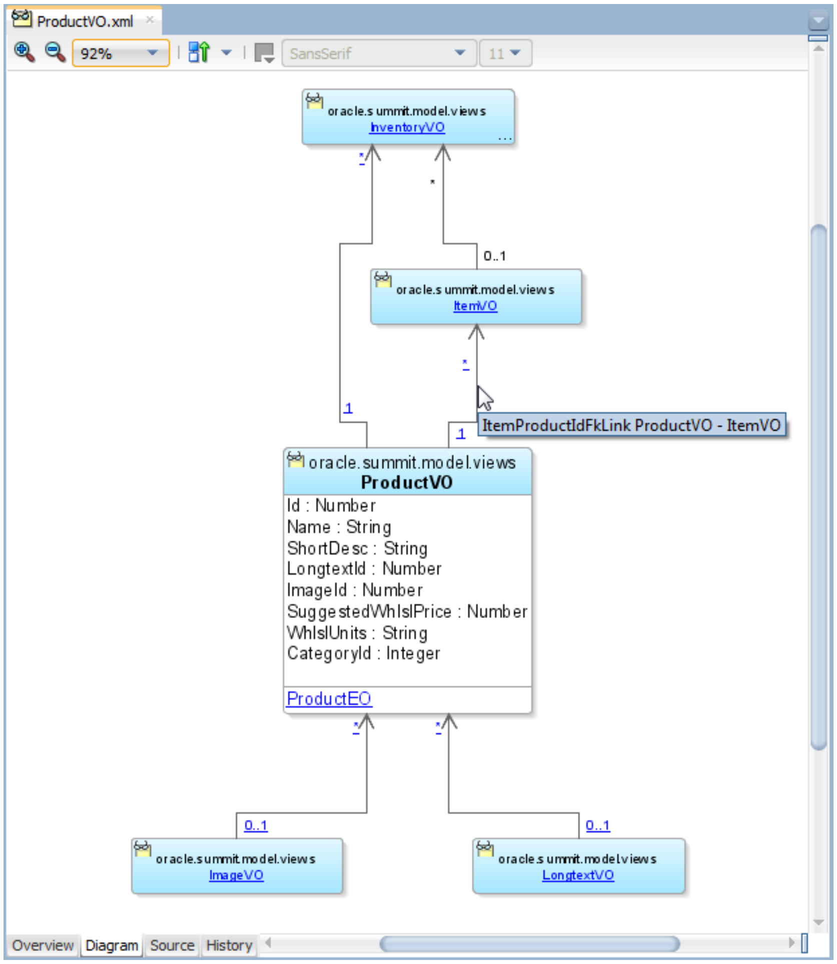
   The Rename page of the Log window links the named items to editors in JDeveloper. Optionally, click an item in the list to view its details in JDeveloper.
5. Click **Refactor** to apply the name changes shown in the Log window.

How to Display Related Business Components Using Diagrams

As the number of business components that your project defines increases, you may decide to refactor components to change the relationships that you originally created. To help you understand the relationship between components in the data model project, open any business component in the overview editor and click the **Diagram** tab. The relationship diagram in the editor identifies the component you are editing in bold text. Related components appear as link text that you can click to display the relationship diagram for the component identified by the link.

For example, Figure 3-10 displays the **Diagram** tab in the editor for the view object `ProductVO`. The diagram identifies the entity objects that `ProductVO` can access (for example, `ProductEO`), the **view link** that defines the view object's relationship to a related view object (for example, mousing over the link between `ProductVO` and `ItemVO`, displays the view link `ItemProductIdFkLink`), and the related view object (in this example, `ItemVO`) named by the view link. Each of these related components displays as a link that you can click to open the component in the **Diagram** tab for its editor. By clicking on related component links, you can use the diagrams to navigate the component relationships that your project defines.

Figure 3-10 Relationship Diagram Displays Main Object and All Related Components



Before you begin:

It may be helpful to have an understanding of JDeveloper support for modeling applications with UML class diagrams. See Developing Applications Using Modeling in *Developing Applications with Oracle JDeveloper*.

You will need to complete this task:

Create the business components in the data model project, as described in How to Create New Components Using Wizards.

To view relationship diagrams for the business components of the data model project:

1. In the Applications window, right-click the business component that you want to view and choose **Open**.
2. In the overview editor, click the Diagram tab to view the component you are editing and all of its related components in a relationship diagram.

   The relationship diagram identifies the component you are editing in bold text. Related components appear as link text that you can click to display the relationship diagram for the component identified by the link. By clicking on related component links, you can use the diagram to navigate the component relationships that your project defines.

What You May Need to Know About Using UML Diagrams

JDeveloper offers extensive UML diagramming support for ADF Business Components. You can drop components that you've already created onto a business components diagram to visualize them. You can also use the diagram to create and modify components. The diagrams are kept in sync with changes you make in the editors.

To create a new business components diagram, use the **Business Components Diagram** item in the **ADF Business Components** category of the JDeveloper New Gallery. This category is part of the **Business Tier** choices.

Customizing Business Components

JDeveloper allows you to extend or customize capabilities of ADF Business Components by creating a custom Java class.
When you need to add custom code to extend the base functionality of a component or to handle events, you must create a custom Java class for any of the key types of ADF Business Components you create, including application modules, entity objects, and view objects.

For example, you can add custom methods to the Java classes of the application module when you want to perform specific business logic. This includes, but is not limited to, code that:

- Configures view object properties to query the correct data to display
- Iterates over view object rows to return an aggregate calculation
- Performs any kind of multistep procedural logic with one or more view objects

By centralizing these implementation details in your application module, you gain the following benefits:

- You make the intent of your code more clear to clients.
- You allow multiple client pages to easily call the same code if needed.
- You simplify regression-testing of your complete business service functionality.
- You keep the option open to improve your implementation without affecting clients.
- You enable *declarative* invocation of logical business functionality in your pages.

How to Generate Business Component Java Subclasses

You can specify company-level subclasses for the entity objects, view objects, and application modules of the data model project. To enable this option so that new business components that you generate are based on these custom classes, you must create Java source files that extend the ADF Business Components implementation classes (in the `oracle.jbo` package) to which extended functionality may eventually be added. Doing this gives you the flexibility to later make changes to the base framework classes that can be picked up by their subclasses in your application.
You can then choose **ADF Business Components > Base Classes** in the Project Properties dialog to specify the names of your subclasses.

You can further enable the generation of custom classes that you wish to generate for the business components for individual components. When you enable this option on the Java page of its respective overview editor, JDeveloper creates a Java source file for a custom class related to the component whose name follows a configurable naming standard. This class, whose name is recorded in the component's XML document, provides a place where you can write further custom Java code required by that component only. Once you've enabled a custom Java class for a component, you edit the class by expanding the component in the Applications window and double-clicking the Java class.

Alternatively, you can change the project-level settings that control how JDeveloper generates Java classes for each component type, choose **Tools > Preferences** and open the **ADF Business Components** page. The settings you choose will apply to all future business components that you create.

> **Best Practice:**
>
> Oracle recommends that developers getting started with ADF Business Components consider overriding the base framework classes to enable all generated custom Java classes to pick up customized behavior. This practice is preferred over creating custom classes for individual entity objects and view objects. You use the **ADF Business Components > Base Classes** page of the Project Properties dialog to specify the framework classes to override when you generate custom component.

Before you begin:

It may be helpful to have an understanding of working programmatically with business components. For more information, see these sections:

- Working Programmatically with an Application Module's Client Interface
- Working Programmatically with Entity Objects and Associations
- Working Programmatically with Multiple Named View Criteria

You will need to complete this task:

Create the business components in the data model project, as described in How to Create New Components Using Wizards.

To override framework business component classes with a custom class:

1. In the Application window, double-click the component for which you want to create the custom class.
2. In the overview editor for the component, select the Java navigation tab.
3. On the Java page, click the **Edit Java options** icon.
4. In the Select Java Options dialog, select generate Java class options to create the desired implementation classes:
   - **Generate Application Module Class**: generates the application module implementation class that may include custom methods to encapsulate functionality that is a logical aspect of the complete business service..

- **Generate Entity Object Class**: generates the entity object implementation class that may include custom methods to act on representations of each row in the underlying database table.
- **Generate View Object Class**: generates the view object implementation class that may include custom methods to act on a particular view object definition within the application module definition.
- **Generate View Row Class**: generates the view row implementation class that may include custom methods to act on representations of a single row returned by the view object.

5. Select the options to generate methods that will support your custom code.

   In the Select Java Options dialog, when you create these classes and select **Include Accessors**, JDeveloper generates accessors for all attributes defined by the business component. Because JDeveloper uses the attribute names in the accessor method names, these attribute names will be difficult to refactor and you should edit the generated class files to remove methods that your custom code will not use.

6. Click **OK**.
7. In the Applications window, expand the business component for which you created the class and double-click the `componentNameImpl.java` file.
8. If you created an entity object class or a view row class, edit the file to remove generated accessor methods for attributes that you do not need to expose for your business use case.

> **Tip:**
>
> Edit the generated class files to remove generated code that is not used by any custom logic to improve overall performance.

How to Expose Business Component Methods to Clients

When you begin adding custom code to your ADF business components that you want clients to be able to call, you can "publish" that functionality to clients for any client-visible component. For each of your components that publishes at least one custom method to clients on its client interface, JDeveloper automatically maintains the related Java interface file. So, assuming you were working with an application module like `SummitAppModule`, you could have custom interfaces like:

- Custom application module interface

  `SummitAppModule extends ApplicationModule`

- Custom view object interface

  `OrderItemsInfo extends ViewObject`

- Custom view row interface

  `OrderItemsInfoRowClient extends Row`

Client code can then cast one of the generic client interfaces to the more specific one that includes the selected set of client-accessible methods you've selected for your particular component.

Before you begin:

You may find it helpful to have an understanding of the methods of the ADF Business Component interfaces that you can override with custom code. For more information, see Most Commonly Used ADF Business Components Methods.

You will need to complete this task:

> Generate the implementation class for the application module or view object and add the custom methods that you want to expose to the client, as described in How to Generate Business Component Java Subclasses.

To expose client methods from the component implementation class:

1. In the Application window, double-click the component for which you want to create the custom class.
2. In the overview editor for the component, select the Java navigation tab.
3. On the Java page, click the **Edit client interface** icon.
4. In the Edit Client Interface dialog, select one or more desired methods from the **Available** list and click the **Add** button to shuttle them into the **Selected** list.
5. Click **OK**.

What Happens When You Generate Custom Classes

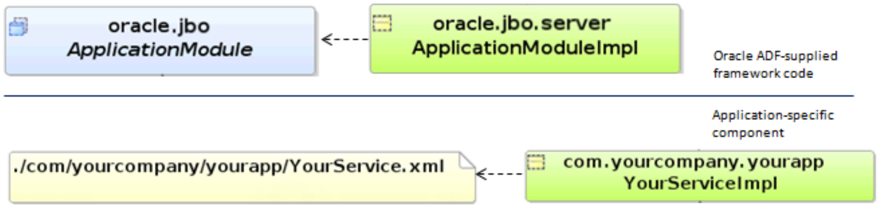
When you select one or more custom Java classes to generate, JDeveloper creates the Java file(s) you've indicated. For example, assuming an application module named `oracle.summit.model.service.SummitAppModule`, the default names for its custom Java files will be `SummitAppModuleImpl.java` for the application module class and `SummitAppModuleDefImpl.java` for the application module definition class. Both files are created in the same `./oracle/summit/model/services` directory as the component's XML document file.

> **Note:**
>
> The examples in this guide use default settings for generated names of custom component classes and interfaces. If you want to change these defaults for your own applications, use the ADF Business Components: Class Naming page of the JDeveloper Preferences dialog. Changes you make only affect newly created components.

The Java generation options for the business components continue to be reflected on subsequent visits to the Java page of the overview editor. Just as with the XML definition file, JDeveloper keeps the generated code in your custom Java classes up to date with any changes you make in the editor. If later you decide you do not require a custom Java file, disabling the relevant options on the Java page removes the corresponding custom Java files.

Figure 3-11 illustrates what occurs when you enable a custom Java class for the *`YourService`* application module. A *`YourServiceImpl`*`.java` source code file is created in the same source path directory as your component's XML document file. The *`YourServiceImpl`*`.xml` file is updated to reflect the fact that at runtime the component should use the com.*yourcompany*.*yourapp*.*YourServiceImpl* class instead of the base ApplicationModuleImpl class.

Figure 3-11 Component with Custom Java Class



oracle.jbo
ApplicationModule
oracle.jbo.server
ApplicationModuleImpl
Oracle ADF-supplied framework code
Application-specific component
./com/yourcompany/yourapp/YourService.xml
com.yourcompany.yourapp
YourServiceImpl

What You May Need to Know About Custom Interface Support

The Java interfaces of the oracle.jbo package provide a client-accessible API for your business service. Your client code works with interfaces like:

- ApplicationModule, to work with the application module
- ViewObject, to work with the view objects
- Row, to work with the view rows

Only these components of the business service are visible to the client:

- Application module, representing the service itself
- View objects, representing the query components
- View rows, representing each row in a given query component's results

This package intentionally does not contain an Entity interface, or any methods that would allow clients to directly work with entity objects. The entity objects in the business service implementation are intentionally not designed to be referenced directly by clients. Instead, clients work with the data queried by view objects as part of an application module's data model. Behind the scenes, the view object cooperates automatically with entity objects in the business services layer to coordinate validating and saving data that the end user changes. For more information about this runtime interaction, see What Happens at Runtime: How View Objects and Entity Objects Cooperate.

What You May Need to Know About Generic Versus Strongly Typed APIs

When working with application modules, view objects, and entity objects, you can choose to use a set of generic APIs or you can have JDeveloper generate code into a custom Java class to enable a strongly typed API for that component. For example, when working with an view object, if you wanted to access the value of an attribute in any row of its result, the generic API would look like this:

```
Row row = ordersVO.getCurrentRow();
Date shippedDate = (Date)row.getAttribute("OrderShippedDate");
```

Notice that using the generic APIs, you pass string names for parameters to the accessor, and you have to cast the return type to the expected type, as with `Date` shown in the example.

Alternatively, when you enable the strongly typed style of working you can write code like this:

```
OrdersRow row = (OrdersRow)ordersVO.getCurrentRow();
Date shippedDate = row.getOrderShippedDate();
```

In this case, you work with generated method names whose return type is known at compile time, instead of passing string names and having to cast the results. Typically, it is necessary to use strongly typed accessors when you need to invoke the methods from the business logic code without sacrificing compile-time safety. This can also be useful when you are writing custom validation logic in setter methods, although in this case, you may want to consider using Groovy expressions instead of generating entity and view row implementation classes for Business Components. Subsequent chapters explain how to enable this strongly typed style of working by generating Java classes for business logic that you choose to implement using Java.

Using Groovy Scripting Language With Business Components

Groovy is a scripting language with Java-like syntax for the Java platform. The Groovy scripting language simplifies the authoring of code by employing dot-separated notation, yet still supports syntax to manipulate collections, Strings, and JavaBeans.

Currently, Groovy expressions are supported on entity object and view object business components. The user can utilize Groovy expressions in ADF Business Components to specify runtime-determined values for view criteria, bind variables, default values of entity or view object attributes, business rules, triggers and more. Additionally, ADF Business Components provides a limited set of built-in keywords that can be used in Groovy expressions. See What You May Need to Know About Where Groovy Expressions May Be Used in the Model Project for details about what you can do using Groovy scripting language.

Generation of the Business Components Script (.bcs) file

When you enter Groovy expressions for an entity object or view object, all of these Groovy expressions populate into a `.bcs` (Business Components Script) file for this business component. View the `.bcs` file for a business component as one among a list of artifacts (such as the Java class, XML file, Operations XML file) belonging to a particular entity object or view object. See How to Enter Groovy Expressions on Business Component to learn how to enter Groovy expressions at various UI contexts in JDeveloper, depending on the context and purpose. The `.bcs` file offers debugging capabilities, and functions like a regular Java editor. Set breakpoints, import annotation packages, compile the Groovy syntax, and fix errors displayed in the Log window.

Type-checking support for Groovy expressions

JDeveloper supports type-checking for Groovy expressions. Type-checking scrutinizes the syntax of Groovy expressions that you create at design time and identifies errors and displays these errors in the JDeveloper Log window. Rectify these errors in your ADF Model project to successfully execute these Groovy expressions at runtime without errors. By default, type-checking is enabled. Type-checking can be disabled.

If type-checking is disabled, type-checking is performed only during runtime. However, it is good practice to type-check Groovy expressions before runtime. You can enable or disable Groovy type-checking for all projects that are created, and/or for specific projects. See What You May Need to Know About Groovy Project Settings for details about application-wide and project-specific Groovy type-checking settings.

> **Note:**
>
> In order to minimize the execution overhead of the groovy script engine, ADF may use an optimized execution path for simple scripts that directly return String or Boolean literals or use a path that directly return a single attribute value. No developer intervention is required to take advantage of this feature. However, the script developer should keep scripts simple, whenever possible.

Script Class File Support

The application allows you to create a custom script class file. Use Script Classes to define a class that can be used by other script classes. A script class file allows you to maintain common Groovy script methods that can be called from within any business component class. This is unlike a regular `.bcs` file that also maintains Groovy scripts that can only be called by the component that this `.bcs` file is associated. See How to Create a Script Expression Class File for details.

How to Enter Groovy Expressions on Business Components

JDeveloper allows you to define Groovy expressions for entity objects, view objects, and view object usages (on an application module). Enter Groovy expressions in the Edit Expression Editor dialog. You invoke this editor in various UI contexts of the application. ADF Business Components supports the use of the Groovy scripting language in places where access to entity object and view object attributes is useful, including attribute validators (for entity objects), attribute default values (for either entity objects or view objects), transient attribute value calculations (for either entity objects or view objects), bind variable default values (in view object query statements and **view criteria** filters), and placeholders for error messages (in entity object validation rules).

Specifically, ADF Business Components provides support for the use of Groovy language expressions to perform the following tasks:

- Add a Script Expression validator or Compare validator (see Using Groovy Expressions For Business Rules and Triggers)
- Define error message tokens for handling validation failure (see How to Embed a Groovy Expression in an Error Message)
- Handle conditional execution of validators (see How to Conditionally Raise Error Messages Using Groovy)
- Set the default value of a bind variable in the view object query statement (see Working with Bind Variables)
- Set the default value of a bind variable that specifies a criteria item in the view criteria statement (see Working with Named View Criteria).

- Define the default value and optional recalculate condition for an entity object attribute (see How to Define a Static Default Value)
- Determine the value of a transient attribute of an entity object or view object (see Adding Transient and Calculated Attributes to an Entity Object and Adding Calculated and Transient Attributes to a View Object)

> **Note:**
>
> These instructions to define the default value of an attribute using Groovy expressions serve as an example to demonstrate how to enter Groovy expressions in the Edit Expression Editor dialog. Given this premise, there is a mention of the Refresh Expression Value, which is defined by you also using the Edit Expression Editor dialog. Now the Refresh Expression Value is specific to defining the default value of an attribute. Therefore, any activity that involves entering Groovy expressions in the Edit Expression Editor dialog may or may not have the associated activity of defining a Refresh Expression Value.

To define the default value of an attribute using Groovy expressions:

1. Open the XML editor view of the entity object or view object. For example, for an entity object named Country, double-click on `CountryEO.xml` to open the Overview Editor of this entity object.
2. Click the **Attributes** tab.
3. Navigate to the **Details** page of the **Attributes** tab and to the **Default Value** section.
4. Click the **Expression** radio-button.
5. Click the icon beside to open the Edit Expression Editor dialog to define the Groovy expression that calculates the default value and click **OK**.
6. If required, in the field immediately below the default value expression as described in the aforementioned step, enter a Refresh Expression Value. Use the same process in the aforementioned step to define the Refresh Expression Value.

What Happens When You Enter Expressions

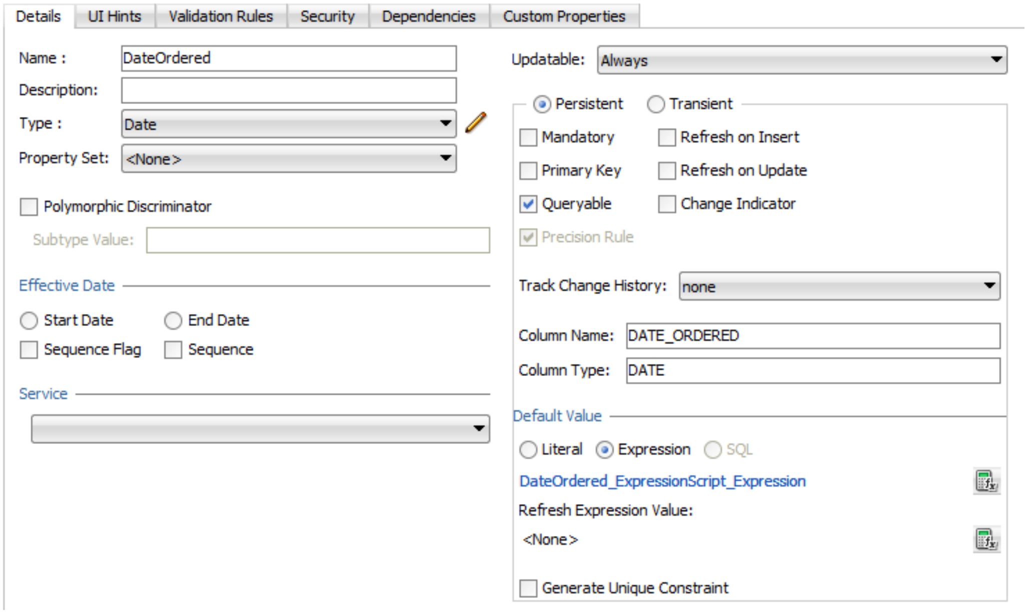
When you enter Groovy expressions for a business component such as an entity object or view object and save the project, the entered Groovy expressions populate in the `.bcs` file associated with the component. Note that to ensure this happens, you must not disable the setting that controls Groovy file generation, as described in What You May Need to Know About Groovy Project Settings. The application provides you a mechanism to enter Groovy expressions in various UI contexts for an entity object or view object. View these added Groovy expressions in the `.bcs` file associated with the business component.

A Groovy expression is represented as an hyperlink when you add Groovy expressions for a business component in the following UI contexts.

- After defining a Groovy expression for an attribute’s default value and/or setting the refresh expression value.
- After defining UI hints such as label, tooltip and so forth for an attribute.

Figure 3-12 shows a Groovy expression added on a view object, to set the default value of this view object's attribute. The expression is represented as a hyperlink. The hyperlink links to the expression script in the `.bcs` file. Click this hyperlink to open the `.bcs` file associated with this business component.

Figure 3-12 Groovy Expression Represented as a Hyperlink

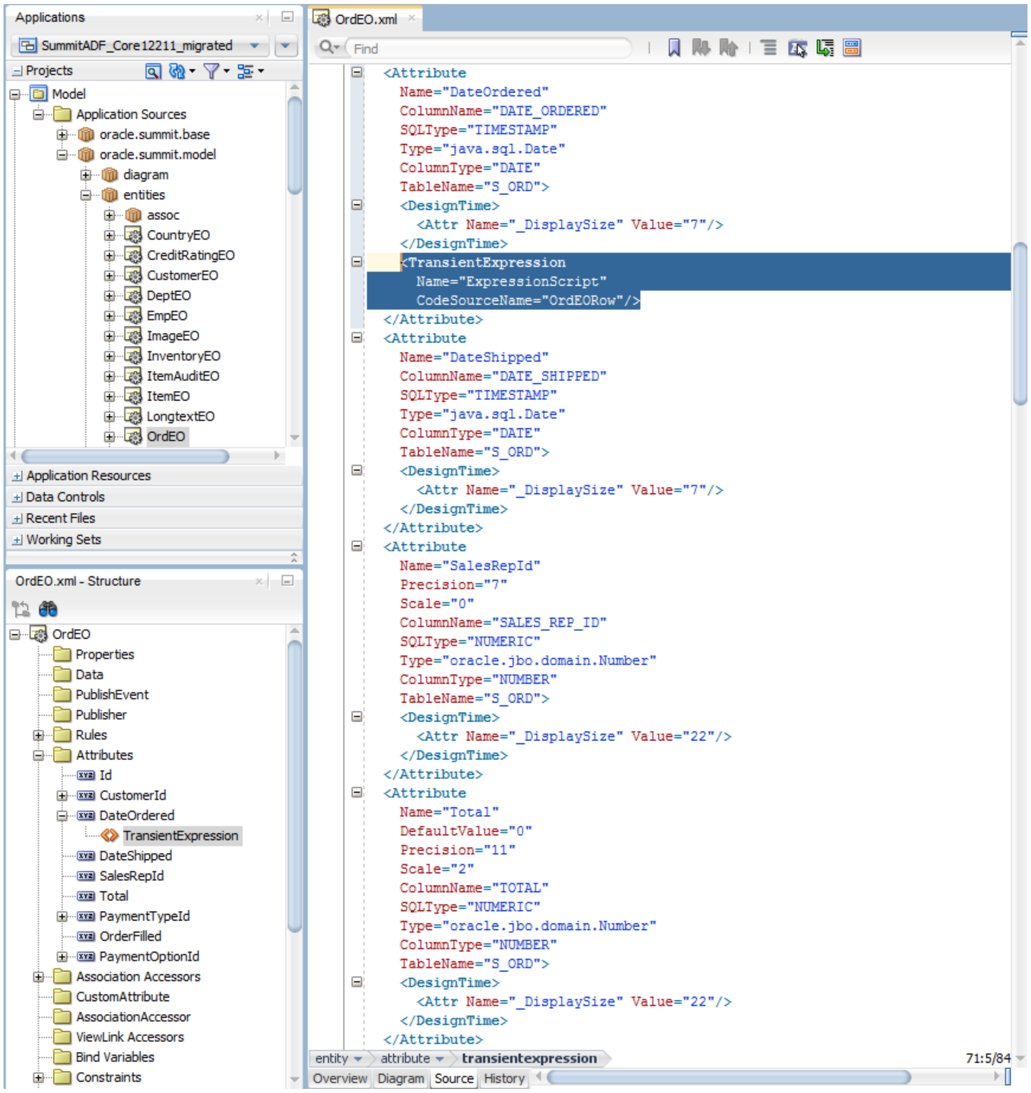


Name : DateOrdered
Description:
Type : Date
Property Set: <None>
□ Polymorphic Discriminator
Subtype Value:
Effective Date
○ Start Date ○ End Date
□ Sequence Flag □ Sequence
Service

Updatable: Always
● Persistent ○ Transient
□ Mandatory □ Refresh on Insert
□ Primary Key □ Refresh on Update
☑ Queryable □ Change Indicator
☑ Precision Rule
Track Change History: none
Column Name: DATE_ORDERED
Column Type: DATE
Default Value
○ Literal ● Expression ○ SQL
DateOrdered_ExpressionScript_Expression
Refresh Expression Value:
<None>
□ Generate Unique Constraint

You can also view Groovy expressions added for an entity object or view object in the component's Structure window. Figure 3-13 shows a Groovy expression added for the `DateOrdered` attribute of the **OrdEO** component in the Structure window in the left-hand bottom side of the screen.

Figure 3-13 Groovy Expression Represented in the Component's Structure Window



```
<Attribute
  Name="DateOrdered"
  ColumnName="DATE_ORDERED"
  SQLType="TIMESTAMP"
  Type="java.sql.Date"
  ColumnType="DATE"
  TableName="S_ORD">
  <DesignTime>
    <Attr Name="_DisplaySize" Value="7"/>
  </DesignTime>
  <TransientExpression
    Name="ExpressionScript"
    CodeSourceName="OrdEORow"/>
</Attribute>
<Attribute
  Name="DateShipped"
  ColumnName="DATE_SHIPPED"
  SQLType="TIMESTAMP"
  Type="java.sql.Date"
  ColumnType="DATE"

  ColumnType="NUMBER"
  TableName="S_ORD">
  <DesignTime>
    <Attr Name="_DisplaySize" Value="22"/>
  </DesignTime>
</Attribute>
<Attribute
  Name="Total"
  DefaultValue="0"
  Precision="11"
  Scale="2"
  ColumnName="TOTAL"
  SQLType="NUMERIC"
  Type="oracle.jbo.domain.Number"
  ColumnType="NUMBER"
  TableName="S_ORD">
  <DesignTime>
    <Attr Name="_DisplaySize" Value="22"/>
  </DesignTime>
</Attribute>
```

JDeveloper represents Groovy expressions in an entity object or view object XML source (visible in the Source tab in the overview editor of the business component), as well as the `.bcs` file associated with this component. In the XML source view of the business component, XML structures define references to Groovy expressions, where the Groovy expressions are represented as scripts in the `.bcs` file for this business component. Annotations in the `.bcs` file provide information about the script, such as the business component on which the Groovy expression is defined, attribute name, and so forth. Therefore, some of the information enclosed as part of the XML definition of a Groovy expression is utilized in the annotations. Importantly, an XML definition of a Groovy expression uses the `CodeSourceName` value to identify the `.bcs` file where this Groovy expression resides as a script. The `CodeSourceName` value is assigned the value of the `operations.xml` file. The `operations.xml` file is another XML file that is associated with a business component that contains the URI of the `.bcs` file.

The following sample shows the resulting XML source of the `DateOrdered` attribute of the `OrdEO` entity object that displays the XML definition referencing a Groovy expression.

```
<Attribute
  Name="DateOrdered"
  ColumnName="DATE_ORDERED"
  SQLType="TIMESTAMP"
  Type="java.sql.Date"
  ColumnType="DATE"
  TableName="S_ORD">
  <DesignTime>
    <Attr Name="_DisplaySize" Value="7"/>
  </DesignTime>
  <TransientExpression
    Name="ExpressionScript"
    CodeSourceName="OrdEORow"/>
</Attribute>
```

And, the following sample shows the `.bcs` file that displays the Groovy script definition for the `DateOrdered` attribute.

```
@TransientValueExpression(attributeName="DateOrdered")
def DateOrdered_ExpressionScript_Expression()
{
  adf.currentDate
}
```

As the samples for the XML source and `.bcs` file show, the `name="DateOrdered` in the XML source corresponds to the method `nameDateOrdered_ExpressionScript_Expression()` in the annotation of the `.bcs` file. These values identify the expression script method name which defines the Groovy expression for this `DateOrdered` attribute. The `CodeSourceName="OrdEORow"` in the XML source indicates the `operations.xml` file, which for the `OrdEO` entity object is `OrdEOOperations.xml`. The `operations.xml` file has a URI which points to the `.bcs` file.

What You May Need to Know About Groovy Project Settings

Enable Groovy type-checking to allow the application to type-check Groovy expressions in the `.bcs` file. Enable Groovy file generation to allow the application to populate all Groovy expressions for a component in its associated `.bcs` file. Groovy type-checking and/or Groovy file generation can be enabled or disabled for a specific Model project or across all projects.

Groovy Expression Type Validation

In JDeveloper from the main menu, navigate to **Application** > **Project Properties** then select **ADF Business Components** from the **Project Properties** dialog and then click the plus icon to expand and select **Options**. On the Options page, select the **Groovy Expression Type Validation** checkbox to enable JDeveloper to perform Groovy expression type validation for this Model project. To set this property for all projects across the application, navigate to **Tools** > **Preferences** and select **ADF Business Components** from the **Preferences** dialog box, and then click the plus icon to expand and select **General**. On the General page, select **Groovy Expression Type Validation** checkbox. When you compile the project, Groovy expressions in the entity object and view object-specific Business Components Script (`.bcs`) files are compiled and errors are reported in the JDeveloper Log window. Deselect this option when you want to prevent type validation from occurring on the Groovy expression scripts defined in the .bcs files; type-checking is disabled for any new projects created from this point onwards, whereas existing projects will continue to receive type-checking. It is recommended that you leave this option enabled (default) to support debugging Groovy expression scripts contained in the component's `.bcs` files. While disabling type checking does not disable debugging of Groovy scripts, leaving type checking enabled does surface problems at compile time instead of at runtime, and will thus make Groovy script debugging easier.

> **Note:**
>
> It is possible to disable type validation at the script level using `.bcs` file annotations. In the `.bcs` file, enter the annotation `@TypeChecked(TypeCheckingMode.SKIP)` above the Groovy expression. In the header section of the `.bcs` file, these import statements-`import groovy.transform.TypeCheckingMode` and `import groovy.transform.TypeChecked` allow the application to comply with the annotations you specify. When you compile Groovy expressions in the `.bcs` file, type-checking is skipped or omitted for the expression for which this annotation is supplied.

Enable Groovy File Generation

In JDeveloper from the main menu, navigate to **Application** > **Project Properties** and select **ADF Business Components** from the **Project Properties** dialog, and then click the plus icon to expand and select **Options** . In the Options page, select the **Enable Groovy File Generation** checkbox to enable JDeveloper to generate Business Components Script (`.bcs`) files in this Model project for the entity objects and view objects with Groovy expressions (default). The `.bcs` file is created on the component, when you define a Groovy expression in the component overview editor (for example, when you enter a default value expression on an entity object attribute or when you define validation rule expressions). Deselect this option when you do not want JDeveloper to aggregate Groovy expressions in `.bcs` files.

If you have already entered Groovy expressions with this checkbox selected, and later deselect the checkbox, the generated `.bcs` files retain all previously added Groovy expressions, but Groovy expressions that you define going forward will not populate in the `.bcs` files and will be saved in the component's XML definition (`.xml`) file. It is recommended that you leave this option enabled (default) to aggregate all expressions into entity object and view object-specific `.bcs` files, where you can edit Groovy expression scripts and compile them for errors. Also, aggregating expressions into Business Components Script files ensures the best runtime performance.

> **Note:**
>
> Users migrating ADF applications to JDeveloper release 12.2.1 and later can retain expressions in the Model project component `.xml` files by clearing this checkbox. However, it is recommended that users leave this checkbox selected and make use of the JDeveloper-provided migration facilities to move all Groovy expressions to `.bcs` files, where script editing and compilation can be performed in the Java source editor.

What You May Need to Know About Where Groovy Expressions Can Be Used

Table 3-3 Groovy Expression Usage in ADF Business Components

Expression Usage	Component Usage	XML Element/Parent XML Element	Description
Transient Attribute Value	entity object / view object	TransientExpression/ Attribute	Calculates a transient attribute value at the row level. Scripts are defined at the row level.
Attribute Default Value	entity object / view object	TransientExpression/ Attribute	Calculates the attribute default value. Scripts are defined at row level.
Attribute Default Value Recalculation	entity object / view object	RecalcCondition/Attribute	When this value evaluates to be true, the default value is recalculated. Scripts are defined at row level.
Variable Default Value	entity object / view object	TransientExpression/ Variable	Calculates the variable default value. Scripts are defined at the object level.
Expression Validator	entity object / view object	TransientExpression/ ExpressionValidationBean (Attribute, ViewAttribute, or Entity)	Executes this expression to validate the current contents of the individual attribute or the whole entity. Scripts are defined at row level.
Compare Validator	entity object / view object	TransientExpression/ CompareValidationBean (under Attribute, ViewAttribute, Entity)	Calculates a value to compare with the new attribute value. Scripts are defined at row level.
Validator OnCondition	entity object / view object	OnCondition/ ExpressionValidationBean, CompareValidationBean, etc. (under Attribute, ViewAttribute, Entity)	Calculates a value to compare with the new attribute value. Scripts are defined at row level.

Table 3-3 (Cont.) Groovy Expression Usage in ADF Business Components

Expression Usage	Component Usage	XML Element/Parent XML Element	Description
Validator Message Parameter	entity object / view object	Expression/ ResExpressions (under all validation types)	In the validator, you can have a text resource to provide an error message when the validator detects an error. Inside the text resource string, you can specify the name of a variable within curly braces {}. This variable refers to a Groovy expression that calculates a value to embed in the text resource. Scripts are defined at row level.
UI Hints	entity object / view object	TransientExpression/ LABEL	In each attribute there are a number of SchemaBasedProperties that are intended to give hints to UI developers as to how the UI should appear for this attribute. Some of these are text resources, such as LABEL and some are just values, such as DISPLAYWIDTH. Any of these UI Hints could be a Groovy expression, calculating the value for the UI Hint. Scripts are defined at row level.
Entity Triggers	entity object	TransientExpression/ ExpressionValidationBean (under Trigger)	The name property under the trigger element identifies the type of this trigger. This expression is fired when the trigger event occurs. Scripts are defined at row level.
View Accessor Parameter	entity object / view object	TransientExpression/PIMap (under ParaeterMap which is under ViewAccessor)	If the view accessor utilizes a view criteria and inside the view criteria an item uses a Bind Variable; this expression provides the value for the Bind Variable. Scripts are defined at the object level.
View Usage Parameter	application module	TransientExpression/PIMap (under ParaeterMap which is under ViewUsage)	If the view usage utilizes a view criteria and inside the view criteria an item uses a Bind Variable; this expression provides the value for the Bind Variable. Scripts are defined at the object level.

Table 3-3 (Cont.) Groovy Expression Usage in ADF Business Components

Expression Usage	Component Usage	XML Element/Parent XML Element	Description
RowFinder Parameter	view object	TransientExpression/ PIMap (under ParaeterMap which is under ViewUsage)	If the rowfinder utilizes a view criteria and inside the view criteria an item uses a Bind Variable; this expression provides the value for the Bind Variable. Scripts are defined at the object level.
View Criteria CompOper	view object	TransientExpression/ CompOper	If the view criteria implements a custom operator, this expression can be used to execute the custom operator. Scripts are defined at the object level.

What You May Need to Know About Groovy Expression Syntax

The following sections provide important details about the syntax of the Groovy expression language in ADF Model projects. Groovy expressions work interactively with ADF Business Components to let you perform numerous activities. There's a lot you can do using Groovy scripts: such as, using `adf.context` in a Groovy expression in order to reference the `ADFContext` object, invoking either custom or ADF Business Components Java APIs, and manipulating business component attribute values using built-in aggregate functions.

What You May Need to Know About Referencing Business Components in Groovy Expressions

There is one top-level object named `adf` that allows you access to objects that the framework makes available to the Groovy script. When you reference an Oracle ADF object in a Groovy expression, the Oracle ADF runtime returns wrapper objects that do not correspond to the actual concrete type of the classes. These wrapper objects support all of the method and field types of the wrapped object. Your expressions can use wrapped objects as if they were the actual object. Note, however, any attempt to cast wrappered objects to its concrete type will fail with a `ClassCastException`. In general, when working with the Groovy language it is not necessary to use explicit casting, and in the case of these wrapped ADF Business Components objects, doing so will cause an exception.

The accessible Oracle ADF objects consist of the following:

- `adf.context` - to reference the `ADFContext` object
- `adf.object` - to reference the object on which the expression is being applied (which can also be referenced using the keyword `object`, without the `adf` prefix). Other accessible member names come from the context in which the Groovy script is applied.

  - Entity object attributes: The context is an instance of the entity implementation class. Through this object you can reference custom methods of the custom entity implementation class, any methods defined by the base implementation class as specified by the Javadoc for `EntityImpl`, and you can reference the attributes of the entity instance.
  - Entity object script validation rules: The context is the validator object (`JboValidatorContext`) merged with the entity on which the validator is applied. For details about keywords that you can use in this context, see Referencing Members of the Same Business Component.
  - View object attributes: The context is an instance of the view row implementation class. Through this object, you can reference custom methods of the custom view row implementation class, any methods defined by the base implementation class as specified by the Javadoc for `ViewRowImpl`, and you can reference the attributes of the view row instance as defined by the query row set. The
  - Bind variable in view object query statements: The context is the variable object itself not the view row. You can reference the `structureDef` property to access other information as well as the `viewObject` property to access the view object in which the bind variable participates. Note that access to view object attributes through the `viewObject` property is not supported.
  - Bind variable in view criteria: The context is the current view criteria row. The view criteria with bind variable may be used to create a query search form component in which a bind variable expression can provide the list of search criteria values. You must reference the `structureDef` property to access the view criteria row, and you can then reference the `findAttributeDef()` method to derive values from a specified attribute. You cannot use the `viewObject` property to access the view object on which the view criteria is defined.
  - Bind variable in view accessors: The context is the current view row. The **view accessor** with bind variable is used to create a cascading List of Value (LOV). The view accessor can derive Groovy-driven values from the current view row in the view accessor view object used to formulate the list of valid choices. You must reference the `structureDef` property to access the view row, and you can then reference the `findAttributeDef()` method to derive values from a specified attribute. You cannot use the `viewObject` property to access the view object for which the view accessor is defined.
  - Transient attributes: The context is the current entity or view row. You can reference attributes by name in the entity or view row in which the attribute appears, as well as public methods on that entity or view row. To access methods on the current object, you must use the `object` keyword to reference the current object (for example, `object.methodName( )`). The `object` keyword is equivalent to the `this` keyword in Java. Without it, in transient expressions, the method will be assumed to exist on the dynamically compiled Groovy script object itself.
- `adf.error` - in validation rules, to access the error handler that allows the validation expression to generate exceptions or warnings
- `adf.userSession` - returns a reference to the ADF Business Components user session (which you can use to reference values in the `userData` hashmap that is part of the session)

You can also reference the current date (time truncated) or current date and time using the following expressions:

- `adf.currentDate`
- `adf.currentDateTime`

What You May Need to Know About Untrusted Groovy Expressions

The ADF Groovy engine restricts Groovy access to general purpose Java APIs. This is done to prevent illegal and/or insecure method calls and property access. An application developer may enhance the security policy to include custom methods defined in the application Java API with the `@AllowUntrustedScriptAccess` annotation.

Custom Java may be used to access Java libraries that are not otherwise supported in ADF scripts. For example, if one wanted to read from a file, in order to support that case, you can create a custom Java class, mark it with the `@AllowUntrustedScriptAccess` annotation, and then invoke the custom class from an ADF script.

In the class file, you need to:

1. Import `oracle.adf.share.security.AllowUntrustedScriptAccess`.
2. Add the annotation `@AllowUntrustedScriptAccess(methodNames={"`*`xyz`*`", "`*`abc`*`"})` at the top of the view object implementation class.

   For example:

   ```
   import oracle.adf.share.security.AllowUntrustedScriptAccess;
   @AllowUntrustedScriptAccess(methodNames = {"testAccessObject"})

   public class ActivityVOImpl extends CRMViewObjectImpl implements
   ActivityVO
   {
       ......

       public boolean testAccessObject(String objectType, Long
   objectKey)
       {
         // your logic here
         return true;
       }
   ```

After you have updated the class file, you can directly access the Java method from the `VOImpl` class inside the Groovy script, just as you would in any source code. For example, to access the `testAccessObject()` method, you would need to invoke the method on the object that you create, as illustrated by the following example.

```
def voActivity = newView('Activity')
def objectType = 'OPPTY'
def objectKey = 100010025532672
voActivity.testAccessObject(objectType, objectKey)
println('Done test');
```

What You May Need to Know About Referencing Custom Business Components Methods and Attributes in Groovy Expressions

Groovy script language simplifies the authoring of code that you might write to access methods and attributes of your entity object and view objects.

Referencing Members of the Same Business Component

The simplest example of referencing business component members, including methods and attributes that the entity object and view object define, is to reference attributes that exist in the same entity object or view object as the attribute that you apply the expression.

For example, you could define a Groovy expression to calculate the value of a transient attribute `AnnualSalary` on an entity object with an attribute `Sal` that specifies the employee's monthly salary:

```
Sal * 12
```

Or, with Groovy you can write a simple validation rule to compare the attributes of a single view object using syntax like:

```
PromotionDate > HireDate
```

Using Java, this same comparison would look like:

```
((Date)getAttribute("PromotionDate")).compareTo((Date)getAttribute("HireDate")) > 0
```

Note that the current object is passed in to the script as the `this` object, so you can reference an attribute in the current object by simply using the attribute name. For example, in an attribute-level or entity-level Script Expression validator, to refer to an attribute named "HireDate", the script can simply reference `HireDate`.

Similar to referencing attributes, when you define custom methods in an entity implementation class, you can invoke those methods as part of your expression. For example, to define an attribute default value:

```
adf.object.getDefaultSalaryForGrade()
```

A method reference requires the prefix `adf.object` which allows you to reference the same entity that defines the attribute on which the expression is applied. This same prefix also allows you to reference the methods of the base class of the entity implementation class (`EntityImpl.java`) that your custom implementation class extends.

Note that when you want to reference the method of an entity implementation class in a validation rule, you use the `source` prefix:

```
source.getDefaultSalaryForGrade()
```

Use of the `source` prefix is necessary in validators because the `object` keyword implies the validation rule object instead of the entity object (where the method is defined).

To allow you to reference members of the validator object (`JboValidatorContext`), you can use these keywords in your validation rule expression:

- `newValue`: in an attribute-level validator, to access the attribute value being set
- `oldValue`: in an attribute-level validator, to access the current value of the attribute being set

For example, you might use the following expression to specify a dynamic validation rule check of the salary for a salesman.

```
if (Job == "SALESMAN")
{
  return newValue < source.getMaxSalaryForGrade(Job)
}
else
return true
```

Referencing Members of Other Business Components

You can also reference the methods and attributes that entity objects and view objects defines in the expressions you apply to a different entity object attribute or validation rule. This is accomplished by referencing the accessor in the **entity association**.

For example, if you define an entity with a master-detail association for `Dept` and `Emp`, by default the accessor for the entity association will be named `Dept` and `Emp`, to identity the source and destination data source. Using that accessor in a Groovy expression to set the default value for a new employee's salary based on the location of their department:

```
adf.object.getDefaultSalaryForGrade(Dept.Loc)
```

This expression does not reference the entity even though it has the same name (`Dept`) as the accessor for the association. Instead, assuming a **master-detail relationship** between departments and employees, referencing the accessor allows the Groovy expression for the employee entity object to walk back to the master department entity and pass in the value of `Loc` from that master.

What You May Need to Know About Manipulating Business Component Attribute Values in Groovy Expressions

You can use the following built-in aggregate functions on Oracle Business Components `RowSet` objects:

- `*rowSetAttr*.sum(*GroovyExpr*)`
- `*rowSetAttr*.count(*GroovyExpr*)`
- `*rowSetAttr*.avg(*GroovyExpr*)`
- `*rowSetAttr*.min(*GroovyExpr*)`
- `*rowSetAttr*.max(*GroovyExpr*)`

These aggregate functions accept a string-value argument that is interpreted as a Groovy expression that is evaluated in the context of each row in the row set as the aggregate is being computed. The Groovy expression must return a numeric value (or number domain).

For example, in a `Dept` entity object you could add a transient attribute that displays the sum of all employee salaries that is calculated by this expression:

```
EmployeesInDept.sum("Sal")
```

To reference the employees of a specific department, the expression supplies the name of the master-detail association's accessor for the destination `Emp` entity. In this case, the accessor is `EmployeesInDept` and salary is interpreted for each record of the `Emp` entity object.

Or, assume that you want the calculation of the salary total for specific departments to include each employee's benefits package, which varies with job role:

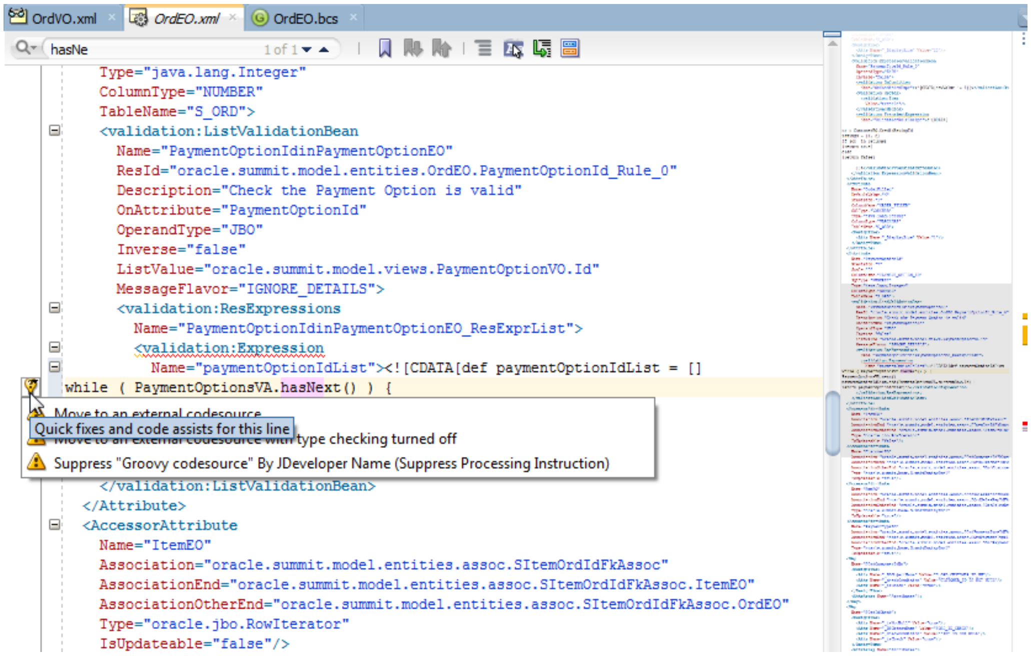
```
EmployeesInDept.sum("Sal + adf.object.getBenefitsValue(Job)")
```

What You May Need to Know About Migrating Groovy Snippets

When migrating to JDeveloper 12.2.1 or later from a previous release, the application allows you to migrate Groovy snippets to the `.bcs` file. In releases prior to JDeveloper 12.2.1, Groovy expressions defined on a business component, such as an entity object or view object, reside in the XML source of this business component. From JDeveloper 12.2.1 onwards, Groovy expressions defined on a business component aggregate into the `.bcs` file associated with this business component, if Groovy file generation is enabled. Type-checking if enabled for the current project or for all projects, is performed by the application in the `.bcs` file, upon compilation. See What You May Need to Know About Groovy Project Settings for details on how to enable/ disable Groovy type-checking and/or Groovy file generation.

Starting in JDeveloper 12.2.1, the settings that enable Groovy file generation into the `.bcs` file and type-checking of Groovy expressions in the `.bcs` file are enabled by default. So when you migrate an ADF application to JDeveloper 12.2.1 from a previous release, the application displays prompts in the gutter of the XML source of the business component. Click the prompts to display options that allow you to move Groovy expressions into the `.bcs` file. Figure 3-14 displays the prompts that JDeveloper displays for a Groovy snippet in the XML source (visible in the Source tab of the overview editor for the business component).

Figure 3-14   Code Assist Performs Groovy Snippet Migration



```
    Type="java.lang.Integer"
    ColumnType="NUMBER"
    TableName="S_ORD">
    <validation:ListValidationBean
      Name="PaymentOptionIdinPaymentOptionEO"
      ResId="oracle.summit.model.entities.OrdEO.PaymentOptionId_Rule_0"
      Description="Check the Payment Option is valid"
      OnAttribute="PaymentOptionId"
      OperandType="JBO"
      Inverse="false"
      ListValue="oracle.summit.model.views.PaymentOptionVO.Id"
      MessageFlavor="IGNORE_DETAILS">
      <validation:ResExpressions
        Name="PaymentOptionIdinPaymentOptionEO_ResExprList">
        <validation:Expression
          Name="paymentOptionIdList"><![CDATA[def paymentOptionIdList = []
while ( PaymentOptionsVA.hasNext() ) {
```

Move to an external codesource
Quick fixes and code assists for this line
Move to an external codesource with type checking turned off
Suppress "Groovy codesource" By JDeveloper Name (Suppress Processing Instruction)

```
    </validation:ListValidationBean>
  </Attribute>
  <AccessorAttribute
    Name="ItemEO"
    Association="oracle.summit.model.entities.assoc.SItemOrdIdFkAssoc"
    AssociationEnd="oracle.summit.model.entities.assoc.SItemOrdIdFkAssoc.ItemEO"
    AssociationOtherEnd="oracle.summit.model.entities.assoc.SItemOrdIdFkAssoc.OrdEO"
    Type="oracle.jbo.RowIterator"
    IsUpdateable="false"/>
```

- Select **Move to an external codesource** to move this Groovy snippet for which this prompt displays, into the `.bcs` file for this business component.
- Select **Move to an external codesource with type checking turned off** to move this Groovy snippet for which this prompt displays, into the `.bcs` file for this business component, with type-checking turned off.
- Select **Suppress "Groovy codesource" By JDeveloper Name (Suppress Processing Instruction)** to turn-off these prompts. Once turned-off, prompts do not display in the XML source for any other migrated business component having Groovy expressions.

After a Groovy snippet is migrated from the XML source to the `.bcs` file, the XML definition in the XML source displays a reference to the `.bcs` file where this migrated Groovy snippet resides. A migrated Groovy expression (as with any Groovy expression) has common information in the XML definition of the XML source that overlaps with the information contained in the annotations in the `.bcs` file. This common information helps identify a Groovy expression across the XML source and `.bcs` file. See What Happens When You Enter Expressions for details on the common information about a Groovy expression across the XML source and `.bcs` file contexts.

> **Note:**
>
> JDeveloper facilitates migration capabilities with audit rules that execute when you open the application. Audit rules are part of an audit profile — which is a collection of audit rules. A set of pre-enabled Groovy-specific audit rules achieve migration. To view these flags, from the main menu of JDeveloper navigate to **Tools** > select **Preferences**. In the Preferences dialog, select **Audit**. Click **Manage Profiles** to view the list of audit profiles. From this list, select and expand the **Application Development Framework (ADF)** audit profile to view the list of sub-rules. Select and expand **ADFbc Audit Rules** to view the list of sub-rules within this rule. Select and expand **Common** to view the Groovy-specific Audit rules that are pre-enabled, and which facilitate migration of Groovy snippets. See Understanding Audit Rules of *Developing Applications with Oracle JDeveloper*.

How to Create a Script Expression Class File

ADF Business Components allows you to create a script expression class file that you use to maintain common Groovy script methods that can be called by from anywhere within the application.

To create a script expression class file:

1. From the **File** menu, click **New**, select **From Gallery**, select **ADF Business Components** in the Business Tier section of the New Gallery dialog and select **Script Class** in the right-hand pane of this dialog.
2. In the Create Script Expression Class dialog, enter the class name of this script expression class in the **Class Name** field.
3. Specify the package that this script expression class resides in the **Package Name** field.

4. Optionally, specify the script expression classes that this script expression class extends in **Extends**.
5. Click **OK**.

The script expression class file is created and can be opened in JDeveloper from the package it resides.

4

Creating a Business Domain Layer Using Entity Objects

This chapter describes how to use ADF entity objects to create a reusable business layer of Java objects that describe the business domain in an Oracle ADF application. This chapter includes the following sections:

About Entity Objects

You use ADF entity objects to represent rows of a data source. ADF entity objects allow you to modify row attributes, encapsulate domain business logic and implement business policies and rules.

An entity object is the ADF business component that represents a row in the specified data source (generally a single database table, view, or synonym) and simplifies modifying its associated attributes. Importantly, it allows you to encapsulate domain business logic to ensure that your business policies and rules are consistently validated.

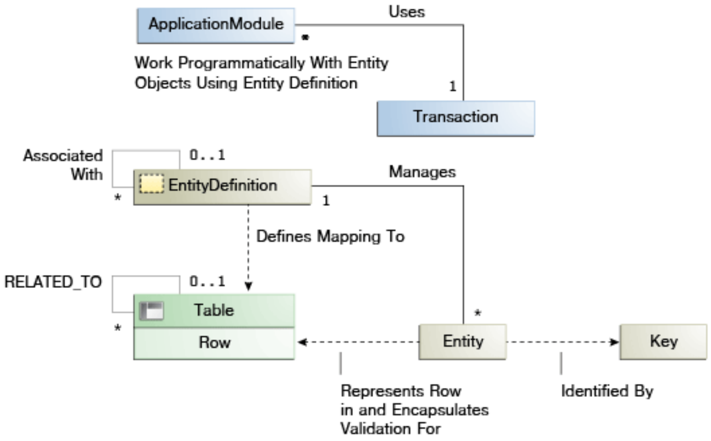
Entity Object Use Cases and Examples

Entity objects support numerous declarative business logic features to enforce the validity of your data. You will typically complement declarative validation with additional custom application logic and business rules to cleanly encapsulate a maximum amount of domain business logic into each entity object. Your associated set of entity objects forms a reusable business domain layer that you can exploit in multiple applications.

The key concepts of entity objects (as illustrated in Figure 4-1) are the following:

- You define an entity object by specifying the database table whose rows it will represent.
- You can create associations to reflect relationships between entity objects.
- At runtime, entity rows are managed by the entity definition object.
- Each entity row is identified by a related row key.
- You retrieve and modify entity rows in the context of an **application module** that provides the database transaction.

Figure 4-1 Entity Object Encapsulates Business Logic for a Table



Additional Functionality for Entity Objects

You may find it helpful to understand other **Oracle ADF** features before you start working with entity objects. Following are links to other functionality that may be of interest.

- For information about using declarative validation in entity objects, see Defining Validation and Business Rules Declaratively.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Creating Entity Objects and Associations

Create ADF entity objects and associations from existing tables. You can also create ADF entity objects from scratch and generate tables.

If you already have a database schema to work from, the simplest way to create entity objects and associations is to reverse-engineer them from existing tables. When needed, you can also create an entity object from scratch, and then generate a table for it later.

How to Create Multiple Entity Objects and Associations from Existing Tables

To create one or more entity objects, use the Business Components from Tables wizard, which is available from the New Gallery.

Before you begin:

It may be helpful to have an understanding of the options you have for creating entity objects. For more information, see Creating Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create one or more entity objects and associations from existing tables:

1. In the Applications window, right-click the project in which you want to create the entity objects and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Business Components from Tables**, and click **OK**.

   If this is the first component you're creating in the project, the Initialize Business Components Project dialog appears to allow you to select a database connection.
3. In the Initialize Business Components Project dialog, select the database connection or click the **Create a new database connection** icon to create a connection. Click **OK**.
4. On the Entity Objects page, do the following to create the entity objects:
   - Enter the name of the package in which all of the entity objects will be created.
   - Select the tables from the **Available** list for which you want to create entity objects.

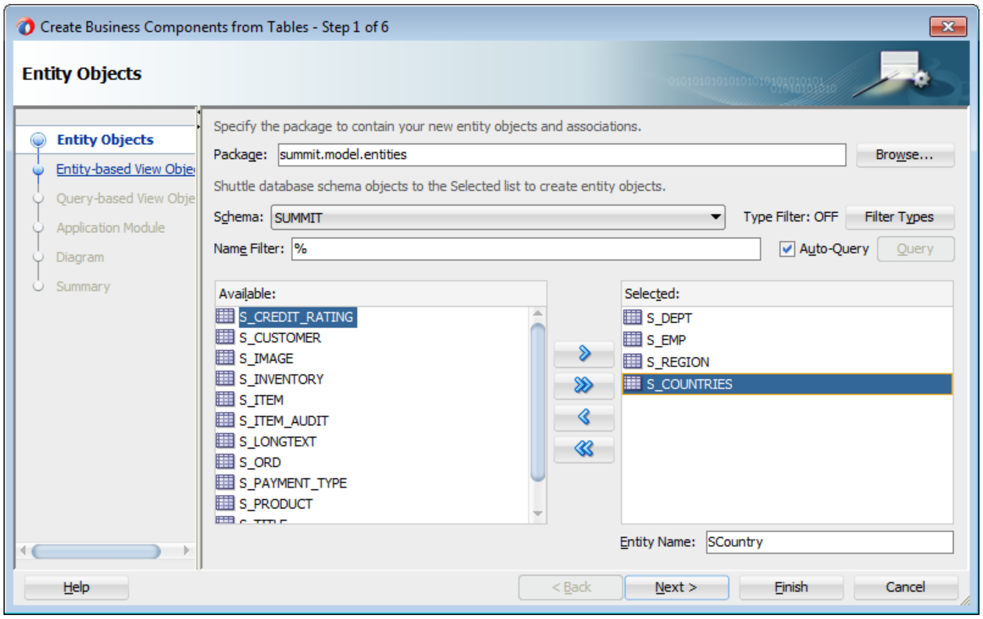
     If the **Auto-Query** checkbox is selected, then the list of available tables appears immediately. In the **Name Filter** field, you can optionally enter a full or partial table name to filter the available tables list in real time. As an alternative to the auto-query feature, click the **Query** button to retrieve the list based on an optional table name filter. When no name filter is entered, JDeveloper retrieves all table objects for the chosen schema.
   - Click **Filter Types** if you want to see only a subset of the database objects available. You can filter out tables, views, or synonyms.

Once you have selected a table from the **Available** list, the proposed entity object name for that table appears in the **Selected** list with the related table name in parenthesis.

- Select an entity object name in the **Selected** list and use the **Entity Name** field to change the default entity object name.

> **Best Practice:**
>
> Because each entity object instance represents a *single* row in a particular table, name the entity objects with a singular noun (like Address, Order, and Person), instead of their plural counterparts. Figure 4-2 shows what the wizard page looks like after selecting the `S_COUNTRIES` table in the Summit ADF schema, setting a package name of `summit.model.entities`, and renaming the entity object in the singular.

Figure 4-2 Create Business Components from Tables Wizard, Entity Objects Page



Create Business Components from Tables - Step 1 of 6

Entity Objects

Specify the package to contain your new entity objects and associations.

Package: summit.model.entities

Shuttle database schema objects to the Selected list to create entity objects.

Schema: SUMMIT

Type Filter: OFF

Name Filter: %

☑ Auto-Query

Available:
S_CREDIT_RATING
S_CUSTOMER
S_IMAGE
S_INVENTORY
S_ITEM
S_ITEM_AUDIT
S_LONGTEXT
S_ORD
S_PAYMENT_TYPE
S_PRODUCT
S_TITLE

Selected:
S_DEPT
S_EMP
S_REGION
S_COUNTRIES

Entity Name: SCountry

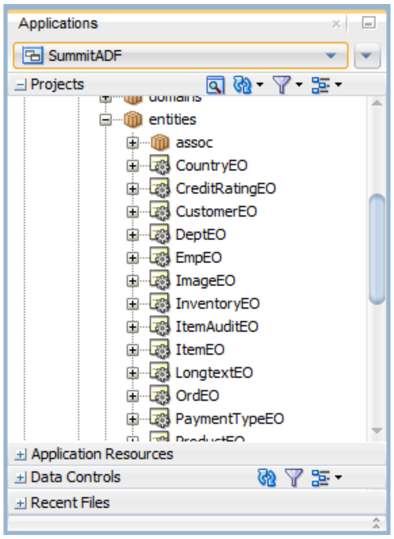
5. When you are satisfied with the selected table objects and their corresponding entity object names, click **Finish**.

The Applications window displays the entity objects in the package you specified.

Best Practice:

After you create associations, move all of your associations to a separate package so that you can view and manage them separately from the entity objects. In Figure 4-3, the associations have been moved to a subpackage (`assoc`) and do not appear in the `entities` package in the Applications window. For more information, see How to Rename and Move Associations to a Different Package.

Figure 4-3 New Entity Objects in Applications window



How to Create Single Entity Objects Using the Create Entity Wizard

To create a single entity object, you can use the Create Entity Object wizard, which is available in the New Gallery.

Note:

Associations are not generated when you use the Create Entity Object wizard. However, the Business Components from Tables wizard does generate associations. If you use the Create Entity Object wizard to create entity objects, you will need to create the corresponding associations manually.

Before you begin:

It may be helpful to have an understanding of the options you have for creating entity objects. For more information, see Creating Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create a single entity object:

1. In the Applications window, right-click the project in which you want to create the entity object and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Entity Object**, and click **OK**.

   If this is the first component you're creating in the project, the Initialize Business Components Project dialog appears to allow you to select a database connection.
3. In the Initialize Business Components Project dialog, select the database connection or choose **New** to create a connection. Click **OK**.
4. On the Name page, do the following to create the entity object:
   - Enter a name for the entity object.
   - Enter the package name in which the entity object will be created.
   - Click **Browse** (next to the **Schema Object** field) to select the table for which you want to create the entity object.

     Or, if you plan to create the table later, you can enter a name of a table that does not exist.
5. If you manually entered a table name in the **Schema Object** field, you will need to define each attribute on the Attributes page of the wizard. Click **Next**.

   You can create the table manually or generate it, as described in How to Create Database Tables from Entity Objects.
6. When you are satisfied with the table object and its corresponding entity object name, click **Finish**.

What Happens When You Create Entity Objects and Associations from Existing Tables

When you create an entity object from an existing table, first JDeveloper interrogates the data dictionary to infer the following information:

- The Java-friendly entity attribute names from the names of the table's columns (for example, `USER_ID` -> `UserId`)
- The SQL and Java data types of each attribute based on those of the underlying column
- The length and precision of each attribute
- The primary and unique key attributes
- The mandatory flag on attributes, based on `NOT NULL` constraints
- The relationships between the new entity object and other entities based on foreign key constraints

Note:

Since an entity object represents a database row, it seems natural to call it an **entity row**. Alternatively, since at runtime the entity row is an instance of a Java object that encapsulates business logic for that database row, the more object-oriented term **entity instance** is also appropriate. Therefore, these two terms are interchangeable.

JDeveloper then creates the XML document file that represents its declarative settings and saves it in the directory that corresponds to the name of its package. For example, when an entity named `Order` appears in the `genericbcmodel.entities` package, JDeveloper will create the XML file `genericbcmodel/entities/Order.xml` under the project's source path. This XML file contains the name of the table, the names and data types of each entity attribute, and the column name for each attribute.

You can inspect the XML description for the entity object by opening the object in the overview editor and clicking the **Source** tab.

Note:

If your IDE-level Business Components Java generation preferences so indicate, the wizard may also create an optional custom entity object class (for example, `OrderImpl.java`).

Foreign Key Associations Generated When Entity Objects Are Derived from Tables

In addition to the entity objects, the Business Components from Tables wizard also generates named association components that capture information about the relationships between entity objects. For example, the database diagram in Figure 4-4 shows that JDeveloper derives default association names like `SItemOrdIdFkAssoc` by converting the foreign key constraint names to a Java-friendly name and adding the `Assoc` suffix. For each association created, JDeveloper creates an appropriate XML document file and saves it in the directory that corresponds to the name of its package.

Note:

Associations are generated when you use the Business Components from Tables wizard. However, the Create Entity Object wizard does not generate associations. If you use the Create Entity Object wizard to create entity objects, you will need to create the corresponding associations manually.

By default the associations reverse-engineered from foreign keys are created in the same package as the entities. For example, for the association `SItemOrdIdFkAssoc` with entities in the `summit.model.entities` package, JDeveloper creates the association XML file named `./summit/model/entities/SItemOrdIdFkAssoc.xml`.

Entity Object Key Generated When a Table Has No Primary Key

If a table has no primary key constraint, then JDeveloper cannot infer the primary key for the entity object. Because every entity object must have at least one attribute marked as a primary key, the wizard marks all columns as part of the primary key for the entity. If appropriate, you can edit the entity object later to mark a different attribute as a primary key and remove the setting from other attributes. When you use the Create Entity Object wizard and you have not set any other attribute as primary key, you will be prompted to use all columns as the primary key.

What Happens When You Create an Entity Object for a Synonym or View

When you create an entity object using the Business Components from Tables wizard or the Create Entity Object wizard, the object can represent an underlying table, synonym, or view. The framework can infer the primary key and related associations for a table or synonym by inspecting database primary and foreign key constraints in the data dictionary.

However, when your selected schema object is a database view, then neither the primary key nor associations can be inferred since database views do not have database constraints. In this case, if you use the Business Components from Tables wizard, the primary key defaults to `RowID`. If you use the Create Entity Object wizard, you'll need to specify the primary key manually by marking at least one of its attributes as a primary key. For more information, see RowID Generated When a Table Has No Primary Key.

When your selected schema object is a synonym, there are two possible outcomes. If the synonym is a synonym for a table, then the wizard and editor behave as if you had specified a table. If instead the synonym refers to a database view, then they behave as if you had specified a view.

How to Edit an Existing Entity Object or Association

After you've created a new entity object or association, you can edit any of its settings in the overview editor. To launch the editor, choose **Open** from the context menu for the entity object or association in the Applications window or double-click the object. By clicking the different tabs of the editor, you can adjust the settings that define the object and govern its runtime behavior.

How to Create Database Tables from Entity Objects

To create database tables based on entity objects, right-click the package in the Applications window that contains the entity objects and choose **Create Database Objects** from the context menu. A dialog appears to let you select the entities whose tables you'd like to create. This tool can be used to generate a table for an entity object you created from scratch, or to drop and re-create an existing table.

> **Caution:**
>
> This feature performs its operations directly against the database and will drop existing tables. It does *not* generate a script to run later. A dialog appears to confirm that you want to do this before proceeding. For entities based on existing tables, use with caution.

In the overview editor for an association, the **Use Database Key Constraints** checkbox on the Association Properties page controls whether the related foreign key constraint will be generated when creating the tables for entity objects. Selecting this option does not have any runtime implications.

How to Synchronize an Entity with Changes to Its Database Table

Inevitably you (or your DBA) might alter a table for which you've already created an entity object. Your existing entity will not be disturbed by the presence of additional attributes in its underlying table; however, if you want to access the new column in the table in your Java EE application, you'll need to synchronize the entity object with the database table.

For example, suppose you had done the following at the SQL*Plus command prompt to add a new `SECURITY_QUESTION` column to the `PERSONS` table:

```
ALTER TABLE PERSONS ADD (security_question VARCHAR2(60));
```

Then you can use the synchronization feature to add the new column as an attribute on the entity object.

Before you begin:

It may be helpful to have an understanding of the options you have for creating entity objects. For more information, see Creating Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To synchronize an entity with changes to its database table:

1. In the Applications window, right-click the entity object you want to synchronize and choose **Synchronize with Database**.

   The Synchronize with Database dialog shows the list of the actions that can be taken to synchronize the business logic tier with the database.

2. Select the action you want to take:

   - Select one or more actions from the list, and click **Synchronize** to synchronize the selected items.
   - Click **Synchronize All** to perform all actions in the list.
   - Click **Write to File** to save the action list to a text file. This feature helps you keep track of the changes you make.

3. Click **OK**.

Removing an Attribute Associated with a Dropped Column

The synchronize feature does not handle dropped columns. When a column is dropped from the underlying database after an entity object has been created, you can delete the corresponding attribute from the entity object. If the attribute is used in other parts of your application, you must remove those usages as well.

Before you begin:

It may be helpful to have an understanding of the options you have for creating entity objects. For more information, see Creating Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To remove an entity attribute:

1. In the Applications window, double-click the entity object that contains the attribute you want to remove.
2. In the overview editor, click the **Attributes** navigation tab.
3. On the Attributes page, right-click the attribute and choose **Delete**.

   If there are other usages, the Confirm Delete dialog displays the message "Usages were found."

4. If usages were found, click **Show Usages**.

   The dialog shows all usages of the attribute, which you can click to display the usage in the source editor.

5. Click **Preview** to display usages of the attribute in the Log window, and then work through the list to delete all usages of the entity attribute.

Addressing a Data Type Change in the Underlying Table

The synchronize feature does not handle changed data types. For a data type change in the underlying table (for example, precision increased), you must locate all usages of the attribute and manually make changes, as necessary.

Before you begin:

It may be helpful to have an understanding of the options you have for creating entity objects. For more information, see Creating Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To locate all usages of an entity attribute:

1. In the Applications window, double-click the entity object.
2. In the overview editor, click the **Attributes** navigation tab.
3. On the Attributes page, right-click the attribute and choose **Find Usages**.

   If there are other usages, they are displayed in the Log window.

How to Store Data Pertaining to a Specific Point in Time

Effective dated tables are used to provide a view into the data set pertaining to a specific point in time. Effective dated tables are widely used in applications like HRMS and Payroll to answer queries like:

- What was the tax rate for an employee on August 31st, 2005?
- What are the employee's benefits as of October 2004?

In either case, the employee's data may have changed to a different value since then.

The primary difference between the effective dated entity type and the dated entity type is that the dated entity does not cause row splits during update and delete.

> **Note:**
>
> Do not use effective dating on a parent entity object in a **master-detail relationship**. Because child objects can raise events on parent objects, and effective dated entity objects cause row splits during update and delete operations, it is possible for the child object to raise an event on the wrong parent object if both the parent and child are updated during the same transaction.

When you create an effective dated entity object, you identify the entity as effective dated and specify the attributes of the entity that represent the start and end dates. The start date and end date attributes must be of the Date type.

Additionally, you can specify an attribute that represents the sequence for the effective dated entity and an attribute that represents a flag for the sequence. These attributes allow for tracking of multiple changes in a single day.

Before you begin:

It may be helpful to have an understanding of the options you have for creating entity objects. For more information, see Creating Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create an effective dated entity object

1. In the Applications window, double-click the entity object on which you want enable effective dating.
2. In the Properties window, expand the **Type** category.

   If necessary, choose **Properties** from the **Window** menu to display the Properties window.

   If the **Type** category is not displayed in the Properties window, click the **General** tab in the overview editor to set the proper focus.
3. From the property menu for **Effective Date Type**, choose **Edit**.

   To display the property menu, click the down arrow next to the property field.
4. In the Edit Property dialog, specify the following settings:
   - For **Effective Date Type**, select **EffectiveDated**.
   - For **Start Date Attribute**, select the attribute that corresponds to the start date.
   - For **End Date Attribute**, select the attribute that corresponds to the end date.
5. You can optionally specify attributes that allow for tracking of multiple changes in a single day.
   - For **Effective Date Sequence**, select the attribute that stores the sequence of changes.
   - For **Effective Date Sequence Flag**, select the attribute that stores a flag indicating the most recent change in the sequence.

   Without specifying the **Effective Date Sequence** and **Effective Date Sequence Flag** attributes, the default granularity of effective dating is one day. For this reason, multiple changes in a single day are not allowed. An attempt to update the entity a second time in a single day will result in an exception being thrown. After these two attributes are specified, the framework inserts and updates their values as necessary to track multiple changes in a single day.
6. Click **OK**.

> **Note:**
>
> You can also identify the start and end date attributes using the Properties window for the appropriate attributes. To do so, select the appropriate attribute in the overview editor and set the **Start Date** or **End Date** property to **true** in the Properties window.

What Happens When You Create Effective Dated Entity Objects

When you create an effective dated entity object, JDeveloper creates a transient attribute called SysEffectiveDate to store the effective date for the row. Typically the Insert, Update, and Delete operations modify the transient attribute while the **ADF Business Components** framework decides the appropriate values for the effective start date and the effective end date.

The following example shows some sample XML entries that are generated when you create an effective dated entity. For more information about working with effective dated objects, see Limiting View Object Rows Using Effective Date Ranges.

```
// In the effective dated entity
<Entity
  ...
  EffectiveDateType="EffectiveDated">

// In the attribute identified as the start date
  <Attribute
    ...
    IsEffectiveStartDate="true">

// In the attribute identified as the end date
  <Attribute
    ...
    IsEffectiveEndDate="true">

// The SysEffectiveDate transient attribute
  <Attribute
    Name="SysEffectiveDate"
    IsQueriable="false"
    IsPersistent="false"
    ColumnName="$none$"
    Type="oracle.jbo.domain.Date"
    ColumnType="$none$"
    SQLType="DATE"/>
```

What You May Need to Know About Creating Entities from Tables

The Business Components from Tables wizard makes it easy to quickly generate many business components at the same time. In practice, this does not mean that you should use it to immediately create entity objects for every table in your database schema just because it is possible to do so. If your application requires all of the tables, then that strategy might be appropriate. But because you can use the wizard whenever needed, you should create the entity objects for the tables that you know will be involved in the application.

Defining Nested Application Modules, describes a use case-driven design approach for your business services that can assist you in understanding which entity objects are required to support your application's business logic needs. You can always add more entity objects later as necessary.

Creating and Configuring Associations

Create entity associations manually if foreign key constraints don’t exist so that JDeveloper is able to infer associations between ADF entity objects.

If your database tables have no foreign key constraints defined, JDeveloper won't be able to infer the associations between the entity objects that you create. Since several ADF Business Components runtime features depend on the presence of **entity associations**, create them manually if the foreign key constraints don't exist.

How to Create an Association

To create an association, use the Create New Association wizard, which is available in the New Gallery.

Before you begin:

It may be helpful to have an understanding of why you create associations. For more information, see Creating and Configuring Associations.

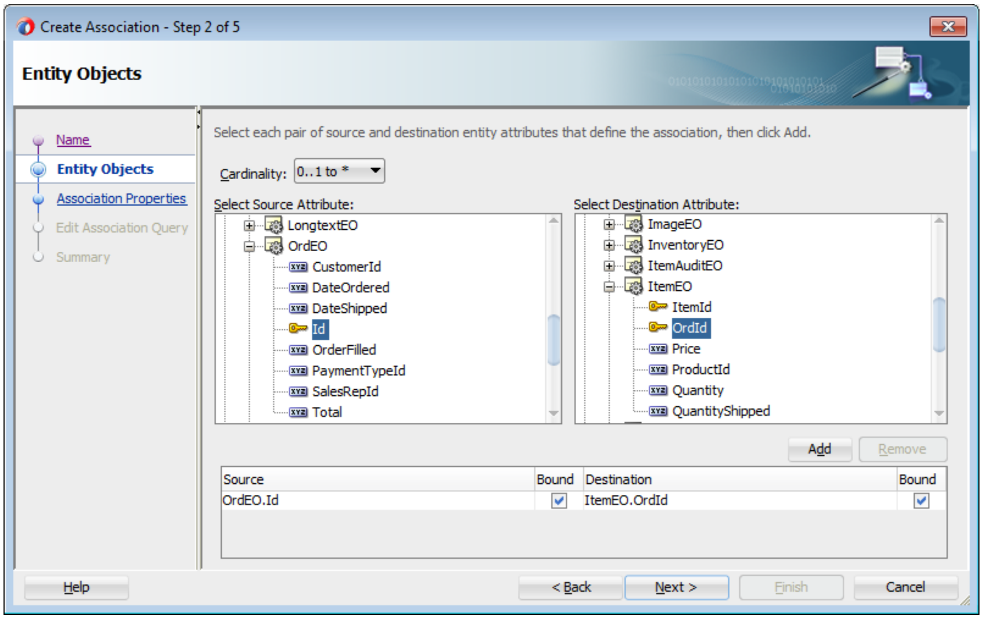
You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create an association:

1. In the Applications window, right-click the project in which you want to create the association and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Association**, and click **OK**.
3. In the Create Association wizard, on the Name page, do the following:
   - Enter the package name in which the association will be created.
   - Enter the name of the association component.
   - Click **Next**.
4. On the Entity Objects page, select the source and destination entity attributes:
   - Select a source attribute from one of the entity objects that is involved in the association to act as the master.
   - Select a corresponding destination attribute from the other entity object involved in the association.

   For example, Figure 4-5 shows the selected `Id` attribute from the `OrdEO` entity object as the source entity attribute. Because the `ItemEO` rows contain an order ID that relates them to a specific `OrdEO` row, you would select this `OrdId` foreign key attribute in the `ItemEO` entity object as the destination attribute.

Figure 4-5 Create Association Wizard, Attribute Pairs That Relate Two Entity Objects Defined



Create Association - Step 2 of 5

Entity Objects

Select each pair of source and destination entity attributes that define the association, then click Add.

Cardinality: 0..1 to *

Select Source Attribute:

- LongtextEO
- OrdEO
  - CustomerId
  - DateOrdered
  - DateShipped
  - Id
  - OrderFilled
  - PaymentTypeId
  - SalesRepId
  - Total

Select Destination Attribute:

- ImageEO
- InventoryEO
- ItemAuditEO
- ItemEO
  - ItemId
  - OrdId
  - Price
  - ProductId
  - Quantity
  - QuantityShipped

Source	Bound	Destination	Bound
OrdEO.Id	☑	ItemEO.OrdId	☑

5. Click **Add** to add the matching attribute pair to the table of source and destination attribute pairs below.

   By default, the **Bound** checkbox is selected for both the source and destination attribute. This checkbox allows you to specify whether or not the value will be bound into the association SQL statement that is created internally when navigating from source entity to target entity or from target entity to source entity (depending on which side you select).

   Typically, you would deselect the checkbox for an attribute in the relationship that is a transient entity attribute whose value is a constant and therefore should not participate in the association SQL statement to retrieve the entity.

6. If the association requires multiple attribute pairs to define it, you can repeat the preceding steps to add additional source/target attribute pairs.

7. Finally, ensure that the **Cardinality** dropdown correctly reflects the cardinality of the association. The default is a one-to-many relationship. Click **Next**.

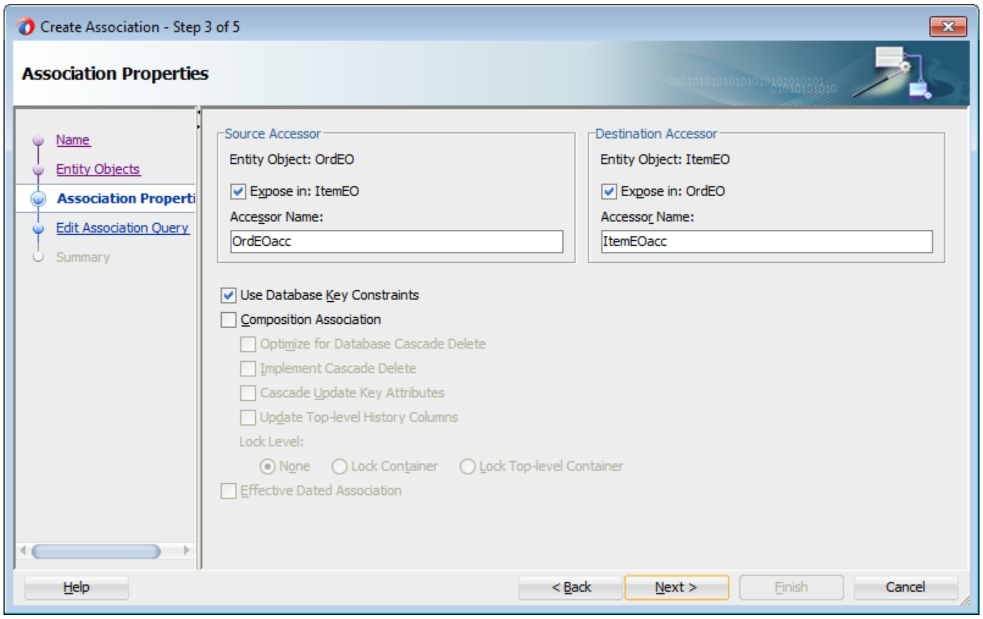
   For example, since the relationship between an `OrdEO` row and its related `ItemEO` rows is one-to-many, you can leave the default setting.

8. On the Association SQL page, you can preview the association SQL predicate that will be used at runtime to access the related destination entity objects for a given instance of the source entity object.

9. On the Association Properties page, disable the **Expose Accessor** checkbox on either the **Source** or the **Destination** entity object when you want to create an association that represents a one-way relationship. The default, bidirectional navigation is more convenient for writing business validation logic, so in practice, you typically leave these default checkbox settings.

   For example, Figure 4-6 shows an association that represents a bidirectional relationship, permitting either entity object to access the related entity row(s) on the other side when needed. In this example, this means that if you are working with an instance of an `OrdEO` entity object, you can easily access the collection of its related `OrderItemEO` rows. With any instance of a `OrderItemEO` entity object, you can also easily access the `Order` to which it belongs.

Figure 4-6   Association Properties Control Runtime Behavior



Source Accessor
Entity Object: OrdEO
☑ Expose in: ItemEO
Accessor Name: OrdEOacc

Destination Accessor
Entity Object: ItemEO
☑ Expose in: OrdEO
Accessor Name: ItemEOacc

☑ Use Database Key Constraints
□ Composition Association
□ Optimize for Database Cascade Delete
□ Implement Cascade Delete
□ Cascade Update Key Attributes
□ Update Top-level History Columns
Lock Level:
● None ○ Lock Container ○ Lock Top-level Container
□ Effective Dated Association

10. When you are satisfied with the association definition, click **Finish**.

What Happens When You Create an Association

When you create an association, JDeveloper creates an appropriate XML document file and saves it in the directory that corresponds to the name of its package. For example, if you created an association named `SItemOrderIdFkAssoc` in the `oracle.summit.model.entities.assoc` subpackage, then the association XML file would be created in the `./oracle/summit/model/entities/assoc` directory with the name `SItemOrderIdFkAssoc.xml`. At runtime, the entity object uses the association information to automate working with related sets of entities.

How to Change Entity Association Accessor Names

You should consider the default settings for the accessor names on the Association Properties page and decide whether changing the names to something more intuitive is appropriate. The default settings define the names of the accessor attributes you will use at runtime to programmatically access the entities on the other side of the relationship. By default, the accessor names will be the names of the entity object on the other side. Since the accessor names on an entity must be unique among entity object attributes and other accessors, if one entity is related to another entity in *multiple* ways, then the default accessor names are modified with a numeric suffix to make the name unique.

In an existing association, you can rename the accessor using the Association Properties dialog.

Before you begin:

It may be helpful to have an understanding of why you create associations. For more information, see Creating and Configuring Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To rename the entity accessor in an association:

1. In the Applications window, double-click the association that contains the entity accessor you want to rename.
2. In the overview editor, click the **Relationships** navigation tab.
3. On the Relationships page, expand the **Accessors** section and click the **Edit** icon.

   The Association Properties dialog displays the current settings for the association's accessors.
4. In the Association Properties dialog, modify the name as necessary, and click **OK**.

How to Rename and Move Associations to a Different Package

Since associations are a component that you typically configure at the outset of your project and don't change frequently thereafter, you might want to move the associations to a different package so that your entity objects are easier to see.

Both renaming components and moving them to a different package is straightforward using JDeveloper's refactoring functionality. However, it is not advisable to rename or move ADF Business Components objects manually, as missed references can break your application. For more information about JDeveloper's refactoring functionality, see Refactoring a Fusion Web Application .

Before you begin:

It may be helpful to have an understanding of why you create associations. For more information, see Creating and Configuring Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

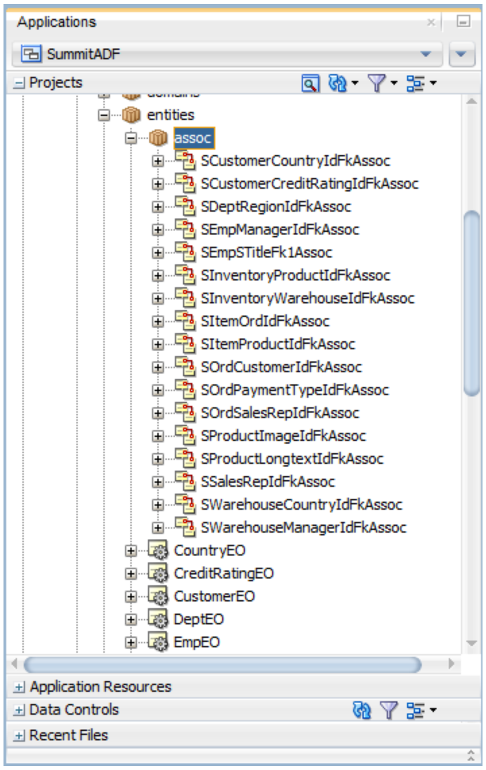
To move a set of business components to a different package:

1. In the Applications window, select the components you want to move.
2. Right-click one of the selected components, and choose **Refactor > Move**.
3. In the Move Business Components dialog, enter the name of the package to move the component(s) to, or click **Browse** to navigate to and select the package.
4. Click **OK**.

If you just want to rename a component, right-click the component you want to rename, and choose **Refactor > Rename**. When you refactor ADF Business Components, JDeveloper moves the XML and Java files related to the components, and updates any other components that might reference them.

Figure 4-7 shows what the Applications window would look like after renaming all of the associations and moving them to the `oracle.summit.model.entities.assoc` subpackage. While you can refactor the associations into any package name you choose, picking a subpackage keeps them logically related to the entities, and allows you to collapse the package of associations to better manage which files display in the Applications window.

Figure 4-7 Applications Window After Association Refactoring



What You May Need to Know About Using a Custom View Object in an Association

You can associate a custom **view object** with the source end or destination end (or both) of an entity association.

When you traverse entity associations in your code, if the entities are not already in the cache, then the ADF Business Components framework performs a query to bring the entity (or entities) into the cache. By default, the query performed to bring an entity into the cache is the find-by-primary-key query that selects values for all persistent entity attributes from the underlying table. If the application performs a lot of programmatic entity association traversal, you could find that retrieving all of the attributes might be heavy-handed for your use cases.

Entity associations support the ability to associate a custom, entity-based view object with the source entity or destination entity in the association, or both. The primary entity usage of the entity-based view object you supply must match the entity type of the association end for which you use it.

Using a custom view object can be useful because the custom view object's query can include fewer columns and it can include an `ORDER BY` clause. This allows you to control how much data is retrieved when an entity is brought into the cache due to association traversal, as well as the order in which any collections of related entities will appear.

For more information about creating a custom view object, see How to Create an Entity-Based Programmatic View Object.

What You May Need to Know About Composition Associations

An association represents a relationship between entities, such as a `Customer` referenced by an `Order` or an `Item` contained in an `Order`. When you create associations, it is useful to know about the kinds of relationships you can represent, and the various options.

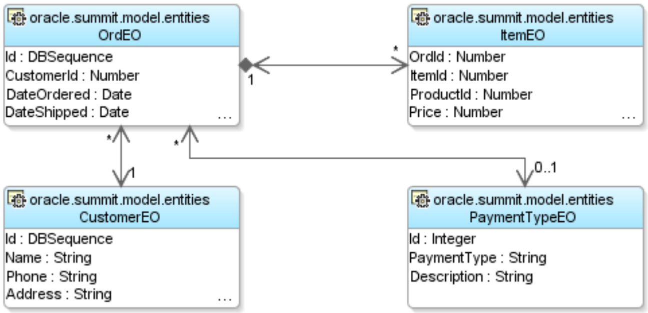
Associations between entity objects can represent two styles of relationships depending on whether the source entity:

- *References* the destination entity
- *Contains* the destination entity as a logical, nested part

Figure 4-8 depicts an application business layer that represents both styles of relationships. For example, an `OrdEO` entry references a `CustomerEO`. This relationship represents the first kind of association, reflecting that a `CustomerEO` or an `OrdEO` entity object can exist independent from each other. In addition, the removal of an `Order` does not imply the cascade removal of the `Customer` to which it was referring.

In contrast, the relationship between an `OrdEO` and its collection of related `ItemEO` details is stronger than a simple reference. The `ItemEO` entries comprise a logical part of the overall `OrdEO`. In other words, an `OrdEO` is composed of `ItemEO` entries. It does not make sense for an `ItemEO` entity row to exist independently from an `OrdEO`, and when an `OrdEO` is removed — assuming the removal is allowed — all of its composed parts should be removed as well. This kind of logical containership represents the second kind of association, called a **composition**. The UML diagram in Figure 4-8 illustrates the stronger composition relationship using the solid diamond shape on the side of the association which composes the other side of the association.

Figure 4-8 OrdEO Composed of ItemEO Entries and References Both CustomerEO and PaymentTypeEO



The Business Components from Tables Wizard creates composition associations by default for any foreign keys that have the `ON DELETE CASCADE` option. You can use the Create Association wizard or the overview editor for the association to indicate that an association is a composition association. Select the **Composition Association** checkbox on either the Association Properties page of the Create Association wizard or the Relationships page of the overview editor.

> **Note:**
>
> A composition association cannot be based on a transient attribute.

An entity object offers additional runtime behavior in the presence of a composition. For the settings that control the behavior, see How to Configure Composition Behavior.

Creating a Diagram of Entity Objects for Your Business Layer

You can use JDeveloper to create a UML diagram of business services based on ADF Business Components. The UML diagram serves as a visualization, visual navigation, and editing tool.

Since your layer of business domain objects represents a key reusable asset for your team, it is often convenient to visualize the business domain layer using a UML model. JDeveloper supports easily creating a diagram for your business domain layer that you and your colleagues can use for reference.

The UML diagram of business components is not just a static picture that reflects the point in time when you dropped the entity objects onto the diagram. Rather, it is a UML-based rendering of the current component definitions, that will always reflect the current state of affairs. What's more, the UML diagram is both a visualization aid and a visual navigation and editing tool. To open the overview editor for any entity object in a diagram, right-click the desired object and choose **Open**. You can also perform some entity object editing tasks directly on the diagram, like renaming entity objects and attributes, and adding or removing attributes. However, changes to the entity objects in a business components diagram have no impact on the underlying database objects.

How to Show Entity Objects in a Business Components Diagram

To create a diagram of your entity objects, you can use the Create Business Components Diagram dialog, which is available in the New Gallery.

Before you begin:

It may be helpful to have an understanding of how entity diagrams are used in the application. For more information, see Creating a Diagram of Entity Objects for Your Business Layer.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create a business components diagram that models existing entity objects:

1. In the Applications window, right-click the project in which you want to create the entity diagram and choose **New > From Gallery**.

2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Business Components Diagram**, and click **OK**.
3. In the dialog, do the following to create the diagram:
   - Enter a name for the diagram, for example `Business Domain Objects`.
   - Enter the package name in which the diagram will be created. For example, you might create it in a subpackage like `myproject.model.design`.
4. Click **OK**.
5. To add existing entity objects to the diagram, select them in the Applications window and drop them onto the diagram surface.

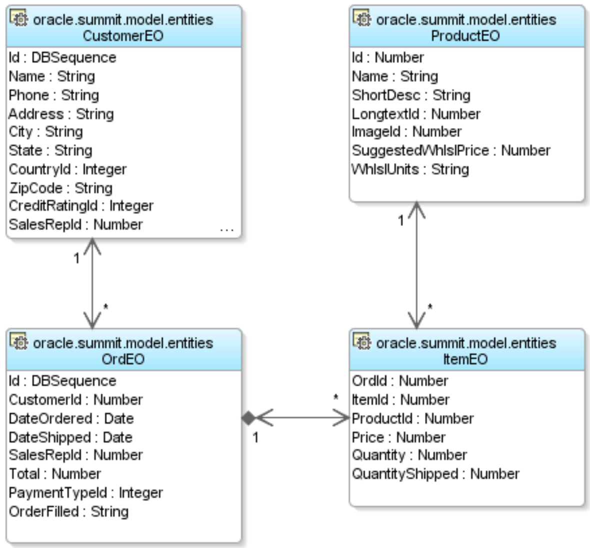
After you have created the diagram you can use the Properties window to adjust visual properties of the diagram. For example you can:

- Hide or show the package name
- Change the font
- Toggle the grid and page breaks on or off
- Display association names that may otherwise be ambiguous

You can also create an image of the diagram in `PNG`, `JPG`, `SVG`, or compressed `SVG` format, by choosing **Publish Diagram** from the context menu on the diagram surface.

Figure 4-9 shows a sample diagram that models various entity objects from the business domain layer.

Figure 4-9 UML Diagram of Business Domain Layer

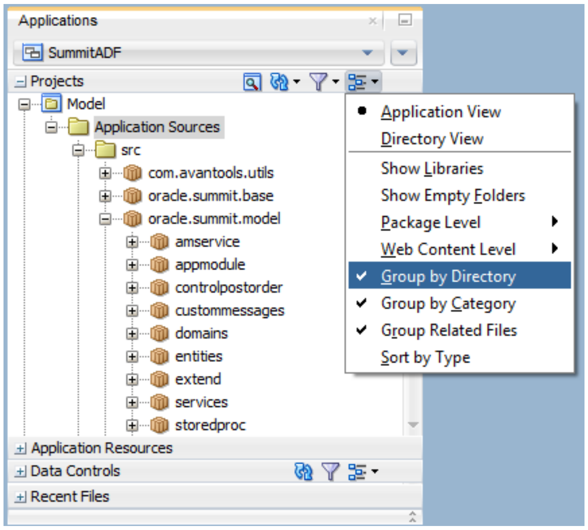


What Happens When You Create an Entity Diagram

When you create a business components diagram, JDeveloper creates an XML file `*.adfbc_diagram` representing the diagram in a subdirectory of the project's model path that matches the package name in which the diagram resides.

By default, the Applications window unifies the display of the project contents paths so that ADF components and Java files in the source path appear in the same package tree as the UML model artifacts in the project model path. However, as shown in Figure 4-10, using the **Applications Window Options** button in the Applications window, you can see the distinct project content path root directories when you prefer.

Figure 4-10 Toggling the Display of Separate Content Path Directories



What You May Need to Know About the XML Component Descriptors

When you include a business component like an entity object in a UML diagram, JDeveloper adds extra metadata to a `<Data>` section of the component's XML component descriptor as shown in the following example. This additional information is used at design time only.

```
<Entity Name="OrderEO" ... >
   <Data>
      <Property Name ="COMPLETE_LIBRARY" Value ="FALSE" />
      <Property Name ="ID"
                Value ="ff16fca0-0109-1000-80f2-8d9081ce706f::::EntityObject" />
      <Property Name ="IS_ABSTRACT" Value ="FALSE" />
      <Property Name ="IS_ACTIVE" Value ="FALSE" />
      <Property Name ="IS_LEAF" Value ="FALSE" />
      <Property Name ="IS_ROOT" Value ="FALSE" />
      <Property Name ="VISIBILITY" Value ="PUBLIC" />
   </Data>
   :
</Entity>
```

What You May Need to Know About Changing the Names of Components

On an entity diagram, the names of entity objects, attributes, and associations can be changed for clarity. Changing names on a diagram does not affect the underlying data names. The name change persists for the diagram only. The new name may contain spaces and mixed case for readability. To change the actual entity object names, attribute names, or association names, open the entity object or association in the overview editor.

Defining Property Sets

Define ADF property sets to use them as control hints and error messages.

A property set is a named collection of properties, where a property is defined as a name/value pair. Property sets are a convenience mechanism to group properties and then reference them from other ADF Business Components objects. Property sets can be used with entity objects and their attributes, view objects and their attributes, and application modules.

Property sets can be used for a variety of functions, such as **control hints** and error messages. A property set may contain control hints and other custom properties, and you can associate them with multiple attributes of different objects.

Properties defined in a property set can be configured to be translatable, in which case the translations are stored in a message bundle file owned by the property set. Because property sets are schema driven, in addition to adding names, you can add descriptions as well.

When defining property sets that contain translatable content, be sure not to overload common terms in different contexts. Even though a term in several contexts might be the same in the source language, a separate distinguishable term should be used for each context. For example, the term "Name" used as a value for a field's label might be applied to both an object and a person in one language, but then translated into two different terms in a target language. In this case you would provide two name/value pairs in which the value in the source language is "Name" for both. Then, when translated into a target language with one term for an object name and a different term for a person name, each term can be translated appropriately. You can use the property's description to provide the distinct context for each term.

How to Define a Property Set

To define a property set, you create a new property set using a dialog and then specify properties using the Properties window.

Before you begin:

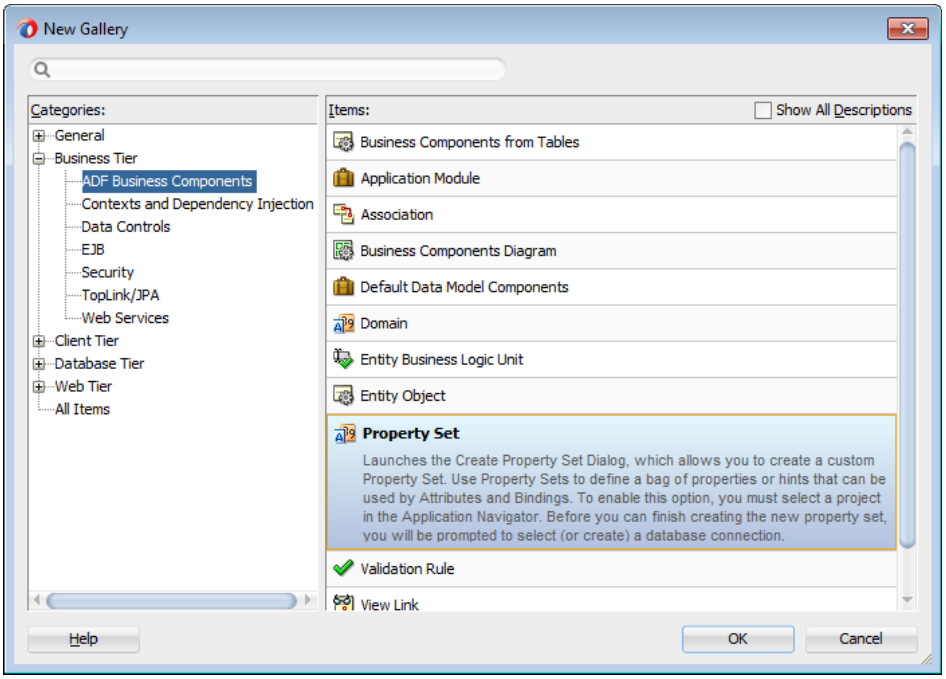
It may be helpful to have an understanding of how property sets can be used. For more information, see Defining Property Sets.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To define a property set:

1. In the Applications window, right-click the project in which you want to create the property set, and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Property Set**, and click **OK**.

Figure 4-11 Property Set in New Gallery



Launches the Create Property Set Dialog, which allows you to create a custom Property Set. Use Property Sets to define a bag of properties or hints that can be used by Attributes and Bindings. To enable this option, you must select a project in the Application Navigator. Before you can finish creating the new property set, you will be prompted to select (or create) a database connection.

3. In the Create Property Set dialog, enter the name and location of the property set and click **OK**.
4. From the main menu, choose **Window > Properties**.
5. In the Properties window, define the properties for the property set.

How to Apply a Property Set

After you have created the property set, you can apply the property set to an entity object or attribute, and use the defined properties (or override them, if necessary).

Before you begin:

It may be helpful to have an understanding of how property sets can be used. For more information, see Defining Property Sets.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To apply a property set to an entity object or view object:

1. In the Applications window, double-click the object (entity object or view object) to which you want to apply a property set.
2. In the overview editor, click the **General** navigation tab and then click the **Edit** icon for **Property Set**.
3. In the Select Property Set dialog, select the appropriate property set and click **OK**.

To apply a property set to an attribute:

1. In the Applications window, double-click the object (entity object or view object) that contains the attribute to which you want to apply a property set.

2. In the overview editor, click the **Attributes** navigation tab, select the attribute you want to edit, and then click the **Details** tab.
3. On the Details page, select the appropriate property set from the **Property Set** dropdown list.

Defining Attribute Control Hints for Entity Objects

Control hints are inherited by ADF entity-based view objects. Use them to set label text, tooltip and format mask hints for attributes of entity objects.

Control hints allow you to define label text, tooltip, and format mask hints for entity object attributes. If desired, you can use a Groovy expression to calculate the value of the UI hint. The UI hints you define on your business domain layer are inherited by entity-based view objects as well. You can also set additional control hints on view objects and application modules in a similar manner.

How to Add Attribute Control Hints

To add attribute control hints to an entity object, use the overview editor.

Before you begin:

It may be helpful to have an understanding of how control hints are used in an entity object. For more information, see Defining Attribute Control Hints for Entity Objects.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

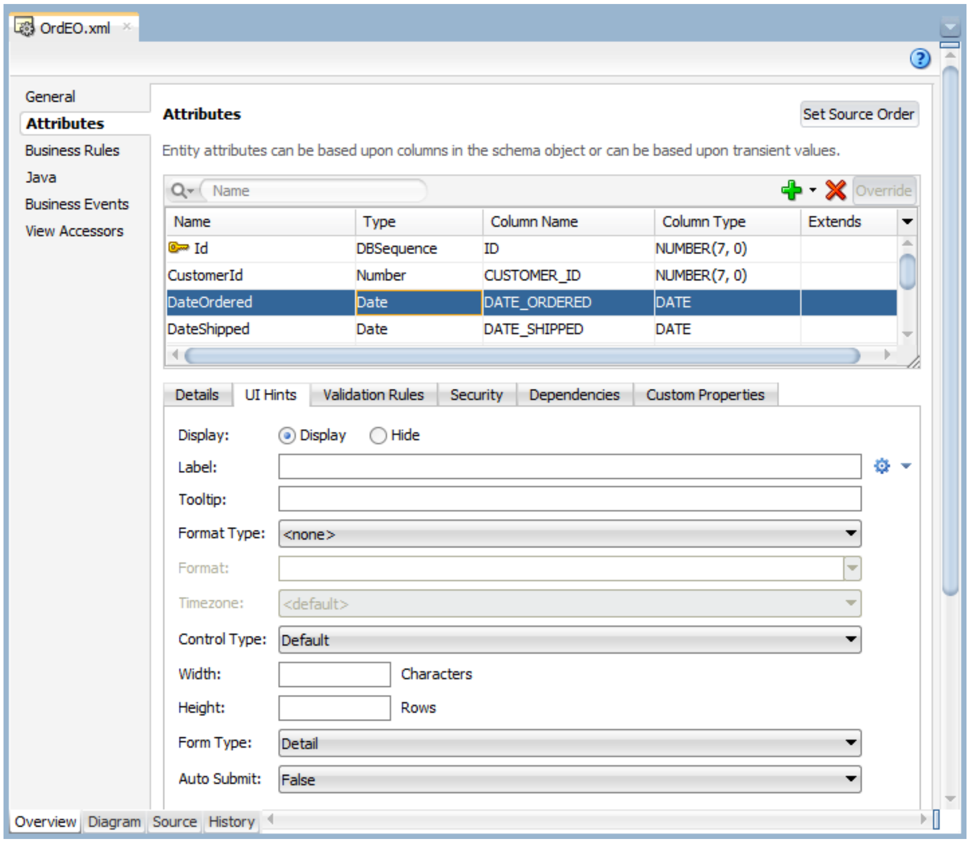
To add attribute control hints to an entity object:

1. In the Applications window, double-click the entity object that contains the attribute to which you want to add control hints.
2. In the overview editor, click the **Attributes** navigation tab and select the attribute you want to edit.
3. In the Attributes page, click the **UI Hints** tab and specify control hints as necessary.

   For example, Figure 4-12 shows control hints defined for the attribute `ExpireDate` of the `PaymentOptionEO` entity object. The defined hints include the following:

   - **Format Type** of `Simple Date`
   - **Format** mask of `mm/yy`

Figure 4-12   Overview Editor, Attributes Page, UI Hints Tab



Attributes

Entity attributes can be based upon columns in the schema object or can be based upon transient values.

Name	Type	Column Name	Column Type	Extends
Id	DBSequence	ID	NUMBER(7, 0)	
CustomerId	Number	CUSTOMER_ID	NUMBER(7, 0)	
DateOrdered	Date	DATE_ORDERED	DATE	
DateShipped	Date	DATE_SHIPPED	DATE	

Details | UI Hints | Validation Rules | Security | Dependencies | Custom Properties

Display:	● Display ○ Hide
Label:	
Tooltip:	
Format Type:	<none>
Format:	
Timezone:	<default>
Control Type:	Default
Width:	Characters
Height:	Rows
Form Type:	Detail
Auto Submit:	False

4. If you want to define the UI hint using a Groovy expression, click the arrow beside the text box and choose **Show Expression**. The application displays the **New Expression Method** hyperlink. Click this hyperlink to display the Edit Expression Editor. Enter the Groovy expression in this editor and click **OK**.

> **Note:**
>
> Java defines a standard set of format masks for numbers and dates that are different from those used by the Oracle database's SQL and PL/SQL languages. For reference, see the Javadoc for the `java.text.DecimalFormat` and `java.text.SimpleDateFormat` classes.

What Happens When You Add Attribute Control Hints

When you define attribute control hints for an entity object, JDeveloper creates a resource bundle file in which to store them. The hints that you define can be used by generated forms and tables in associated view clients. The type of file and its granularity are determined by Resource Bundle options in the Project Properties dialog. For more information, see Working with Resource Bundles.

About Formatters and Masks

When you set the **Format Type** control hint (on the **UI Hints** tab) for an attribute (for example, to **Simple Date**), you can also specify a format mask for the attribute to customize how the UI displays the value. If the mask you want to use is not listed in the **Format** dropdown list, you can simply type it into the field.

Not all formatters require format masks. Specifying a format mask is only needed if that formatter type requires it. For example, the date formatter requires a format mask, but the currency formatter does not. In fact, the currency formatter does not support format mask at all.

The mask elements that you can use are defined by the associated Java format class. For information about the mask elements for the Simple Date format type, see the Javadoc for `java.text.SimpleDateFormat`. For information about the mask elements for the Number format type, see the Javadoc for `java.text.DecimalFormat`.

To map a formatter to a domain for use with control hints, you can either amend one of the default formatters provided in the `oracle.jbo.format` package, or create a new formatter class by extending the `oracle.jbo.format.Formatter` class. The default formatters provided with JDeveloper aggregate the formatters provided in the `java.text` package.

For information on how to define a format mask to use from the **UI Hints** tab in JDeveloper, see How to Define Format Masks.

How to Define Format Masks

If you have a format mask that you will continue to use on multiple occasions, you can add it to the `formatinfo.xml` file, so that it is available from the **Format** dropdown list on the **UI Hints** tab. The entries in this file define the format masks and formatter classes for a domain class. The following example shows the format definitions for the `java.util.Date` domain.

```
<?xml version="1.0"?><FORMATTERS>
. . .
  <DOMAIN CLASS="java.util.Date">
     <FORMATTER name="Simple Date"
class="oracle.jbo.format.DefaultDateFormatter">
        <FORMAT text="yyyy-MM-dd" />
        <FORMAT text="EEE, MMM d, ''yy"  />
        <FORMAT text="dd-MM-yy" />
        <FORMAT text="dd-MMM-yyyy" />
        <FORMAT text="dd/MMM/yyyy" />
     </FORMATTER>
  </DOMAIN>
. . .
</FORMATTERS>
```

You can find the `formatinfo.xml`file in the BC4J subdirectory of the JDeveloper system directory (for example, `C:\Documents and Settings\`*`username`*`\Application Data\JDeveloper\`*`system##`*`\o.BC4J\formatinfo.xml`).

The definition of the format mask belongs to a formatter and a domain class, and includes the text specification of the mask as it appears on the **UI Hints** tab. When you specify the **Format Type** (FORMATTER name) for an attribute of a given type (DOMAIN CLASS), the masks (FORMAT text) appear in the **Format** dropdown list.

It is not necessary to create new domain to map a formatter. You can use an existing domain when the business components project contains a domain of the same data type as the formatter.

Before you begin:

It may be helpful to have an understanding of how control hints are used in an entity object. For more information, see Defining Attribute Control Hints for Entity Objects.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To make a new format mask available in JDeveloper:

1. Open the formatinfo.xml file in a text editor.
2. Find the domain class and formatter name for which you want to add a format mask.
3. Insert a new FORMAT entry within the FORMATTER element.

If you create a new domain for the format mask, the XML definition of the formatter must include the new DOMAIN CLASS in addition to the FORMATTER (which includes the name and class) and the list of FORMAT definitions the formatter class specifies.

After defining a format mask, you can select the new format mask from the **Format** dropdown list on the **UI Hints** tab.

Working with Resource Bundles

JDeveloper stores translatable strings that you define on ADF Business Components in project-level resource bundle files.

When you define translatable strings (such as validator error messages, or attribute control hints for an entity object or view object), by default JDeveloper creates a project-level resource bundle file in which to store them. For example, when you define control hints for an entity object in the Model project, JDeveloper creates the message bundle file named ModelBundle.*xxx* for the package. The hints that you define can be used by generated forms and tables in associated view clients.

The resource bundle option that JDeveloper uses is determined by an option on the Resource Bundle page of the Project Properties dialog. By default JDeveloper sets the option to **Properties Bundle**, which produces a .properties file. For more information on this and other resource bundle options, see How to Set Message Bundle Options.

You can inspect the message bundle file for the entity object by selecting the object in the Applications window and looking in the corresponding **Sources** node in the Structure window. The Structure window shows the implementation files for the component you select in the Applications window.

The following example shows a sample message bundle file where the control hint information appears. The first entry in each String array is a message key; the second entry is the locale-specific String value corresponding to that key.

```
oracle.summit.model.views.ItemVO.QuantityShipped_LABEL=Shipped
oracle.summit.model.views.ItemVO.ItemTotal_LABEL=Item Total
oracle.summit.model.views.ItemVO.ItemTotal_FMT_FORMATTER=oracle.jbo.format.Defaul
tCurrencyFormatter
oracle.summit.model.views.ItemVO.Price_FMT_FORMATTER=oracle.jbo.format.DefaultCur
rencyFormatter
oracle.summit.model.views.OrdVO.DateOrdered_FMT_FORMATTER=oracle.jbo.format.Defau
ltDateFormatter
oracle.summit.model.views.OrdVO.DateOrdered_FMT_FORMAT=dd-MM-yyyy
oracle.summit.model.views.OrdVO.DateShipped_FMT_FORMATTER=oracle.jbo.format.Defau
ltDateFormatter
oracle.summit.model.views.OrdVO.DateShipped_FMT_FORMAT=dd-MM-yyyy
oracle.summit.model.entities.OrdEO_Rule_0=You cannot have a shipping date that
is before the order date
oracle.summit.model.entities.OrdEO.CustomerId_Rule_0=This is an invalid
customer id
errorId=This customer must pay cash
oracle.summit.model.entities.ItemEO.ProductId_Rule_0=Invalid Product Id
oracle.summit.model.views.OrdVO.Total_LABEL=Order Total
oracle.summit.model.views.OrdVO.Total_FMT_FORMATTER=oracle.jbo.format.DefaultCurr
encyFormatter
oracle.summit.model.views.OrdVO.OrderFilled_LABEL=Order Filled
. . .
```

How to Set Message Bundle Options

The resource bundle option JDeveloper uses to save control hints and other translatable strings is determined by an option on the Resource Bundle page of the Project Properties dialog. By default, JDeveloper sets the option to **Properties Bundle** which produces a `.properties` file.

Before you begin:

It may be helpful to have an understanding of how resource bundles are used. For more information, see Working with Resource Bundles.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To set resource bundle options for your project:

1. In the Applications window, right-click the project for which you want to specify resource bundle options, and choose **Project Properties**.
2. In the Project Properties dialog, click **Resource Bundle**.
3. On the Resource Bundle page, specify whether to use project or custom settings.

   If you select **Use Custom Settings**, the settings apply only to your work with the current project. They are preserved between sessions, but are not recorded with the project and cannot be shared with other users. If you select **Use Project Settings**, your choices are recorded with the project and can be shared with others who use the project.
4. Specify your preference with the following options by selecting or deselecting the option:
   - **Automatically Synchronize Bundle**
   - **Warn About Hard-coded Translatable Strings**

- **Always Prompt for Description**

  For more information on these options, click **Help** to see the online help.

5. Select your choice of resource bundle granularity.
   - **One Bundle Per Project** (default)
   - **One Bundle Per File**
   - **Multiple Shared Bundles** (not available for ADF Business Components)
6. Select the type of file to use.
   - **List Resource Bundle**

     The `ListResourceBundle` class manages resources in a name/value array. Each ListResourceBundle class is contained within a Java class file. You can store any locale-specific object in a ListResourceBundle class.
   - **Properties Bundle** (default)

     A text file containing translatable text in name/value pairs. Property files (like the one described in How to Set Message Bundle Options) can contain values only for String objects. If you need to store other types of objects, you must use a ListResourceBundle instead.
   - **Xliff Resource Bundle**

     The XML Localization Interchange File Format (XLIFF) is an XML-based format for exchanging localization data.
7. Click **OK**.

How to Use Multiple Resource Bundles

When you define translatable strings (for example, for attribute control hints), the Select Text Resource dialog allows you to enter a new string or select one that is already defined in the default resource bundle for the object. You can also use a different resource bundle if necessary. This is helpful when you use a common resource bundle that is shared between projects.

Before you begin:

It may be helpful to have an understanding of how resource bundles are used. For more information, see Working with Resource Bundles.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To use strings in a nondefault resource bundle:

1. In the Select Text Resource dialog, select the bundle you want to use from the **Resource Bundle** dropdown list.

   If the desired resource bundle is not included in the **Resource Bundle** dropdown list, click the **Browse** icon to locate and select the resource bundle you want to use.

   The dialog displays the strings that are currently defined in the selected resource bundle.

2. Select an existing string and click **Select**, or enter a new string and click **Save and Select**.

   If you entered a new string it is written to the selected resource bundle.

How to Internationalize the Date Format

Internationalizing the model layer of an application built using ADF Business Components entails producing translated versions of each component message bundle file. For example, the Italian version of the `OrdersImplMsgBundle` message bundle would be a class named `OrdersImplMsgBundle_it` and a more specific *Swiss* Italian version would have the name `OrdersImplMsgBundle_it_ch`. These classes typically extend the base message bundle class, and contain entries for the message keys that need to be localized, together with their localized translation.

The following example shows the Italian version of an entity object message bundle. Notice that in the Italian translation, the format masks for `RequestDate` and `AssignedDate` have been changed to `dd/MM/yyyy HH:mm`. This ensures that an Italian user will see a date value like May 3rd, 2006, as `03/05/2006 15:55`, instead of `05/03/2006 15:55`, which the format mask in the default message bundle would produce. Notice the overridden `getContents()` method. It returns an array of messages with the more *specific* translated strings merged together with those that are not overridden from the superclass bundle. At runtime, the appropriate message bundles are used automatically, based on the current user's locale settings.

```
package oracle.summit.model;
import oracle.jbo.common.JboResourceBundle;
public class ModelImplMsgBundle_it
       extends ModelImplMsgBundle {
  static final Object[][] sMessageStrings = {
    { "AssignedDate_FMT_FORMAT", "dd/MM/yyyy HH:mm" },
    { "AssignedDate_LABEL", "Assegnato il" },
    { "AssignedTo_LABEL", "Assegnato a" },
    { "CreatedBy_LABEL", "Aperto da" },
    { "ProblemDescription_LABEL", "Problema" },
    { "RequestDate_FMT_FORMAT", "dd/MM/yyyy HH:mm" },
    { "RequestDate_LABEL", "Aperto il" },
    { "RequestDate_TOOLTIP", "La data in cui il ticket è stato aperto" },
    { "Status_LABEL", "Stato" },
    { "SvrId_LABEL", "Ticket" }
  };
  public Object[][] getContents() {    return
super.getMergedArray(sMessageStrings, super.getContents());  }
}
```

Defining Business Logic Groups

Use Business Logic Groups to store related control hints, default values and validation logic of ADF entity objects in a separate file for optimized performance and easy maintenance.

Business logic groups allow you to encapsulate a set of related control hints, default values, and validation logic. A business logic group is maintained separate from the base entity in its own file, and can be enabled dynamically based on context values of the current row.

This is useful, for example, for an HR application that defines many locale-specific validations (like national identifier or tax law checks) that are maintained by a dedicated team for each locale. The business logic group eases maintenance by storing these validations in separate files, and optimizes performance by loading them only when they are needed.

Each business logic group contains a set of business logic units. Each unit identifies the set of business logic that is loaded for the entity, based on the value of the attribute associated with the business logic group.

For example, you can define a business logic group for an `Employee` entity object, specifying the `EmpRegion` attribute as the discriminator. Then define a business logic unit for each **region**, one that specifies a range validator for the employee's salary. When the application loads a row from the `Employee` entity, the appropriate validator for the `EmpSalary` attribute is loaded (based on the value of the `EmpRegion` attribute).

In another example, you might have a `Orders` entity object has a business logic group called `FilledOrderGroup` that uses `OrderFilled` as the discriminator attribute. Because this attribute has two valid values (`N` and `Y`), there are two corresponding business logic units.

In this scenario, each business logic unit contains new or modified business logic that pertains only to that person type:

- The `Orders_FilledOrderGroup_N` business logic unit contains logic that pertains to orders that have not yet been filled. For example, the `DateShipped` attribute is configured to be hidden.
- The `Orders_FilledOrderGroup_Y` business logic unit contains logic that pertains to orders that have been filled. For example, the `DateShipped` attribute is configured to be displayed.

How to Create a Business Logic Group

You create the business logic group for an entity object from the overview editor.

Before you begin:

It may be helpful to have an understanding of how business logic groups are used. For more information, see Defining Business Logic Groups.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create a business logic group:

1. In the Applications window, double-click the entity for which you want to create a business logic group.
2. In the overview editor, click the **General** navigation tab.
3. On the General page, expand the **Business Logic Groups** section and click the **Add** icon.
4. In the creation dialog, select the appropriate group discriminator attribute and specify a name for the group.

> **Tip:**
>
> To enhance the readability of your code, you can name the group to reflect the discriminator. For example, if the group discriminator attribute is `OrderFilled`, you can name the business logic group `FilledOrderGroup`.

5. Click **OK**.

The new business logic group is added to the table in the overview editor. After you have created the group, you can add business logic units to it.

How to Create a Business Logic Unit

You can create a business logic unit from the New Gallery, or directly from the context menu of the entity that contains the business logic group.

Before you begin:

It may be helpful to have an understanding of how business logic groups are used. For more information, see Defining Business Logic Groups.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create a business logic unit:

1. In the Applications window, right-click the entity object that contains the business logic group and choose **New Entity Business Logic Unit**.
2. In the Create Business Logic Unit dialog, specify the name of the base entity and select the appropriate business logic group.
3. Enter a name for the business logic unit.

   The name of each business logic unit must reflect a valid value of the group discriminator attribute with which this business logic unit will be associated. For example, if the group discriminator attribute is `OrderFilled`, the name of the business logic unit associated with the `OrderFilled` value of `Y` must be `Y`.
4. Specify the package for the business logic unit.

> **Note:**
>
> The package for the business logic unit does not need to be the same as the package for the base entity or the business logic group. This allows you to develop and deliver business logic units separately from the core application.

5. Click **OK**.

JDeveloper creates the business logic unit and opens it in the overview editor. The name displayed for the business logic unit in the Applications window contains the name of the entity object and business logic group in the format *`EntityName_BusLogicGroupName_BusLogicUnitName`*. For example, when you create a business logic unit with the name Y in the FilledOrderGroup business logic group of the Orders entity object, the displayed name of the business logic unit is Orders_FilledOrderGroup_Y.

After you have created the unit, you can redefine the business logic for it.

How to Add Logic to a Business Logic Unit

After you have created a business logic unit, you can open it in the overview editor and add business logic (such as adding an entity-level validator) just as you would in the base entity.

Before you begin:

It may be helpful to have an understanding of how business logic groups are used. For more information, see Defining Business Logic Groups.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To add an entity validator to a business logic unit:

1. In the Applications window, double-click the business logic unit to which you want to add an entity validator.
2. In the overview editor, click the **Business Rules** navigation tab.
3. On the Business Rules page, select the **Entity Validators** node and click the **Add** icon.
4. In the Add Validation Rule dialog, define your validation rule, and click **OK**.

How to Override Attributes in a Business Logic Unit

When you view the Attributes page for the business logic unit (in the overview editor), you can see that the **Extends** column in the attributes table shows that the attributes are "extended" in the business logic unit. Extended attributes are editable only in the base entity, not in the business logic unit. To implement changes in the business logic unit rather than the base entity, you must define attributes as overridden in the business logic unit before you edit them.

Before you begin:

It may be helpful to have an understanding of how business logic groups are used. For more information, see Defining Business Logic Groups.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To override attributes in a business logic unit:

1. In the Applications window, double-click the business logic unit that contains the attributes you want to override.
2. In the overview editor, click the **Attributes** navigation tab.
3. On the Attributes page, select the desired attribute and click the **Override** button.

After you make an attribute overridden, you can edit the attribute as you normally would in the tabs below the table. You will notice that in an overridden attribute, you are limited to making modifications to only control hints, validators, and default values.

What Happens When You Create a Business Logic Group

When you create a business logic group, JDeveloper adds a reference to the group in the base entity's XML file, as shown below.

```
<BusLogicGroup
    Name="FilledOrderGroup"
    DiscrAttrName="OrderFilled"/>
```

When you create a business logic unit, JDeveloper generates an XML file similar to that of an entity object. The following example shows XML code for a business logic unit.

> **Note:**
>
> The package for the business logic unit does not need to be the same as the package for the base entity or the business logic group. This allows you to develop and deliver business logic units separately from the core application.

```
<Entity
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="Orders_FilledOrderGroup_N"
  Version="12.1.2.66.11"
  Extends="oracle.summit.model.buslogic.Orders"
  InheritPersonalization="merge"
  DBObjectType="table"
  DBObjectName="S_ORD"
  BindingStyle="OracleName"
  BusLogicGroupName="FilledOrderGroup"
  BusLogicUnitName="N">
  <Attribute
    Name="Total"
    Precision="11"
    Scale="2"
    ColumnName="TOTAL"
    SQLType="NUMERIC"
    Type="java.math.BigDecimal"
    ColumnType="NUMBER"
    TableName="S_ORD">
    <DesignTime>
      <Attr Name="_OverrideAttr" Value="true"/>
    </DesignTime>
    <Properties>
      <SchemaBasedProperties>
        <LABEL

ResId="oracle.summit.model.buslogic.Orders_FilledOrderGroup_N.Total_LABEL"/>
      </SchemaBasedProperties>
    </Properties>
  </Attribute>
  <Attribute
    Name="DateShipped"
    ColumnName="DATE_SHIPPED"
    SQLType="DATE"
    Type="java.sql.Date"
    ColumnType="DATE"
    TableName="S_ORD">
    <DesignTime>
      <Attr Name="_OverrideAttr" Value="true"/>
    </DesignTime>
    <Properties>
      <SchemaBasedProperties>
        <DISPLAYHINT
          Value="Hide"/>
      </SchemaBasedProperties>
    </Properties>
  </Attribute>
  <ResourceBundle>
    <PropertiesBundle
      PropertiesFile="oracle.summit.model.ModelBundle"/>
  </ResourceBundle>
</Entity>
```

What Happens at Runtime: How Business Logic Groups Are Invoked

When a row is loaded in the application at runtime, the entity object decides which business logic units to apply to it.

The base entity maintains a list of business logic groups. Each group references the value of an attribute on the entity, and this value determines which business logic unit to load for that group. This evaluation is performed for each row that is loaded.

If the logic for determining which business logic unit to load is more complex than just a simple attribute value, you can create a transient attribute on the entity object, and use a Groovy expression to determine the value of the transient attribute.

Configuring Runtime Behavior Declaratively

Use ADF entity objects to implement business logic and validation rules for the business layer using its declarative runtime features.

Entity objects offer numerous declarative features to simplify implementing typical enterprise business applications. Depending on the task, sometimes the declarative facilities *alone* may satisfy your needs. The declarative runtime features that describe the basic persistence features of an entity object are covered in this section, while declarative validation and business rules are covered in Defining Validation and Business Rules Declaratively.

> **Note:**
>
> It is possible to go beyond the declarative behavior to implement more complex business logic or validation rules for your business domain layer when needed. In Implementing Validation and Business Rules Programmatically, you'll see some of the most typical ways that you extend entity objects with custom code.

Also, it is important to note as you develop your application that the business logic you implement, either programmatically or declaratively, should not assume that the attributes of an entity object or view row will be set in a particular order. This will cause problems if the end user enters values for the attributes in an order other than the assumed one.

How to Configure Declarative Runtime Behavior

To configure the declarative runtime behavior of an entity object, use the overview editor.

Before you begin:

It may be helpful to have an understanding of declarative configuration of runtime behavior. For more information, see Configuring Runtime Behavior Declaratively.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To configure the declarative runtime behavior of an entity object:

1. In the Applications window, double-click an entity object.
2. In the overview editor, click the **General** navigation tab to view the name and package of the entity object, and configure aspects of the object at the entity level, such as its associated schema, alternative keys, custom properties, and security.
   - The **Alternate Keys** section allows you to select entity object attributes mapped to the database that can serve as an alternative primary key. For information on alternative keys, see How to Define Alternate Key Values.
   - The **Tuning** section allows you to set options to make database operations more efficient when you create, modify, or delete multiple entities of the same type in a single transaction. For more information, see How to Use Update Batching.
   - The **Custom Properties** section allows you to define custom metadata that you can access at runtime on the entity.
   - The **Security** section allows you to define role-based updatability permissions for the entity. For more information, see Enabling ADF Security in a Fusion Web Application.
   - The **Business Logic Groups** section allows you to add and edit business logic groups. For more information, see Defining Business Logic Groups.
3. Click the **Attributes** navigation tab to create or delete attributes that represent the data relevant to an entity object, and configure aspects of the attribute, such as validation rules, custom properties, and security.

   Select an attribute and click the **Edit** icon to access the properties of the attribute. For information on how to set these properties, see Setting Attribute Properties.

> **Note:**
>
> If your entity has a long list of attribute names, there's a quick way to find the one you're looking for. In the Structure window with the **Attributes** node expanded, you can begin to type the letters of the attribute name and JDeveloper performs an incremental search to take you to its name in the tree.

4. Click the **Business Rules** navigation tab to define declarative validators for the entity object and its attributes. The script box allows you to view and edit Groovy script for your business rules, and set breakpoints for debugging. For more information, see Defining Validation and Business Rules Declaratively.
5. Click the **Java** navigation tab to select the classes you generate for custom Java implementation. You can use the Java classes for such things as defining programmatic business rules, as in Implementing Validation and Business Rules Programmatically.
6. Click the **Business Events** navigation tab to define events that your entity object can use to notify others of interesting changes in its state, optionally including some or all of the entity object's attributes in the delivered event. For more information about business events, see Creating Business Events.
7. Click the **View Accessors** navigation tab to create and manage view accessors. For more information, see How to Create a View Accessor for an Entity Object or View Object.

What Happens When You Configure Declarative Runtime Behavior

The declarative settings that describe and control an entity object's runtime behavior are stored in its XML document file. When you use the overview editor to modify settings of your entity, JDeveloper updates the component's XML definition file and optional custom Java files.

How to Use Update Batching

You can use update batching to reduce the number of DML statements issued with multiple entity modifications.

By default, the ADF Business Components framework performs a single DML statement (`DELETE`, `INSERT`, `UPDATE`) for each modified entity of a given entity definition type. For example, say you have an Employee entity object type for which multiple instances are modified during typical use of the application. If two instances were created, three existing instances modified, and four existing instances deleted, then at transaction commit time the framework issues nine DML statements (4 `DELETE`s, 2 `INSERT`s, and 3 `UPDATE`s) to save these changes.

If you will frequently be updating more than one entity of a given type in a transaction, consider using the update batching feature for that entity definition type. In the example, update batching (with a threshold of 1) causes the framework to issue just three DML statements: one bulk `DELETE` statement processing four deletes, one bulk `INSERT` statement processing two inserts, and one bulk `UPDATE` statement processing three updates.

The threshold value indicates the number of modified entity rows for a given operation that will be processed individually. When the number of modified entity rows exceeds the threshold value, batch processing will be used for that operation. In this example, if the threshold is 3, `DELETE` will perform batch update (because there are 4 `DELETE`s), but `INSERT`s and `UPDATE`s will not use batch (because there are only 2 `INSERT`s and 3 `UPDATE`s).

> **Note:**
>
> When update batching is used in entity objects with a composition relationship, all composed child objects must define a threshold value greater than 1 if the parent object defines a threshold value greater than 1.

The batch update feature is disabled if any of following conditions are present:

- The entity object has attributes of BLOB or CLOB type. Batch DML with streaming data types is not supported.
- The entity object has attributes that are set to **Refresh After Insert** or **Refresh After Update**. There is no method to bulk-return all of the trigger-assigned values in a single round trip, so retrieving and updating attributes doesn't work with batch DML.
- The entity object was created from a table that did not have a primary key. If an entity object is reverse-engineered from a table that does not have a primary key, a ROWID-valued attribute is created and assigned as the primary key instead. The ROWID value is managed as a Retrieve-on-Insert value, so it will not work with batch DML.

Before you begin:

It may be helpful to have an understanding of the declarative configuration of runtime behavior. For more information, see Configuring Runtime Behavior Declaratively.

You may also find it useful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To enable update batching for an entity

1. In the Applications window, double-click the entity for which you want to enable update batching.
2. In the overview editor, click the **General** navigation tab.
3. On the General page, expand the **Tuning** section, select the **Use Update Batching** checkbox, and specify the appropriate threshold.

This establishes a batch processing threshold beyond which Oracle ADF will process the modifications in a bulk DML operation.

Setting Attribute Properties

Use the declarative framework to set attribute properties on the Attributes page of the overview editor of ADF Business Components.

The declarative framework helps you set attribute properties easily. In all cases, you set these properties on the Attributes page of the overview editor.

How to Set Database and Java Data Types for an Entity Object Attribute

The `Persistent` property controls whether the attribute value corresponds to a column in the underlying table, or whether it is just a transient value. If the attribute is persistent, the **Database Column** area lets you change the name of the underlying column that corresponds to the attribute and indicate its column type with precision and scale information (for example, `VARCHAR2(40)` or `NUMBER(4,2)`). Based on this information, at runtime the entity object enforces the maximum length or precision and scale of the attribute value, and throws an exception if a value does not meet the requirements.

Both the Business Components from Tables wizard and the Create Entity Object wizard infer the Java type of each entity object attribute from the SQL type of the database column type of the column to which it is related.

> **Note:**
>
> The project's Type Map setting also plays a role in determining the Java data type. You specify the Type Map setting when you initialize your business components project, before any business components are created. For more information, see How to Initialize the Data Model Project With a Database Connection.

The **Type** field (on the **Details** tab) allows you to change the Java type of the entity attribute to any type you might need. The **Column Type** field reflects the SQL type of the underlying database column to which the attribute is mapped. The value of the **Column Name** field controls the column to which the attribute is mapped.

Your entity object can handle tables with various column types, as listed in Table 4-1. The default Java attribute types are in the `oracle.jbo.domain` and various `java` packages, and support efficiently working with Oracle database data of the corresponding type. The dropdown list for the **Type** field includes a number of other common Java types that are also supported.

Table 4-1 Default Entity Object Attribute Type Mappings

Oracle Column Type	Entity Column Type	Entity Java Type
`NVARCHAR2(n)`, `VARCHAR2(n)`, `NCHAR VARYING(n)`, `VARCHAR(n)`	`VARCHAR2`	`java.lang.String`

`NUMBER`	`NUMBER`	`oracle.jbo.domain.Number`
		`java.math.BigDecimal`
		`java.math.BigInteger`
		`java.lang.Integer`
		`java.lang.Long`

`DATE`	`DATE`	`java.sql.Timestamp`

Table 4-1 (Cont.) Default Entity Object Attribute Type Mappings

Oracle Column Type	Entity Column Type	Entity Java Type
TIMESTAMP(n), TIMESTAMP(n) WITH TIME ZONE, TIMESTAMP(n) WITH LOCAL TIME ZONE	TIMESTAMP	java.sql.Timestamp
LONG	LONG	java.lang.String
RAW(n)	RAW	oracle.jbo.domain.Raw
LONG RAW	LONG RAW	oracle.jbo.domain.Raw
ROWID	ROWID	oracle.jbo.domain.RowID
NCHAR, CHAR	CHAR	oracle.jbo.domain.Char
CLOB	CLOB	oracle.jbo.domain.ClobDomain
NCLOB	NCLOB	oracle.jbo.domain.NClobDomain
BLOB	BLOB	oracle.jbo.domain.BlobDomain
BFILE	BFILE	oracle.jbo.domain.BFileDomain

Note:

In addition to the types mentioned here, you can use any Java object type as an entity object attribute's type, provided it implements the oracle.jbo.domain.DomainInterface interface.

How to Indicate Data Type Length, Precision, and Scale

When working with types that support defining a maximum length like VARCHAR2(n), the **Column Type** field (on the **Details** tab) includes the maximum attribute length as part of the value. For example, an attribute based on a VARCHAR2(10) column in the database will initially reflect the maximum length of 10 characters by showing VARCHAR2(10) as the database column type. If for some reason you want to restrict the maximum length of the String-valued attribute to fewer characters than the underlying column will allow, just change the maximum length of the **Column Type** value.

For example, if the EMAIL column in the PERSONS table is VARCHAR2(50), then by default the Email attribute in the Persons entity object defaults to the same. But if you know that the actual email addresses are always 8 characters or fewer, you can update the database column type for the Email attribute to be VARCHAR2(8) to enforce a maximum length of 8 characters at the entity object level.

The same holds for attributes related to database column types that support defining a precision and scale like NUMBER(p[,s]). For example, to restrict an attribute based on a NUMBER(7,2) column in the database to instead have a precision of 5 and a scale of 1, just update the value of the **Column Type** field to be NUMBER(5,1).

> **Note:**
>
> Use this feature judiciously. If other applications can access this database column, then you cannot be sure that the other applications will respect the more restrictive constraints.

How to Control the Updatability of an Attribute

The `Updatable` property controls when the value of a given attribute can be updated. You can select the following values:

- **Always,** the attribute is always updatable
- **Never**, the attribute is read-only
- **While New**, the attribute can be set during the transaction that creates the entity row for the first time, but after being successfully committed to the database the attribute is read-only

> **Note:**
>
> In addition to the static declaration of updatability, you can also add custom code in the `isAttributeUpdateable()` method of the entity to determine the updatability of an attribute at runtime.

How to Make an Attribute Mandatory

Select the **Mandatory** checkbox if the field is required. The mandatory property is enforced during entity-level validation at runtime (and not when the attribute validators are run).

How to Define the Primary Key for the Entity

The `Primary Key` property indicates whether the attribute is part of the key that uniquely identifies the entity. Typically, you use a single attribute for the primary key, but multiattribute primary keys are fully supported.

At runtime, when you access the related `Key` object for any entity row using the `getKey()` method, this `Key` object contains the value of the primary key attribute for the entity object. If your entity object has multiple primary key attributes, the `Key` object contains each of their values. It is important to understand that these values appear in the same *relative* sequential order as the corresponding primary key attributes in the entity object definition.

For example, if the `ItemEO` entity object has multiple primary key attributes `OrdId` and `ItemId`. On the Attribute page of the overview editor, `OrdId` is first, and `ItemId` is second. An array of values encapsulated by the `Key` object for an entity row of type `ItemEO` will have these two attribute values in exactly this order.

It is crucial to be aware of the order in which multiple primary key attributes appear on the Entity Attributes page. If you try to use `findByPrimaryKey()` to find an entity with a multiattribute primary key, and the `Key` object you construct has these multiple primary key attributes in the wrong order, the entity row will not be found as expected.

In addition, to populate the primary key in new rows, you might want to use a trigger to assign the value from the database. For more information, see How to Get Trigger-Assigned Primary Key Values from a Database Sequence

How to Define a Static Default Value

The value field on the **Details** tab allows you to specify a static default value for the attribute when the value type is set to **Literal**. For example, you can set the default value of the `ServiceRequest` entity object's `Status` attribute to `Open`, or set the default value of the `User` entity object's `UserRole` attribute to `user`.

> **Note:**
>
> When more than one attribute is defaulted for an entity object, the attributes are defaulted in the order in which they appear in the entity object's XML file.

How to Define a Default Value Using an Expression

You can use a Groovy expression or SQL statement to define a default value for an attribute. This approach is useful if you want to be able to dynamically define default values at runtime, but if the default value is always the same, the value is easier to see and maintain using a value field with the **Literal** type (on the **Details** tab). For general information about using Groovy, see Using Groovy Scripting Language with Business Components.

Before you begin:

It may be helpful to have an understanding of how you set attribute properties. For more information, see Setting Attribute Properties.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To define a default value using an expression:

1. In the Applications window, double-click the entity object that contains the attribute for which you want to define a default value.
2. In the overview editor, click the **Attributes** navigation tab.
3. On the Attributes page, select the attribute you want to edit, and then click the **Details** tab.
4. In the Details page, select the value type, and click the **Edit** icon for the **Value** field.
   - To use a Groovy expression, select **Expression**.
   - To use a SELECT statement, select **SQL**.

5. To enter:
   - SQL statement, enter the statement in the field provided and click **OK**. Note that you can enter an SQL statement only for transient attributes.
   - Groovy expression, click the icon beside to open the Edit Expression Editor dialog. In the Edit Expression Editor dialog, enter an expression in the field provided. Attributes that you reference can include any attribute that the business component defines. Specify the attributes on which this attribute is dependent by moving these attributes from **Available to Selected.** Click **OK** to save the expression

What Happens When You Create a Default Value Using a Groovy expression

When you define a default value using a Groovy expression, a `<TransientExpression>` tag is added to this business object's XML file within the appropriate attribute. The following example shows XML code for a Groovy expression that has been added for the `ID` attribute of the `CountryVO` view object. The XML definition informs you that the `.bcs` file where this Groovy expression script resides in is pointed to by the `operations.xml` file, which in this example is `CodeSourceName=”CountryVOOperations.xml”`. The `operations.xml` file has an URI which points the user to the `.bcs` file.

```
<View Attribute
    Name="Id"
    IsNotNull="true"
    PrecisionRule="true"
    EntityAttrName="Id"
    EntityUsage="CountryEO"
    AliasName="ID">
    <TransientExpression
        Name="ExpressionScript"
        trustMode="untrusted"
        CodeSourceName="CountryVORow"/>

</ViewAttribute>
```

> **Note:**
>
> If Groovy file generation is enabled for this Model project or application-wide, then the Groovy expression displays as a hyperlink in Overview Editor page of this business component under the Default Value section. Click this hyperlink to open the `.bcs` file associated with this business component. Refer the topic What You May Need to Know About Groovy Project Settings to read more about project settings. Refer this topic What Happens When You Enter Expressions to read about how the application manages Groovy expressions when you enter them.

How to Synchronize with Trigger-Assigned Values

If you know that the underlying column value will be updated by a database trigger during insert or update operations, you can enable the respective **Refresh on Insert** or **Refresh on Update** checkboxes on the **Details** tab to ensure that the framework automatically retrieves the modified value and keeps the entity object and database row in sync. The entity object will use the Oracle SQL RETURNING INTO feature, while performing the INSERT or UPDATE to return the modified column back to your application in a single database roundtrip.

> **Note:**
>
> If you create an entity object for a synonym that resolves to a remote table over a DBLINK, use of this feature will give an error at runtime like:
>
> ```
> JBO-26041: Failed to post data to database during "Update"
> ## Detail 0 ##
> ORA-22816: unsupported feature with RETURNING clause
> ```
>
> Basing an Entity Object on a Join View or Remote DBLink describes a technique to circumvent this database limitation.

How to Get Trigger-Assigned Primary Key Values from a Database Sequence

One common case for refreshing an attribute after insert occurs when a primary key attribute value is assigned by a BEFORE INSERT FOR EACH ROW trigger. Often the trigger assigns the primary key from a database sequence using PL/SQL logic, as shown in the following example.

```
CREATE OR REPLACE TRIGGER ASSIGN_SVR_ID
BEFORE INSERT ON SERVICE_REQUESTS FOR EACH ROW
BEGIN
 IF :NEW.SVR_ID IS NULL OR :NEW.SVR_ID < 0 THEN
   SELECT SERVICE_REQUESTS_SEQ.NEXTVAL
     INTO :NEW.SVR_ID
     FROM DUAL;
   END IF;
END;
```

> **Note:**
>
> You can create a trigger in a live database or, as an alternative, create it in an offline database and subsequently import the trigger to the live database. For more information about working with offline database objects, see the "Creating, Editing, and Dropping Database Objects" section in *Developing Applications with Oracle JDeveloper*.

On the **Details** tab (on the Attributes page of the overview editor), you can set the value of the **Type** field to the built-in data type named DBSequence, and the primary key will be assigned automatically by the database sequence. Setting this data type automatically selects the **Refresh on Insert** checkbox.

> **Note:**
>
> The sequence name shown on the **Sequence** tab is used only at design time when you use the **Create Database Tables** feature described in How to Create Database Tables from Entity Objects. The sequence indicated here will be created along with the table on which the entity object is based.

When you create a new entity row whose primary key is a `DBSequence`, a unique negative number is assigned as its temporary value. This value acts as the primary key for the duration of the transaction in which it is created. If you are creating a set of interrelated entities in the same transaction, you can assign this temporary value as a foreign key value on other new, related entity rows. At transaction commit time, the entity object issues its `INSERT` operation using the `RETURNING INTO` clause to retrieve the actual database trigger-assigned primary key value. In a composition relationship, any related new entities that previously used the temporary negative value as a foreign key will get that value updated to reflect the actual new primary key of the master.

You will typically also set the **Updatable** property of a DBSequence-valued primary key to **Never**. The entity object assigns the temporary ID, and then refreshes it with the actual ID value after the `INSERT` operation. The end user never needs to update this value.

For information on how to implement this functionality for an association that is not a composition, see Associations Based on DBSequence-Valued Primary Keys.

> **Note:**
>
> For a metadata-driven alternative to the DBSequence approach, see Assigning the Primary Key Value Using an Oracle Sequence.

What You May Need to Know About Changing the Value of Primary Keys

The updating of primary key values through the user interface is not supported by ADF Business Components. You can, however, update a primary key value using DBSequence, as described in How to Get Trigger-Assigned Primary Key Values from a Database Sequence or programmatically, as described in Assigning the Primary Key Value Using an Oracle Sequence. In some cases, this kind of user interface behavior can be implemented using a surrogate key rather than allowing the user to change the primary key.

How to Protect Against Losing Simultaneously Updated Data

At runtime, the framework provides "lost update" detection for entity objects to ensure that a user cannot unknowingly modify data that another user has updated and committed in the meantime. Typically, this check is performed by comparing the original values of each persistent entity attribute against the corresponding current column values in the database at the time the underlying row is locked. Before updating a row, the entity object verifies that the row to be updated is still consistent with the current state of the database. If the row and database state are inconsistent, then the entity object raises the RowInconsistentException.

You can make the lost update detection more efficient by identifying any attributes of your entity whose values you know will be updated whenever the entity is modified. Typical candidates include a version number column or an updated date column in the row. The change-indicator attribute's value might be assigned by a database trigger you've written and refreshed in the entity object, because you selected the **Refresh on Insert** or **Refresh on Update** option (on the **Details** tab). Alternatively, you can indicate that the entity object should manage updating the change-indicator attribute's value using the history attribute feature described in How to Track Created and Modified Dates Using the History Column.

To detect, in the most efficient way, whether an entity row has been modified since the user queried it, select the **Change Indicator** option to compare only the change-indicator attribute values. Entity objects without a change-indicator attribute may perform less efficiently because values in all attributes will be used in data consistency checks. Entity objects without a change-indicator attribute are also subject to a loss of data consistency when the a user session loses affinity with its application module (when **application module pooling** is used). For more information, see What You May Need to Know About State Management and Data Consistency. For more information about application module pooling, see Tuning Application Module Pools.

How to Protect Against Truncated Attribute Values at Runtime

In rare situations, at runtime during application module passivation, string values may not be preserved correctly. For example, whitespace may get truncated. You may define a custom property on the entity object attribute to encapsulate your string value in CDATA section.

To define the XML_CDATA custom property and preserve whitespace formatting of an entity object attribute's default value:

1. In the overview editor for the entity object, select the **Attribute** page and then select the attribute and click the Custom Properties tab.
2. In the Custom Properties tab, add the property with the name XML_CDATA and set the value to true.

JDeveloper adds the custom property to the entity object XML definition, as the following example for an attribute CategoryCode shows.

```
<Attribute
   Name="CategoryCode"
   ...
   <Properties>
     <CustomProperties>
       <Property
         Name="XML_CDATA"
         ResId="model.Departments.LocationId.XML_CDATA_VALUE"/>
     </CustomProperties>
   </Properties>
</Attribute>
```

How to Track Created and Modified Dates Using the History Column

If you need to keep track of historical information in your entity object, such as when an entity was created or modified and by whom, or the number of times the entity has been modified, you specify an attribute with the **Track Change History** option selected (on the **Details** tab).

If an attribute's data type is `Number`, `String`, or `Date`, and if it is not part of the primary key, then you can enable this property to have your entity automatically maintain the attribute's value for historical auditing. How the framework handles the attribute depends which type of history attribute you indicate:

- **Created On**: This attribute is populated with the time stamp of when the row was created. The time stamp is obtained from the database.
- **Created By**: The attribute is populated with the name of the user who created the row. The user name is obtained using the `getUserPrincipalName()` method on the `Session` object.
- **Modified On**: This attribute is populated with the time stamp whenever the row is updated/created.
- **Modified By**: This attribute is populated with the name of the user who creates or updates the row.
- **Version Number**: This attribute is populated with a long value that is incremented whenever a row is created or updated.

How to Configure Composition Behavior

An entity object exhibits composition behavior when it creates (or composes) other entities, such as an `OrdEO` entity creating an `ItemEO` entity. This additional runtime behavior determines its role as a logical container of other nested entity object parts. Because of this relationship, a composition association cannot be based on a transient attribute.

> **Note:**
>
> Composition also affects the order in which entities are validated. For more information, see Understanding the Impact of Composition on Validation Order.

The features that are always enabled for composing entity objects are described in the following sections:

- Orphan-Row Protection for New Composed Entity Objects
- Ordering of Changes Saved to the Database
- Cascade Update of Composed Details from Refresh-On-Insert Primary Keys

The additional features, and the properties that affect their behavior, are described in the following sections:

- Cascade Delete Support
- Cascade Update of Foreign Key Attributes When Primary Key Changes
- Locking of Composite Parent Entity Objects
- Using Batch Update with Composition Entity Objects
- Updating of Composing Parent History Attributes

Orphan-Row Protection for New Composed Entity Objects

When a composed entity object is created, it performs an existence check on the value of its foreign key attribute to ensure that it identifies an existing entity as its owning parent entity. At create time, if no foreign key is found or else a value that does not identify an existing entity object is found, the entity object throws an `InvalidOwnerException` instead of allowing an orphaned child row to be created without a well-identified parent entity.

> **Note:**
>
> The existence check finds new pending entities in the current transaction, as well as existing ones in the database if necessary.

Ordering of Changes Saved to the Database

Composition behavior ensures that the sequence of data manipulation language (DML) operations performed in a transaction involving both composing and composed entity objects is performed in the correct order. For example, an `INSERT` statement for a new composing parent entity object will be performed before the DML operations related to any composed children.

Cascade Update of Composed Details from Refresh-On-Insert Primary Keys

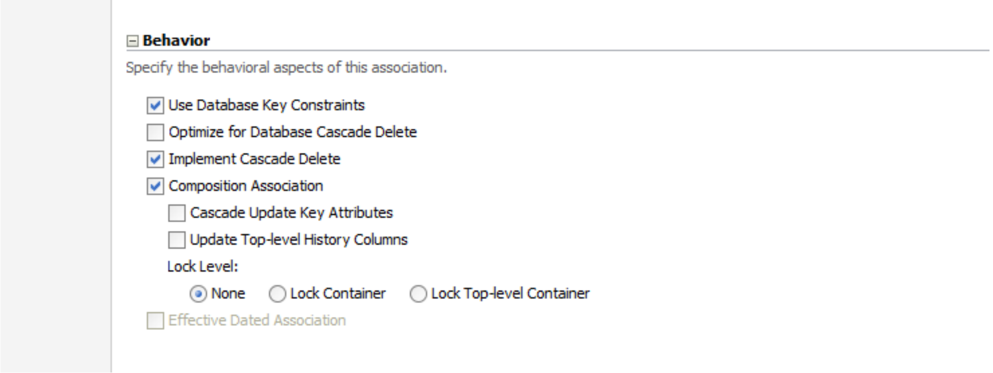
When a new entity row having a primary key configured to refresh on insert is saved, then after its trigger-assigned primary value is retrieved, any composed entities will have their foreign key attribute values updated to reflect the new primary key value.

There are a number of additional composition related features that you can control through settings on the Association Properties page of the Create Association wizard or the overview editor. Figure 4-13 shows the Relationships page for the `SItemOrdIdFkAssoc` association between two entity objects: `ItemEO` and `OrdEO`.

Cascade Delete Support

You can either enable or prevent the deletion of a composing parent while composed children entities exist. When the **Implement Cascade Delete** option (see Figure 4-13) is deselected, the removal of the composing entity object is prevented if it contains any composed children.

Figure 4-13 Behavior Settings on Relationship Page of Overview Editor for Associations



⊟ **Behavior**

Specify the behavioral aspects of this association.

☑ Use Database Key Constraints
□ Optimize for Database Cascade Delete
☑ Implement Cascade Delete
☑ Composition Association
□ Cascade Update Key Attributes
□ Update Top-level History Columns

Lock Level:

● None ○ Lock Container ○ Lock Top-level Container

□ Effective Dated Association

When selected, this option allows the composing entity object to be removed unconditionally together with any composed children entities. If the related **Optimize for Database Cascade Delete** option is deselected, then the composed entity objects perform their normal `DELETE` statement at transaction commit time to make the changes permanent. If the option is selected, then the composed entities do not perform the `DELETE` statement on the assumption that the database `ON DELETE CASCADE` constraint will handle the deletion of the corresponding rows.

Cascade Update of Foreign Key Attributes When Primary Key Changes

Select the **Cascade Update Key Attributes** option (see Figure 4-13) to enable the automatic update of the foreign key attribute values in composed entities when the primary key value of the composing entity is changed.

Locking of Composite Parent Entity Objects

Select the **Lock Top-Level Container** option (see Figure 4-13) to control whether adding, removing, or modifying a composed detail entity row should attempt to lock the composing entity before allowing the changes to be saved.

Using Batch Update with Composition Entity Objects

When update batching is used in entity objects with a composition relationship, all composed child objects must define a threshold value greater than 1 if the parent object defines a threshold value greater than 1.

Updating of Composing Parent History Attributes

Select the **Update Top-Level History Columns** option (see Figure 4-13) to control whether adding, removing, or modifying a composed detail entity object should update the **Modified By** and **Modified On** history attributes of the composing parent entity.

How to Set the Discriminator Attribute for Entity Object Inheritance Hierarchies

Sometimes a single database table stores information about several different kinds of logically related objects. For example, a payroll application might work with hourly, salaried, and contract employees all stored in a single `EMPLOYEES` table with an `EMPLOYEE_TYPE` column. In this case, the value of the `EMPLOYEE_TYPE` column contains values like `H`, `S`, or `C` to indicate respectively whether a given row represents an hourly, salaried, or contract employee. And while it is possible that many attributes and behavior are the same for all employees, certain properties and business logic may also depend on the type of employee.

In situations where common information exists across related objects, it may be convenient to represent these different types of entity objects using an inheritance hierarchy. For example, attributes and methods common to all employees can be part of a base `Employee` entity object, while subtype entity objects like `HourlyEmployee`, `SalariedEmployee`, and `ContractEmployee` extend the base `Employee` object and add additional properties and behavior. The **Discriminator** attribute setting is used to indicate which attribute's value distinguishes the type of row. Using Inheritance in Your Business Domain Layer, explains how to set up and use inheritance.

How to Define Alternate Key Values

Database primary keys are often generated from a sequence and may not be data you want to expose to the user for a variety of reasons. For this reason, it's often helpful to have alternate key values that are unique. For example, you might want to enforce that every customer have a unique email address. Because a customer may change their email address, you won't want to use that value as a primary key, but you still want the user to have a unique field they can use for login or other purposes.

Alternate keys are useful for direct row lookups via the `findByKey` class of methods. Alternate keys are frequently used for efficient uniqueness checks in the middle tier. For information on how to find out if a value is unique, see How to Ensure That Key Values Are Unique.

To define an alternate key, you use the Create Entity Constraint wizard.

Before you begin:

It may be helpful to have an understanding of how you set attribute properties. For more information, see Setting Attribute Properties.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To define alternate key values:

1. In the Applications window, right-click the entity object for which you want to define an alternate key and choose **New Entity Constraint**.
2. Follow the steps in the Create Entity Constraint wizard to name your constraint and select the attribute or attributes that participate in the key.
3. On the Properties page, select **Alternate Key** and choose the appropriate **Key Properties** options.

For more information about the **Key Properties** options, press the F1 key or click **Help**.

What Happens When You Define Alternate Key Values

When you define alternate key values, a hash map is created for fast access to entities that are already in memory.

What You May Need to Know About Alternate Key Values

The Unique key constraint is used only for forward generation of `UNIQUE` constraints in the database, not for alternate key values.

Adding Transient and Calculated Attributes to an Entity Object

Add transient attributes in ADF entity objects based on one-to-many columns. Use an entity object’s Java class or use a Groovy expression to define a calculated attribute of a transient attribute.

In addition to having attributes that map to columns in an underlying table, your entity objects can include transient attributes that display values calculated (for example, using Java or Groovy) or that are value holders. For example, a transient attribute you create, such as `FullName`, could be calculated based on the concatenated values of `FirstName` and `LastName` attributes.

Once you create the transient attribute, you can perform a calculation in the entity object Java class, or use a Groovy expression in the attribute definition to specify a default value.

If you want to be able to change the way the value is calculated at runtime, you can use a Groovy expression. If the way the value is calculated is not likely to change (for example, if it's a sum of the line items), you can perform the calculation directly in the entity object Java class.

How to Add a Transient Attribute

Use the Attributes page of the overview editor to create a transient attribute.

Before you begin:

It may be helpful to have an understanding of the use of transient and calculated attributes. For more information, see Adding Transient and Calculated Attributes to an Entity Object.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To add a transient attribute to an entity object:

1. In the Applications window, double-click the entity object to which you want to add a transient attribute.

2. In the overview editor, click the **Attributes** navigation tab, and then click the **New** icon and choose **New Attribute**.
3. In the New Entity Attribute dialog, enter a name for the attribute, select the Java attribute type from the **Type** dropdown list, and click **OK**.
4. On the Attributes page of the overview editor, click the **Details** tab and select the **Transient** radio button.
5. If the value will be calculated, select **Never** from the **Updatable** dropdown list.

What Happens When You Add a Transient Attribute

When you add a transient attribute, JDeveloper updates the XML document for the entity object to reflect the new attribute. The `<Attribute>` tag of a transient attribute has no `TableName` or `ColumnName`, as shown in the following example.

```
<Attribute
   Name="FullName"
   IsUpdateable="false"
   IsQueriable="false"
   IsPersistent="false"
   Type="java.lang.String"
   SQLType="VARCHAR" >
</Attribute>
```

In contrast, a persistent entity attribute has both a `TableName` and a `ColumnName`, as shown in the following example.

```
<Attribute
   Name="FirstName"
   IsNotNull="true"
   Precision="30"
   ColumnName="FIRST_NAME"
   Type="java.lang.String"
   ColumnType="VARCHAR2"
   SQLType="VARCHAR"
   TableName="USERS" >
</Attribute>
```

How to Base a Transient Attribute on a Groovy Expression

When creating a transient attribute, you can use a Groovy expression to provide the default value.

Before you begin:

It may be helpful to have an understanding of transient and calculated attributes. For more information, see Adding Transient and Calculated Attributes to an Entity Object.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create a transient attribute based on a Groovy expression:

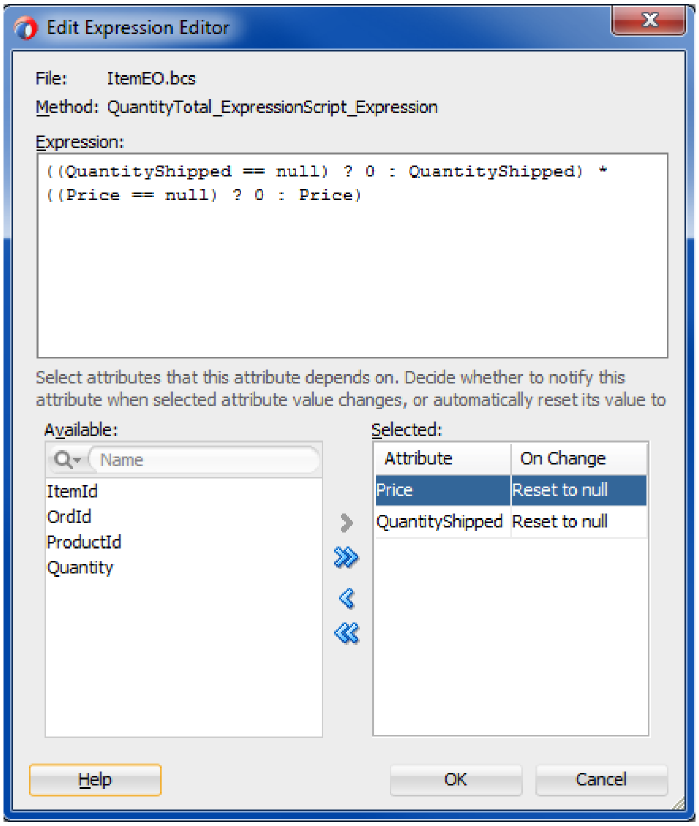
1. In the Applications window, double-click the entity object to which you want to add a transient attribute.

2. In the overview editor, click the **Attributes** navigation tab, and then click the **New** icon and choose **New Attribute**.
3. In the New Entity Attribute dialog, enter a name for the attribute, select the Java attribute type from the **Type** dropdown list, and click **OK**.
4. On the Attributes page of the overview editor, click the **Details** tab and select the **Transient** option.
5. If the value will be calculated, select **Never** from the **Updatable** dropdown list.
6. Select **Expression** checkbox under **Default Value** and click the icon beside to open the **Edit Expression Editor** dialog.

   Expressions that you define are evaluated using the Groovy scripting language, as described in Using Groovy Scripting Language with Business Components. Use the Groovy programming language to insert expressions and variables into strings. The expression is saved as part of the entity object definition.
7. In the Edit Expression Editor dialog, enter an expression in the field provided.

   Attributes that you reference can include any attribute that the entity object defines. For attributes not defined by the entity object, use the appropriate context object to reference these attributes in the expression.

Figure 4-14 Edit Expression Editor



File: ItemEO.bcs

Method: QuantityTotal_ExpressionScript_Expression

Expression:

```
((QuantityShipped == null) ? 0 : QuantityShipped) *
((Price == null) ? 0 : Price)
```

Select attributes that this attribute depends on. Decide whether to notify this attribute when selected attribute value changes, or automatically reset its value to

Available:

ItemId
OrdId
ProductId
Quantity

Selected:

Attribute	On Change
Price	Reset to null
QuantityShipped	Reset to null

8. Specify the attributes on which this attribute is dependent. Move these attributes from **Available** to **Selected**.
9. Click **OK** to save the expression.

10. If required, apply a recalculation expression that if evaluates to be true, recalculates the default expression. In the **Refresh Expression Value** field, click the icon beside to open the Edit Expression Editor dialog. Use the same procedure that you used to define a default expression to define the recalculation expression as well.

    For example, the following expression defined using the Edit Expression Editor dialog for the **Refresh Expression Value** field causes the attribute to be recalculated when either the `QuantityShipped` attribute or the `Price` attributes are changed:

    ```
    return (adf.object.isAttributeChanged("QuantityShipped") ||
    adf.object.isAttributeChanged("Price"));
    ```

> **Note:**
>
> If either the value expression or the optional recalculate expression that you define references an attribute from the base entity object, you must define this as a dependency. If you didn't provide dependencies in the Edit Expression Editor dialog when you defined the expression, you can do so on the **Dependencies** tab (on the Attributes page). On the **Dependencies** tab, locate the attributes in the **Available** list and shuttle each to the **Selected** list.

What Happens When You Base a Transient Attribute on a Groovy Expression

When you base a transient attribute on a Groovy expression, a `<TransientExpression>` tag is added to the entity object's XML file within the appropriate attribute, as shown in the following example.

```
<Attribute
  Name="QuantityTotal"
  ColumnName="QUANTITY_TOTAL"
  ...
  <TransientExpression
    Name="ExpressionScript"
    trustMode="untrusted"
    CodeSourceName="ItemEORow"/>
  <Dependencies>
    <Item
      Value="Price"/>
    <Item
      Value="QuantityShipped"/>
  </Dependencies>
</Attribute>
```

How to Add Java Code in the Entity Class to Perform Calculation

A transient attribute is a placeholder for a data value. If you change the **Updatable** property of the transient attribute to **While New** or **Always**, then the end user can enter a value for the attribute. If you want the transient attribute to display a calculated value, then you'll typically leave the **Updatable** property set to **Never** and write custom Java code that calculates the value.

After adding a transient attribute to the entity object, to make it a *calculated* attribute you need to:

- Enable a custom entity object class on the Java page of the overview editor, choosing to generate accessor methods
- Write Java code inside the accessor method for the transient attribute to return the calculated value
- Specify each dependent attribute for the transient attribute on the **Dependencies** tab of the Attributes page

For example, after generating the view row class, the Java code to return the transient attribute's calculated value would reside in the getter method for the attribute (such as `FullName`), as shown in the following example.

```
// Getter method for FullName calculated attribute in UserImpl.java
public String getFullName() {
  // Commented out original line since we'll always calculate the value
  // return (String)getAttributeInternal(FULLNAME);
      return getFirstName()+" "+getLastName();
}
```

To ensure that the transient attribute is reevaluated whenever the attributes to be concatenated (such as `LastName` and `FirstName`) might be changed by the end user, specify the dependent attributes for the transient attribute. Even though you perform the computation in the code, the dependencies are needed to fire the appropriate events that cause the UI to refresh when any of the dependent attribute values change. To specify dependent attributes, on the Dependencies tab of the Attributes page, locate the attributes in the **Available** list and shuttle each to the **Selected** list.

Creating Business Events

You can define and publish business events from the ADF Model layer and synchronize them with external systems by way of Oracle Mediator.

Business events raised from the model layer are useful for launching business processes and triggering external systems synchronization.

You declaratively define business events at the entity level. You may also specify conditions under which those events should be raised. Business events that meet the specified criteria are raised upon successful commit of the changed data. A business event is raised to the Mediator on a successful create, update, or delete of an entity object.

To implement a business event, you perform the following tasks:

1. Create an event definition, as described in How to Create a Business Event.
2. Map the event definition to an event point and publish the event definition, as described in How to Define a Publication Point for a Business Event.

Introducing Event Definitions

An event definition describes an event that will be published and raised with an event system Mediator. An event definition is stored in an entity object's XML file with the elements shown in Table 4-2.

Table 4-2 Event Definition Elements for Entity Objects

Element	Description
Event Name	Name of the event, for example, `OrderUpdated`
Payload	A list of attributes sent to the subscriber. Attributes marked as optional appear on payload only if changed.

Introducing Event Points

An event point is a place from which an event can be raised. On a successful commit, one of the event points shown in Table 4-3 can be raised to the Mediator for each entity in a transaction.

Table 4-3 Example Event Points Raised to the Mediator

DML Type	Event Name	Event Description
CREATE	*Entity*Created	A new *Entity* has been created.
UPDATE	*Entity*Updated	An existing *Entity* has been updated.
DELETE	*Entity*Deleted	An existing *Entity* has been deleted.

Note that no events are raised by default; all events are custom. When you create the event, you can specify the name and DML operation appropriately.

For each event point, you must specify which event definitions should be raised on a particular event point. In other words, you must declaratively map each event definition to an event point.

What You May Need to Know About Event Points

Event delivery occurs outside the current database transaction, and is asynchronous. Therefore, the following are not supported:

- **Transactional event delivery,** where event delivery is part of the transaction, is not supported by the framework.
- **Synchronous events**, where the publisher waits for further processing until the subscriber has confirmed event reception, is not supported by the framework.

How to Create a Business Event

To create a business event, use the Business Events page of the overview editor.

Before you begin:

It may be helpful to have an understanding of how business events work. For more information, see Creating Business Events.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create a business event:

1. In the Applications window, double-click the entity object for which you want to define a business event.
2. In the overview editor, click the **Business Events** navigation tab.
3. On the Business Events page, expand the **Event Definitions** section and click the **New** icon.
4. In the Create Business Event Definition dialog, provide a name that describes this event, such as `EmployeeContactInfoChanged`.
5. In the payload table, click **New** and **Delete** to select the appropriate attributes for this event.

   Alternatively, you can double-click the cell and pick the attributes you want.

   > **Note:**
   >
   > Only attributes of supported types are displayed in the Entity Attribute column. While `ClobDomain` attributes are supported, very large clob data can impact performance.

6. In the **Value Sent** field, choose whether the value should **Always** be sent, or **Only if changed**.

   The **Only if changed** option provides the best performance because the attribute will be considered optional for the payload. If you leave the default **Always**, the payload will require the attribute whether or not the value has changed. For more details about payload efficiency, see What You May Need to Know About Payload.
7. Use the arrow buttons to rearrange the order of attributes.

   The order that the attributes appear in defines their order in the generated XSD. Since you'll be using the XSD to build your Fabric mediator and BPEL process, you might want the most frequently accessed attributes at the top.
8. Click **OK**.

Repeat the procedure for each business event that you want to define. To publish an event, see How to Define a Publication Point for a Business Event.

What Happens When You Create a Business Event

When you create a business event, the entity object's XML file is updated with the event definition, as shown in the following example.

```
<EventDef
    Name="CustBusEvent1">
    <Payload>
      <PayloadItem
        AttrName="Id"/>
      <PayloadItem
        AttrName="PaymentOptionId"/>
      <PayloadItem
        AttrName="PaymentTypeEO.Id"
        SendOnlyIfChanged="true"/>
    </Payload>
  </EventDef>
```

JDeveloper also generates an associated XSD file for the event schema and an event definition (EDL) file for the entity object. The EDL file provides an event definition, as shown in the following example.

```
<definitions
    targetNamespace="http://oracle/summit/model/entities/events/edl/OrdEO"
    xmlns:ns0="http://oracle/summit/model/entities/events/schema/OrdEO"
    xmlns="http://schemas.oracle.com/events/edl">
  <schema-import
     namespace="http://oracle/summit/model/entities/events/schema/OrdEO"
     location="OrdEO.xsd"/>
  <event-definition name="CustBusEvent1">
     <content element="ns0:CustBusEvent1Info"/>
  </event-definition>
</definitions>
```

The XSD file allows specification of required attributes and optional attributes. Required attributes correspond to **Value Sent - Always** in the Create Business Event Definition dialog, whereas optional attributes are those for which you changed **Value Sent** to **Only if changed**.

The following example shows an XSD event schema for a business event.

```
<?xml version = '1.0' encoding = 'UTF-8'?>
<xs:schema targetNamespace="http://oracle/summit/model/entities/events/schema/
OrdEO" xmlns="http://oracle/summit/model/entities/events/schema/OrdEO"
                                           elementFormDefault="qualified"
attributeFormDefault="unqualified" xmlns:xs="http://www.w3.org/2001/XMLSchema">
   <xs:element name="CustBusEvent1Info">
      <xs:complexType>
         <xs:sequence>
            <xs:element name="Id" type="DecimalValuePair" minOccurs="1"/>
            <xs:element name="PaymentOptionId" type="IntValuePair"
minOccurs="1"/>
         </xs:sequence>
      </xs:complexType>
   </xs:element>
   <xs:complexType name="ValuePair" abstract="true"/>
   <xs:complexType name="IntValuePair">
      <xs:complexContent>
         <xs:extension base="ValuePair">
            <xs:sequence>
               <xs:element name="newValue" minOccurs="0">
                  <xs:complexType>
                     <xs:complexContent>
                        <xs:extension base="xs:anyType">
                           <xs:attribute name="value" type="xs:int"/>
                        </xs:extension>
                     </xs:complexContent>
                  </xs:complexType>
               </xs:element>
               <xs:element name="oldValue" minOccurs="0">
                  <xs:complexType>
                     <xs:complexContent>
                        <xs:extension base="xs:anyType">
                           <xs:attribute name="value" type="xs:int"/>
                        </xs:extension>
                     </xs:complexContent>
                  </xs:complexType>
               </xs:element>
            </xs:sequence>
         </xs:extension>
      </xs:complexContent>
   </xs:complexType>
   <xs:complexType name="DecimalValuePair">
      <xs:complexContent>
         <xs:extension base="ValuePair">
            <xs:sequence>
               <xs:element name="newValue" minOccurs="0">
                  <xs:complexType>
                     <xs:complexContent>
                        <xs:extension base="xs:anyType">
                           <xs:attribute name="value" type="xs:decimal"/>
                        </xs:extension>
                     </xs:complexContent>
                  </xs:complexType>
               </xs:element>
               <xs:element name="oldValue" minOccurs="0">
                  <xs:complexType>
                     <xs:complexContent>
                        <xs:extension base="xs:anyType">
                           <xs:attribute name="value" type="xs:decimal"/>
                        </xs:extension>
                     </xs:complexContent>
                  </xs:complexType>
               </xs:element>
            </xs:sequence>
         </xs:extension>
      </xs:complexContent>
   </xs:complexType>
</xs:schema>
```

What You May Need to Know About Payload

The attributes of the associated entity object constitute the payload of a business event. The payload attributes for a business event are defined by the creator of the event. It isn't automatically optimized. When the event is defined, an attribute can be marked as sent **Always** or **Only if changed**. For events fired during creation, only new values are sent. For events fired during an update or delete, the new and old values are sent for only the attributes that should be sent, based on the **Value Sent** setting. For best performance, you should include only the primary key attribute for delete events.

To support composition scenarios (such as a purchase order with line items), a child entity can raise events defined on the parent entity, and events defined on the child entity can include attributes from the parent entity. When a child entity raises an event on a parent entity, only a single event is raised for a particular top-level entity per transaction, regardless of how many times the child entity raises it.

In the case of entity subtypes (for example, a `Staff` entity object is a subtype of the `Persons` entity), ADF Business Components does not support the overriding of business events. Because the subscriber to a business event listens to the event using the event name, overriding of events could cause the event subscriber to receive payload data unintended for that subscriber. Therefore, this capability is not supported.

When defining business events, remember that while `ClobDomain` attributes are supported, very large clob data can have performance implications.

How to Define a Publication Point for a Business Event

To define a publication point for a business event, use the Business Events page of the entity object overview editor.

Before you begin:

It may be helpful to have an understanding of how business events are used in the application. For more information, see Creating Business Events.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

You need to have already created the event definition, as described in How to Create a Business Event, before you can publish it.

To define a publication point for a business event:

1. In the Applications window, double-click the entity object that contains the business event you want to publish.
2. In the overview editor, click the **Business Events** navigation tab.
3. On the Business Events page, expand the **Event Publication** section and click the **Edit event publications** icon.
4. In the Edit Event Publications dialog, click **New** to create a new event.
5. Click the new cell in **Event** column, and select the appropriate event.
6. Click the corresponding cell in **Event Point** column, and select the appropriate event point action.
7. You can optionally define conditions for raising the event using the **Raise Conditions** table.
8. Click **OK**.

How to Subscribe to Business Events

After you have created a business event, you can subscribe and respond to the event.

> **Note:**
>
> To subscribe to business events or create and deploy SOA composite applications and projects in JDeveloper, you must install the Oracle SOA Suite extension. For instructions on installing this extension for JDeveloper, see Enabling Oracle JDeveloper Extensions in *Installing Oracle JDeveloper*. For more information about the capabilities of Oracle SOA Suite, see Introduction to Building Applications with Oracle SOA Suite in *Developing SOA Applications with Oracle SOA Suite*.

Before you begin:

It may be helpful to have an understanding of business events. For more information, see Creating Business Events.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

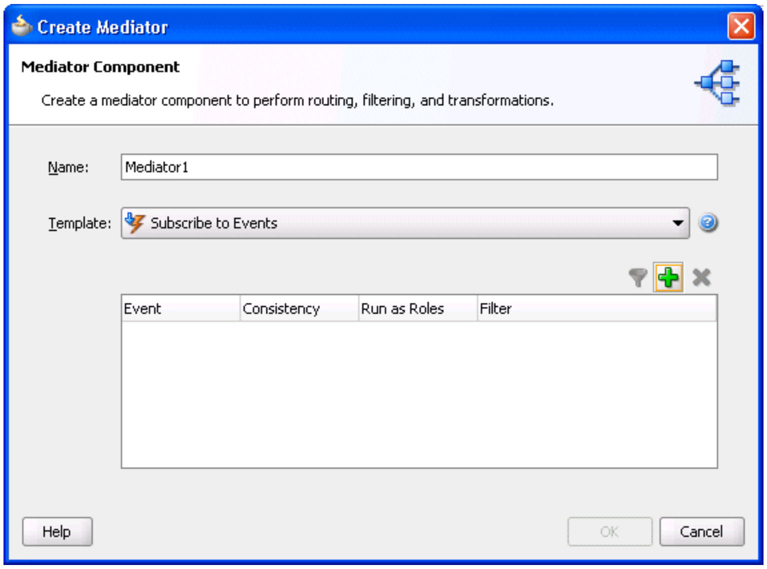
You will also need to complete the following task:

- Publish the business event, as described in How to Define a Publication Point for a Business Event.

To subscribe to a business event:

1. Using the file system, copy the XSD and event definition files for the business event into your SCA project's source path.
2. In JDeveloper, open the SCA project that will subscribe to the business event.
3. In the Applications window, right-click the SCA project that will subscribe to the business event, and choose **New > From Gallery**.
4. In the New Gallery, expand **SOA Tier**, select **Service Components** and then **Mediator**, and click **OK**.
5. In the Create Mediator dialog, select the **Subscribe to Events** template, as shown in Figure 4-15.

Figure 4-15 Create Mediator Dialog, Subscribe to Events



Create Mediator

Mediator Component

Create a mediator component to perform routing, filtering, and transformations.

Name: Mediator1

Template: Subscribe to Events

Event	Consistency	Run as Roles	Filter

6. Click the **Add** icon to add an event.
7. In the Event Chooser dialog, click the **Browse** icon to navigate to and select the event's definition file, and then click **OK**.
8. In the Create Mediator dialog, you can optionally change the **Consistency** option and specify a **Filter** for the event.
9. Click **OK** to generate the mediator.

   The resulting mediator (`.mplan` file) is displayed in the overview editor.

10. In the overview editor, click the **Add** icon in the **Routing Rules** section to add a rule for how to respond to the event.

Generating Custom Java Classes for an Entity Object

Enable custom Java generation for an ADF entity object to implement custom business logic that cannot be achieved using its declarative runtime functionality.

As described in this chapter, all of the database interaction and a large amount of declarative runtime functionality of an entity object can be achieved without using custom Java code. When you need to go beyond the declarative features to implement custom business logic for your entities, you'll need to enable custom Java generation for the entities that require custom code. Most Commonly Used ADF Business Components Methods, provides a quick reference to the most common code that you will typically write, use, and override in your custom entity object and entity definition classes.

> **Best Practice:**
>
> Oracle recommends that developers getting started with ADF Business Components consider overriding the base framework classes to enable all generated custom Java classes to pick up customized behavior. This practice is preferred over creating custom classes for individual entity objects and view objects. You use the **ADF Business Components > Base Classes** page of the Project Properties dialog to specify the framework classes to override when you generate custom component. See Extending Business Components Functionality.

How to Generate Custom Classes

To enable the generation of custom Java classes for an entity object, use the Java page of the overview editor.

Before you begin:

It may be helpful to have an understanding of custom Java classes. For more information, see Generating Custom Java Classes for an Entity Object.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To generate a custom Java class for an entity object:

1. In the Applications window, double-click the entity object for which you want to generate a custom Java class.
2. In the overview editor, click the **Java** navigation tab, and then click the **Edit Java options** icon.
3. In the Select Java Options dialog, select the types of Java classes you want to generate.
   - Entity Object Class — the most frequently customized, it represents each row in the underlying database table.

- Entity Collection Class — rarely customized.
- Entity Definition Class — less frequently customized, it represents the related class that manages entity rows and defines their structure.

4. Click **OK**.

What Happens When You Generate Custom Classes

When you select one or more custom Java classes to generate, JDeveloper creates the Java file(s) you've indicated. For example, assuming an entity object named `summit.model.entities.OrdEO`, the default names for its custom Java files will be `OrdEOImpl.java` for the entity object class and `OrdEODefImpl.java` for the entity definition class. Both files are created in the same `./summit/model/entities` directory as the component's XML document file.

The Java generation options for the entity object continue to be reflected on subsequent visits to the Java page of the overview editor. Just as with the XML definition file, JDeveloper keeps the generated code in your custom Java classes up to date with any changes you make in the editor. If later you decide you didn't require a custom Java file for any reason, disabling the relevant options on the Java page causes the custom Java files to be removed.

What Happens When You Generate Entity Attribute Accessors

When you enable the generation of a custom entity object class, if you also enable the **Accessors** option, then JDeveloper generates getter and setter methods for each attribute in the entity object.

> **Caution:**
>
> Because the resulting hard-coded method names impose limitations on optimizations or customizations for entity and view rows, you should generate an accessor method only if there is a business need for it (such as, having to expose the view row as a Java interface to a client).

For example, an `OrdEO` entity object that has the corresponding custom `OrdEOImpl.java` class might have methods like those shown in the following example.

```
public DBSequence getId() { ... }
public void setId(DBSequence value) { ... }

public Date getDateOrdered() { ... }
public void setDateOrdered(Date value) { ... }

public Integer getPaymentTypeId() { ... }
public void setPaymentTypeId(Integer value) { ... }

public Number getCustomerId() { ... }
public void setCustomerId(Number value) { ... }

public String getOrderFilled() { ... }
public void setOrderFilled(String value) { ... }
```

These methods allow you to work with the row data with compile-time checking of the correct data type usage. That is, instead of writing a line like this to get the value of the `CustomerId` attribute:

```
Number customerId = (Number)order.getAttribute("CustomerId");
```

you can write the code like:

```
Number customerId = order.getCustomerId();
```

You can see that with the latter approach, the Java compiler would catch a typographical error had you accidentally typed `CustomerCode` instead of `CustomerId`:

```
// spelling name wrong gives compile error
Number customerId = order.getCustomerCode();
```

Without the generated entity object accessor methods, an incorrect line of code like the following cannot be caught by the compiler:

```
// Both attribute name and type cast are wrong, but compiler cannot catch it
String customerId = (String)order.getAttribute("CustomerCode");
```

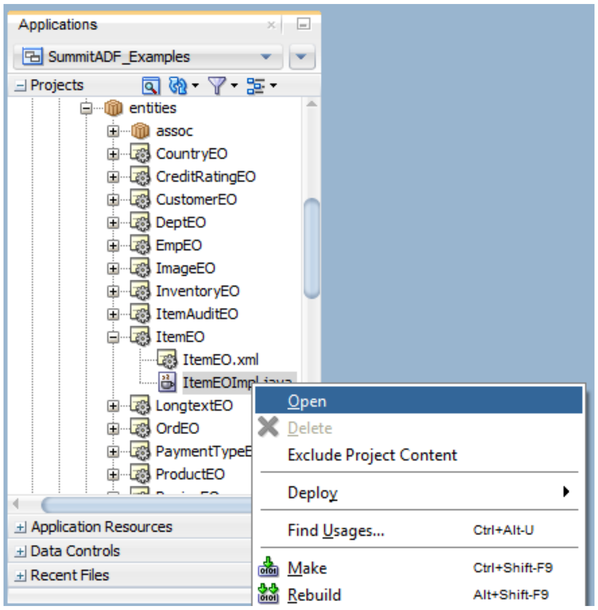
It contains both an incorrectly spelled attribute name, as well as an incorrectly typed cast of the `getAttribute()` return value. When you use the generic APIs on the `Row` interface, which the base `EntityImpl` class implements, errors of this kind raise exceptions at runtime instead of being caught at compile time.

How to Navigate to Custom Java Files

As shown in Figure 4-16, when you've enabled generation of custom Java classes, they also appear as child nodes under the **Application Sources** node for the entity object. As with all ADF components, when you select an entity object in the Applications window, the Structure window provides a structural view of the entity. When you need to see or work with the source code for a custom Java file, there are multiple ways to open the file in the source editor:

- You can right-click the Java file, and choose **Open**, as shown in Figure 4-16.
- You can right-click an item in a node in the Structure window, and choose **Go To Source**.
- You can click the link on the Java page of the overview editor.

Figure 4-16 Seeing and Navigating to Custom Java Classes for an Entity Object



What You May Need to Know About Custom Java Classes

The custom Java classes generated by JDeveloper extend the base classes for your entity object, and allow you the flexibility to implement custom code while maintaining the integrity of the generated code. The following sections provide additional information about custom Java classes.

Framework Base Classes for an Entity Object

When you use an XML-only entity object, at runtime its functionality is provided by the default ADF Business Components implementation classes. Each custom Java class that is generated extends the appropriate ADF Business Components base class so that your code inherits the default behavior and you can easily add to or customize it. An entity object class will extend `EntityImpl`, while the entity definition class will extend `EntityDefImpl` and the entity collection class will extend `EntityCache`. These base classes are in the `oracle.jbo.server` package.

Safely Adding Code to the Custom Component File

Some developers are hesitant to add their own code to generated Java source files. Each custom Java source code file that JDeveloper creates and maintains for you includes the following comment at the top of the file to clarify that it is safe for you to add your own custom code to this file.

```
// ---------------------------------------------------------------------
// ---    File generated by ADF Business Components Design Time.
// ---    Custom code may be added to this class.
// ---    Warning: Do not modify method signatures of generated methods.
// ---------------------------------------------------------------------
```

JDeveloper does not blindly regenerate the file when you click **OK** or **Apply** in an edit dialog. Instead, it performs a smart update to the methods that it needs to maintain, leaving your own custom code intact.

Configuring Default Java Generation Preferences

You can generate custom Java classes for your view objects when you need to customize their runtime behavior or when you simply prefer to have strongly typed access to bind variables or view row attributes.

To configure the default settings for ADF Business Components custom Java generation, you can choose **Tools >Preferences** from the main menu and open the Business Components page to set your preferences to be used for business components created in the future. Developers getting started with ADF Business Components should set their preference to generate no custom Java classes (the default setting). As you run into a specific need for custom Java code, you can enable just the bit of custom Java you need for that one component. Over time, you'll discover which set of defaults works best for you.

Attribute Indexes and InvokeAccessor Generated Code

The entity object is designed to function based on XML only or as an XML document combined with a custom Java class. To support this design choice, attribute values are not stored in private member fields of an entity's class (a file that is not present in the XML-only situation). By default, reflection is used at runtime to assign attribute enumerations and invoke attribute accessors.

When reflection is turned off for the project, attributes are assigned a name and a numerical index in the entity's XML document based on the zero-based, sequential order of the `<Attribute>` and association-related `<AccessorAttribute>` tags in that file. At runtime, attribute values in an entity row are stored in a sparse array structure managed by the base `EntityImpl` class, indexed by the attribute's numerical position in the entity's attribute list.

> **Note:**
>
> To disable reflection, deselect **Use reflection to invoke attribute accessors** on the **Options** page (under **ADF Business Components**) in the Project Properties dialog.

For the most part, this private implementation detail is unimportant, since as a developer using entity objects, you are shielded from having to understand this. However, when you enable a custom Java class for your entity object, this implementation detail relates to some of the generated code that JDeveloper maintains in your entity object class. It is sensible to understand what that code is used for. For example, in the custom Java class for an `Orders` entity object, each attribute or accessor attribute has a corresponding generated integer enum. JDeveloper ensures that the values of these enums correctly reflect the ordering of the attributes in the XML document.

You'll also notice that the automatically maintained, strongly typed getter and setter methods in the entity object class use these attribute enums, as shown in the following example.

```
// In oracle.summit.model.appmodule.OrdersImpl class
    /**
     * Gets the attribute value for DateOrdered, using the alias name DateOrdered.
     * @return the value of DateOrdered
     */
  public Date getDateOrdered() {
    return (Date)getAttributeInternal(DATEORDERED);
  }
    /**
     * Sets <code>value</code> as the attribute value for DateOrdered.
     * @param value to set the DateOrdered
     */
  public void setDateOrdered(Date value) {
    setAttributeInternal(DATEORDERED, value);
  }
```

Another aspect of the maintained code related to entity attribute enums is the `getAttrInvokeAccessor()` and `setAttrInvokeAccessor()` methods. These methods optimize the performance of attribute access by numerical index, which is how generic code in the `EntityImpl` base class typically accesses attribute values when performing generic processing. An example of the `getAttrInvokeAccessor()` method is shown in the following example. The companion `setAttrInvokeAccessor()` method looks similar.

```
// In oracle.summit.model.appmodule.OrdersImpl class
  /**
   * getAttrInvokeAccessor: generated method. Do not modify.
   * @param index the index identifying the attribute
   * @param attrDef the attribute
   * @return the attribute value
   * @throws Exception
   */

protected Object getAttrInvokeAccessor(int index, AttributeDefImpl attrDef)
      throws Exception {
  if ((index >= AttributesEnum.firstIndex()) && (index < AttributesEnum.count())) {
    return AttributesEnum.staticValues()[index - AttributesEnum.firstIndex()].get(this);
  }
  return super.getAttrInvokeAccessor(index, attrDef);
}
```

The rules of thumb to remember about this generated attribute index-related code are the following.

The Do's

- Add custom code if needed inside the strongly typed attribute getter and setter methods.
- Use the overview editor to change the order or type of entity object attributes.

  JDeveloper changes the Java signature of getter and setter methods, as well as the related XML document for you.

The Don'ts

- Don't modify the `getAttrInvokeAccessor()` and `setAttrInvokeAccessor()` methods.
- Don't change the values of the attribute index numbers manually.

Note:

If you need to manually edit the generated attribute enums because of source control merge conflicts or other reasons, you must ensure that the zero-based ordering reflects the sequential ordering of the `<Attribute>` and `<AccessorAttribute>` tags in the corresponding entity object XML document.

Programmatic Example for Comparison Using Custom Entity Class References

To better evaluate the difference between using strongly typed entity references to custom entity classes and working with the generic entity references, consider the following example. The following example shows a version of strongly typed entity references in a custom application module class (`AppModuleImpl.java`). Some important differences to notice are:

- Attribute access is performed using strongly typed attribute accessors.
- Association accessor attributes return the strongly typed entity class on the other side of the association.
- Using the `getDefinitionObject()` method in your custom entity class allows you to avoid working with fully qualified entity definition names as strings.
- The `createPrimaryKey()` method in your custom entity class simplifies creating the `Key` object for an entity.

```
package oracle.summit.model.appmodule.service;

import oracle.jbo.ApplicationModule;
import oracle.jbo.JboException;
import oracle.jbo.Key;
import oracle.jbo.Row;
import oracle.jbo.RowSetIterator;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;
import oracle.jbo.domain.DBSequence;
import oracle.jbo.domain.Number;
import oracle.jbo.server.EntityDefImpl;
import oracle.jbo.server.EntityImpl;
import oracle.jbo.server.ViewLinkImpl;

import oracle.summit.base.SummitApplicationModuleImpl;
import oracle.summit.base.SummitViewObjectImpl;
import oracle.summit.model.appmodule.CustomerImpl;
import oracle.summit.model.appmodule.OrdersImpl;
import oracle.summit.model.appmodule.service.common.AppModule;

// ---------------------------------------------------------------------
// ---    File generated by Oracle ADF Business Components Design Time.
// ---    Custom code may be added to this class.
// ---    Warning: Do not modify method signatures of generated methods.
// ---------------------------------------------------------------------
public class AppModuleImpl extends SummitApplicationModuleImpl
       implements AppModule {
```

```
  /* This is the default constructor (do not remove). */
  public AppModuleImpl() {
  }

  private OrdersImpl retrieveOrderById(long orderId) {
    EntityDefImpl orderDef = OrdersImpl.getDefinitionObject();
    Key orderKey = OrdersImpl.createPrimaryKey(new DBSequence(orderId));
    return (OrdersImpl)orderDef.findByPrimaryKey(getDBTransaction(),orderKey);
  }

  public String findOrderAndCustomer(long orderId) {
    OrdersImpl order = retrieveOrderById(orderId);
    if (order != null) {
      CustomerImpl cust = order.getCustomer();
      if (cust != null) {
        return "Customer: " + cust.getName() + ", Location: " + cust.getCity();
        }
      else {
        return "Unassigned";
      }
    }
    else {
      return null;
    }
  }

    /* Find an Order by Id */
  public String findOrderTotal(long orderId) {
    OrdersImpl order = retrieveOrderById(orderId);
    if (order != null) {
      return order.getTotal().toString();
    }
    return null;
  }

    /* Update the status of an existing order */
  public void updateOrderStatus(long orderId, String newStatus) {
    OrdersImpl order = retrieveOrderById(orderId);
    if (order != null) {
      order.setOrderFilled(newStatus);
      try {
        getDBTransaction().commit();
      }
      catch (JboException ex) {
        getDBTransaction().rollback();
        throw ex;
      }
    }
  }

    /* Create a new Customer and Return the new id */
  public long createCustomer(String name, String city, Integer countryId) {
    EntityDefImpl customerDef = CustomerImpl.getDefinitionObject();
    CustomerImpl newCustomer =
(CustomerImpl)customerDef.createInstance2(getDBTransaction(),null);
    newCustomer.setName(name);
    newCustomer.setCity(city);
    newCustomer.setCountryId(countryId);
    try {
      getDBTransaction().commit();
    }
  catch (JboException ex) {
    getDBTransaction().rollback();
    throw ex;
  }
  DBSequence newIdAssigned = newCustomer.getId();
  return newIdAssigned.getSequenceNumber().longValue();
}

  /* Custom method in an application module implementation class */
public void doSomeCustomProcessing() {
  ViewObject vo = getCustomerView1();
  // create secondary row set iterator with system-assigned name
  RowSetIterator iter = vo.createRowSetIterator(null);
  while (iter.hasNext()) {
    Row r = iter.next();
    // Do something with the current row.
    Integer custId = (Integer)r.getAttribute("Id");
    String name  = (String)r.getAttribute("Name");
    System.out.println(custId + " " + name);
  }
  // close secondary row set iterator
  iter.closeRowSetIterator();
}

  /* Container's getter for CustomerView1.
   * @return CustomerView1 */
public SummitViewObjectImpl getCustomerView1() {
  return (SummitViewObjectImpl) findViewObject("CustomerView1");
}

  /* Container's getter for ItemView1.
   * @return ItemView1 */
public SummitViewObjectImpl getItemView1() {
  return (SummitViewObjectImpl) findViewObject("ItemView1");
}

  /* Container's getter for OrderView1.
   * @return OrderView1 */
public SummitViewObjectImpl getOrderView1() {
  return (SummitViewObjectImpl) findViewObject("OrderView1");
}

  /* Container's getter for ItemView2.
   * @return ItemView2 */
public SummitViewObjectImpl getItemView2() {
  return (SummitViewObjectImpl) findViewObject("ItemView2");
}

  /* Container's getter for OrderView2.
   * @return OrderView2 */
public SummitViewObjectImpl getOrderView2() {
  return (SummitViewObjectImpl) findViewObject("OrderView2");
}

  /*Container's getter for SItemOrdIdFkLink1.
   * @return SItemOrdIdFkLink1 */
public ViewLinkImpl getSItemOrdIdFkLink1() {
  return (ViewLinkImpl) findViewLink("SItemOrdIdFkLink1");
}

  /* Container's getter for SOrdCustomerIdFkLink1.
```

```
     * @return SOrdCustomerIdFkLink1 */
  public ViewLinkImpl getSOrdCustomerIdFkLink1() {
    return (ViewLinkImpl) findViewLink("SOrdCustomerIdFkLink1");
  }
}
```

Working Programmatically with Entity Objects and Associations

JDeveloper allows you to access an ADF application module and work directly in the ADF data model using an external client program.

You may not always need or want UI-based or programmatic clients to work directly with entity objects. Sometimes, you may just want to use an external client program to access an application module and work directly with the view objects in its data model. Defining SQL Queries Using View Objects describes how to easily combine the flexible SQL-querying of view objects with the business logic enforcement and automatic database interaction of entity objects to build powerful applications. The combination enables a fully updatable **application module data model**, designed to meet the needs of the current end-user tasks at hand, that shares the centralized business logic in your reusable domain business object layer.

However, it is important first to understand how view objects and entity objects can be used on their own before learning to harness their combined power. By learning about these objects in greater detail, you will have a better understanding of when you should use them alone and when to combine them in your own applications.

Since clients don't work *directly* with entity objects, any code you write that works programmatically with entity objects will typically be custom code in a custom application module class or in the custom class of another entity object.

How to Find an Entity Object by Primary Key

To access an entity row, you use a related object called the **entity definition**. At runtime, each entity object has a corresponding entity definition object that describes the structure of the entity and manages the instances of the entity object it describes. After creating an application module and enabling a custom Java class for it, imagine you wanted to write a method to return a specific order. It might look like the `retrieveOrderById()` method shown in the sample code below.

Before you begin:

It may be helpful to have an understanding of when to use a programmatic approach for working with entity objects and associations. For more information, see Working Programmatically with Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To find an entity object by primary key:

1. Find the entity definition.

   You obtain the entity definition for an entity object (for example, `Orders`) by passing its fully qualified name to the static `getDefinitionObject()` method imported from the EntityDefImpl class. The EntityDefImpl class in the oracle.jbo.server package implements the entity definition for each entity object.

2. Construct a key.

   You build a Key object containing the primary key attribute that you want to look up. For example, for the Orders entity object you create a key containing the single orderId value passed into the method as an argument.

3. Find the entity object using the key.

   You use the entity definition's findByPrimaryKey() method to find the entity object by key, passing in the current transaction object, which you can obtain from the application module using its getDBTransaction() method. The concrete class that represents an entity object row is the oracle.jbo.server.EntityImpl class.

4. Return the object or some of its data to the caller.

The following example code shows a retrieveOrderById() method developed using this basic procedure.

```
/* Helper method to return an Order by Id  */
private OrdersImpl retrieveOrderById(long orderId) {
  EntityDefImpl orderDef = OrdersImpl.getDefinitionObject();
  Key orderKey = OrdersImpl.createPrimaryKey(new DBSequence(orderId));
  return (OrdersImpl)orderDef.findByPrimaryKey(getDBTransaction(),orderKey);
}
```

> **Note:**
>
> The oracle.jbo.Key object constructor can also take an Object array to support creating multi-attribute keys, in addition to the more typical single-attribute value keys.

How to Access an Associated Entity Using the Accessor Attribute

You can create a method to access an associated entity based on an accessor attribute that requires no SQL code. For example, the method findOrderAndCustomer() might find an order, then access the associated Customer entity object representing the customer assigned to the order. For an explanation of how associations enable easy access from one entity object to another, see Creating and Configuring Associations.

To prevent a conflict with an existing method in the application module that finds the same associated entity using the same accessor attribute, you can refactor this functionality into a helper method that you can then reuse anywhere in the application module it is required. For example, you might create a retrieveOrderById() method to refactor the functionality that finds an order, as the shown in the sample code below.

Before you begin:

It may be helpful to have an understanding of when to use a programmatic approach for working with entity objects and associations. For more information, see Working Programmatically with Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To access an associated entity object using the accessor attribute:

1. Find the associated entity by the accessor attribute.

   For example, the `findOrderAndCustomer()` method uses the `retrieveOrderById()` helper method to retrieve the `Orders` entity object by ID.

2. Access the associated entity using the accessor attribute.

   Using the attribute getter method, you can pass in the name of an association accessor and get back the entity object on the other side of the relationship. (Note that How to Change Entity Association Accessor Names, explains that renaming the association accessor allows it to have a more intuitive name.)

3. Return some of its data to the caller.

   For example, the `findOrderAndCustomer()` method uses the getter methods on the returned `Customer` entity to return the assigned customer's name and location.

Notice that you did not need to write any SQL to access the related `Customer` entity. The relationship information captured in the ADF association between the `Orders` and `Customer` entity objects is enough to allow the common task of data navigation to be automated.

The following example shows the code for `findOrderCustomer()` that uses the helper method.

```
/*  Access an associated Customer entity from the Order entity   */
public String findOrderAndCustomer(long orderId) {
  OrdersImpl order = retrieveOrderById(orderId);
  if (order != null) {
    CustomerImpl cust = order.getCustomer();
    if (cust != null) {
      return "Customer: " + cust.getName() + ", Location: " + cust.getCity();
    }
    else {
      return "Unassigned";
    }
  }
  else {
    return null;
  }
}
```

How to Update or Remove an Existing Entity Row

Once you've got an entity row in hand, it's simple to update it or remove it. For example, you could add a method like `updateOrderStatus()` shown in the sample code below to perform the task.

Before you begin:

It may be helpful to have an understanding of when to use a programmatic approach for working with entity objects and associations. For more information, see Working Programmatically with Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To update an entity row:

1. Find the order by ID.

   Using the `retrieveOrderById()` helper method, the `updateOrderStatus()` method retrieves the `Orders` entity object by Id.

2. Set one or more attributes to new values.

   Using the `EntityImpl` class' `setAttribute()` method, the `updateOrderStatus()` method updates the value of the `OrderFilled` attribute to the new value passed in.

3. Commit the transaction.

   You will then need to use the application module's `getDBTransaction()` method to access the current transaction object and calls its `commit()` method to commit the transaction.

   ```
   /* Update the status of an existing order */
   public void updateOrderStatus(long orderId, String newStatus) {
     OrdersImpl order = retrieveOrderById(orderId);
     if (order != null) {
       order.setOrderFilled(newStatus);
     }
   }
   ```

The code for *removing* an entity row would be the same, except that after finding the existing entity, you would use the following line to remove the entity before committing the transaction:

```
// Remove the entity instead
order.remove();
```

How to Create a New Entity Row

In addition to using the entity definition to find existing entity rows, you can also use it to create new ones. In the case of customer entities, you could write a `createCustomer()` method like the one shown in the following example to accept the name and description of a new customer, and return the new customer ID assigned to it. This example assumes that the `Id` attribute of the `Customer` entity object has been updated to have the `DBSequence` type (see How to Get Trigger-Assigned Primary Key Values from a Database Sequence). This setting ensures that the attribute value is refreshed to reflect the value of the trigger from the corresponding database table, assigned to it from the table's sequence in the application schema.

```
/* Create a new Customer and Return the new id */
public long createCustomer(String name, String city, Integer countryId) {
  EntityDefImpl customerDef = CustomerImpl.getDefinitionObject();
  CustomerImpl newCustomer =
(CustomerImpl)customerDef.createInstance2(getDBTransaction(),null);
    newCustomer.setName(name);
    newCustomer.setCity(city);
    newCustomer.setCountryId(countryId);
  try {
    getDBTransaction().commit();
  }
  catch (JboException ex) {
```

```
    getDBTransaction().rollback();
    throw ex;
  }
  DBSequence newIdAssigned = newCustomer.getId();
  return newIdAssigned.getSequenceNumber().longValue();
}
```

Before you begin:

It may be helpful to have an understanding of when to use a programmatic approach for working with entity objects and associations. For more information, see Working Programmatically with Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create an entity row:

1. Find the entity definition.

   Using the `getDefinitionObject()` method, the `createCustomer()` method finds the entity definition for the `Customer` entity.

2. Create a new instance.

   Using the `createInstance2()` method on the entity definition, the `createCustomer()` method creates a new instance of the entity object.

   > **Note:**
   >
   > The method name has a `2` at the end. The regular `createInstance()` method has `protected` access and is designed to be customized as described EntityImpl Class of Most Commonly Used ADF Business Components Methods. The second argument of type `AttributeList` is used to supply attribute values that *must* be supplied at create time; it is *not* used to initialize the values of all attributes found in the list. For example, when creating a new instance of a composed child entity row using this API, you must supply the value of a composing parent entity's foreign key attribute in the `AttributeList` object passed as the second argument. Failure to do so results in an `InvalidOwnerException`.

3. Set attribute values.

   Using the attribute setter methods on the entity object, the `createCustomer()` method assigns values for the `Name`, `City`, and other attributes in the new entity row.

4. Commit the transaction.

   Calling `commit()` on the current transaction object, the `createCustomer()` method commits the transaction.

5. Return the trigger-assigned customer ID to the caller.

   Using the attribute getter method to retrieve the value of the `Id` attribute as a `DBSequence`, and then calling `getSequenceNumber().longValue()`, the `createCustomer()` method returns the sequence number as a `long` value to the caller.

Assigning the Primary Key Value Using an Oracle Sequence

As an alternative to using a trigger-assigned value (as described in How to Get Trigger-Assigned Primary Key Values from a Database Sequence), you can assign the value to a primary key when creating a new row using an Oracle sequence. This metadata-driven approach allows you to centralize the code to retrieve the primary key into a single Java file that can be reused by multiple entity objects.

The following example shows a simple `CustomEntityImpl` framework extension class on which the entity objects are based. Its overridden `create()` method tests for the presence of a custom attribute-level metadata property named `SequenceName` and if detected, populates the attribute's default value from the next number in that sequence.

Before you begin:

It may be helpful to have an understanding of when to use a programmatic approach for working with entity objects and associations. For more information, see Working Programmatically with Entity Objects and Associations.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To assign the primary key value using an Oracle sequence:

1. Create the `CustomEntityImpl.java` file in your project, and insert the code shown in the sample below.
2. In the Applications window, double-click the entity you want to edit.
3. In the overview editor, click the **Attributes** navigation tab, and select the attribute you want to edit.
4. Click the **Details** tab and select **Number** from the **Type** dropdown list.
5. Click the **Custom Properties** tab, and click the **Add** icon.
6. Create a custom property with `SequenceName` for the name, and the name of the database sequence for the value.

   For example, for a `Dept` entity, you could define the custom property `SequenceName` on its `Deptno` attribute with the value `DEPT_TABLE_SEQ`.

```
package sample;

import oracle.jbo.AttributeDef;
import oracle.jbo.AttributeList;
import oracle.jbo.server.EntityImpl;
import oracle.jbo.server.SequenceImpl;

public class CustomEntityImpl extends EntityImpl {
    protected void create(AttributeList attributeList) {
        super.create(attributeList);
        for (AttributeDef def : getEntityDef().getAttributeDefs()) {
            String sequenceName = (String)def.getProperty("SequenceName");
            if (sequenceName != null) {
               SequenceImpl s = new 
SequenceImpl(sequenceName,getDBTransaction());
               setAttribute(def.getIndex(),s.getSequenceNumber());
```

```
                }
            }
        }
    }
```

How to Update a Deleted Flag Instead of Deleting Rows

For auditing purposes, once a row is added to a table, sometimes your requirements may demand that rows never be physically deleted from the table. Instead, when the end user deletes the row in the user interface, the value of a DELETED column should be updated from "N" to "Y" to mark it as deleted. You can use two method overrides to alter an entity object's default behavior to achieve this effect.

To accomplish this, you need to perform the following tasks:

- Update a deleted flag when a row is removed, as described in Updating a Deleted Flag When a Row Is Removed.
- Force the entity object to be updated instead of deleted, as described in Forcing an Update DML Operation Instead of a Delete.

Updating a Deleted Flag When a Row Is Removed

To update a deleted flag when a row is removed, enable a custom Java class for your entity object and override the remove() method to set the deleted flag before calling the super.remove() method. The following example shows what this would look like in the custom Java class of an entity object. It is important to set the attribute *before* calling super.remove() since an attempt to set the attribute of a deleted row will encounter the DeadEntityAccessException.

This example presumes that you've altered the table to have an additional DELETED column, and synchronized the entity object with the database to add the corresponding Deleted attribute.

The row will still be removed from the row set, but it will have the value of its Deleted flag modified to "Y" in the entity cache. The second part of implementing this behavior involves forcing the entity to perform an UPDATE instead of an DELETE when it is asked to perform its DML operation. You need to implement both parts for a complete solution.

```
// In your custom Java entity class
public void remove() {
  setDeleted("Y");
  super.remove();
}
```

Forcing an Update DML Operation Instead of a Delete

To force an entity object to be updated instead of deleted, override the doDML() method and write code that conditionally changes the operation flag. When the operation flag equals DML_DELETE, your code will change it to DML_UPDATE instead. The following example shows what this would look like in the custom Java class of an entity object.

This example presumes that you've altered the table to have an additional DELETED column, and synchronized the entity object with the database to add the corresponding Deleted attribute.

With this overridden doDML() method in place to complement the overridden remove() method described in Updating a Deleted Flag When a Row Is Removed, any attempt to remove an entity through any view object with a corresponding entity usage will update the DELETED column instead of physically deleting the row. Of course, in order to prevent "deleted" products from appearing in your view object query results, you will need to appropriately modify their WHERE clauses to include only products WHERE DELETED = 'N'.

```
// In your custom Java entity class
protected void doDML(int operation, TransactionEvent e) {
   if (operation == DML_DELETE) {
     operation = DML_UPDATE;
   }
   super.doDML(operation, e);
  }
```

How to Control Entity Posting Order to Prevent Constraint Violations

Due to database constraints, when you perform DML operations to save changes to a number of related entity objects in the same transaction, the order in which the operations are performed can be significant. If you try to insert a new row containing foreign key references *before* inserting the row being referenced, the database can complain with a constraint violation. You must understand what the default order for the processing of entity objects is during commit time and how to programmatically influence that order when necessary.

> **Note:**
>
> The example in this section refers to the oracle.summit.model.controlpostorder package in the SummitADF_Examples application workspace.

Default Post Processing Order

By default, when you commit the transaction the entity objects in the pending changes list are processed in chronological order, in other words, the order in which the entities were added to the list. This means that, for example, if you create a new employee (EmpEO entity object) and then a new department (DeptEO entity object) related to that product, the new EmpEO will be inserted first and the new DeptEO second.

Compositions and Default Post Processing Order

When two entity objects are related by a *composition*, the strict chronological ordering is modified automatically to ensure that composed parent and child entity rows are saved in an order that prevents violating any constraints. This means, for example, that a new parent entity row is inserted before any new composed children entity rows.

Overriding postChanges() to Control Post Order

If your related entities are associated but *not* composed, then you need to write a bit of code to ensure that the related entities get saved in the appropriate order.

Observing the Post Ordering Problem First Hand

Consider the `newEmployeeForNewDepartment()` custom method from the `AppModule` application module in the following example. It accepts a set of parameters and:

1. Creates a new employee.
2. Creates a new department.
3. Sets the department ID to which the employee pertains.
4. Commits the transaction.
5. Constructs a `Result` Java bean to hold new employee ID and department ID.
6. Returns the result.

> **Note:**
>
> The code makes the assumption that both `EmpEO.Id` and `DeptEO.Id` have been set to have `DBSequence` data type to populate their primary keys based on a sequence.

```
// In AppModuleImpl.java
public Result newEmployeeForNewDepartment(String deptName,
                                           Number regionId,
                                           String lastName,
                                           String firstName,
                                           Number salary)  {

   oracle.jbo.domain.Date today = new Date(Date.getCurrentDate());
   Number objectId = new Number(0);

   // 1. Create a new employee
   EmpEOImpl newEmp = createNewEmp();
   // 2. Create a new department
   DeptEOImpl newDept = createNewDept();
   newDept.setName(deptName);
   newDept.setRegionId(regionId);
   // 3. Set the department id to which the employee pertains
   newEmp.setDeptId(newDept.getId().getSequenceNumber());
   newEmp.setLastName(lastName);
   newEmp.setFirstName(firstName);
   newEmp.setUserid((firstName + "." + lastName).substring(8));
   newEmp.setSalary(salary);
   // 4. Commit the transaction
   getDBTransaction().commit();
   // 5. Construct a bean to hold new department id and employee id
   Result result = new Result();
   result.setEmpId(newEmp.getId().getSequenceNumber());
   result.setDeptId(newDept.getId().getSequenceNumber());
   // 6. Return the result
   return result;
}
private DeptEOImpl createNewDept(){
   EntityDefImpl deptDef = DeptEOImpl.getDefinitionObject();
   return (DeptEOImpl) deptDef.createInstance2(getDBTransaction(), null);
}
```

```
private EmpEOImpl createNewEmp(){
   EntityDefImpl empDef = EmpEOImpl.getDefinitionObject();
   return (EmpEOImpl) empDef.createInstance2(getDBTransaction(), null);
}
```

If you add this method to the application module's client interface and test it from a test client program, you get an error:

```
oracle.jbo.DMLConstraintException: JBO-26048:
Constraint "S_EMP_DEPT_ID_FK" is violated during post operation
"Insert" using SQL statement
"BEGIN INSERT INTO S_EMP(ID,LAST_NAME,FIRST_NAME,USERID,DEPT_ID,SALARY)
 VALUES (:1,:2,:3,:4,:5,:6) RETURNING ID INTO :7; END;".
: ORA-02291: integrity constraint (SUMMIT_ADF.S_EMP_DEPT_ID_FK)
violated - parent key not found
```

When the S_EMP row is inserted, the database complains that the value of its DEPT_ID foreign key doesn't correspond to any row in the S_DEPT table. This occurred because:

- The code created the employee before the department.
- The EmpEO and DeptEO entity objects are associated but not composed.
- The DML operations to save the new entity rows is done in chronological order, so the new EmpEO gets inserted before the new DeptEO.

Forcing the Department to Post Before the Employee

To remedy the problem of attempting to add an employee with a not-yet-valid department ID, you could reorder the lines of code in the example to create the DeptEO first, then the EmpEO. While this would address the immediate problem, it still leaves the chance that another application developer could create things in an incorrect order.

The better solution is to make the entity objects *themselves* handle the posting order so the posting will work correctly regardless of the order of creation. To do this, you need to override the postChanges() method in the entity that contains the foreign key attribute referencing the associated entity object and write code as shown in the following example. In this example, since it is the EmpEO that contains the foreign key to the DeptEO entity, you need to update the EmpEO to conditionally force a related, new DeptEO to post before the employee posts itself.

The code tests whether the entity being posted is in the STATUS_NEW or STATUS_MODIFIED state. If it is, it retrieves the related product using the getDeptEO() association accessor. If the related DeptEO also has a post-state of STATUS_NEW, then *first* it calls postChanges() on the related parent row before calling super.postChanges() to perform its own DML.

If you were to run this example, you would see that without changing the creation order in the newEmployeeForNewDepartment() method's code, entities now post in the correct order — first new DeptEO, then new EmpEO. Yet, there is still a problem. The constraint violation still appears, but now for a different reason.

If the primary key for the DeptEO entity object were user-assigned, then the code in the following example would be all that is required to address the constraint violation by correcting the post ordering. In this example, however, the DeptEO.Id is assigned from a database sequence, and not user-assigned. So when a new DeptEO entity row gets posted, its Id attribute is refreshed to reflect the database-assigned sequence value. The foreign key value in the EmpEO.DeptId attribute referencing the new supplier is "orphaned" by this refreshing of the supplier's ID value. When the product's row is saved, its S_DEPT_ID value still doesn't match a row in the S_DEPT table, and the constraint violation occurs again. The next two sections discuss the solution to address this "orphaning" problem.

```
// In EmpEOImpl.java
public void postChanges(TransactionEvent transactionEvent) {
   /* If current entity is new or modified */
   if (getPostState() == STATUS_NEW ||
      getPostState() == STATUS_MODIFIED) {
      /* Get the associated dept for the employee */
      DeptEOImpl dept = getDeptEO();
      /* If there is an associated dept */
      if (dept != null) {
         /* And if it's post-status is NEW */
         if (dept.getPostState() == STATUS_NEW) {
            /*
   * Post the department first, before posting this
   * entity by calling super below
   */
            dept.postChanges(transactionEvent);
         }
      }
   }
   super.postChanges(transactionEvent);
}
```

Note:

An alternative to the programmatic technique discussed here, which solves the problem at the Java EE application layer, is the use of deferrable constraints at the database layer. If you have control over your database schema, consider defining (or altering) your foreign key constraints to be DEFERRABLE INITIALLY DEFERRED. This database setting causes the database to defer checking the constraint until transaction commit time. When this is done, the application can perform DML operations in any order, provided that by COMMIT time all appropriate related rows have been saved and would alleviate the parent/child ordering. However, you would still need to write the code to cascade-update the foreign key values if the parent's primary key is assigned from a sequence, as described in Associations Based on DBSequence-Valued Primary Keys, and Refreshing References to DBSequence-Assigned Foreign Keys.

Associations Based on DBSequence-Valued Primary Keys

Recall from How to Get Trigger-Assigned Primary Key Values from a Database Sequence, that when an entity object's primary key attribute is of DBSequence type, during the transaction in which it is created, its numerical value is a unique, temporary negative number. If you create a number of associated entities in the same transaction, the relationships between them are based on this temporary negative key value. When the entity objects with DBSequence-value primary keys are posted, their primary key is refreshed to reflect the correct database-assigned sequence number, leaving the associated entities that are still holding onto the temporary negative foreign key value "orphaned."

For entity objects based on a *composition*, when the parent entity object's DBSequence-valued primary key is refreshed, the composed children entity rows automatically have their temporary negative foreign key value updated to reflect the owning parent's refreshed, database-assigned primary key. This means that for composed entities, the "orphaning" problem does not occur.

However, when entity objects are related by an association that is not a composition, you need to write a little code to insure that related entity rows referencing the temporary negative number get updated to have the refreshed, database-assigned primary key value. The next section outlines the code required.

Refreshing References to DBSequence-Assigned Foreign Keys

When an entity like DeptEO in this example has a DBSequence-valued primary key, and it is referenced as a foreign key by other entities that are associated with (but not composed by) it, you need to override the postChanges() method as shown in the sample code below to save a reference to the row set of entity rows that might be referencing this new DeptEO row.

If the status of the current DeptEO row is New, then the code assigns the RowSet-valued return of the getEmp() association accessor to the newEmployeesBeforePost member field before calling super.postChanges().

This saved RowSet object is then used by the overridden refreshFKInNewContainees() method shown in the following example. It gets called to allow a new entity row to cascade-update its refreshed primary key value to any other entity rows that were referencing it before the call to postChanges(). It iterates over the EmpEOImpl rows in the newEmployeesBeforePost row set (if non-null) and sets the new department ID value of each one to the new sequence-assigned supplier value of the newly posted DeptEO entity.

```
// In DeptEOImpl.java
protected void refreshFKInNewContainees() {
   if (newEmployeesBeforePost != null) {
      Number newDeptId = getId().getSequenceNumber();
      /*
       * Process the rowset of employees that referenced
       * the new department prior to posting, and update their
       * Id attribute to reflect the refreshed Id value
       * that was assigned by a database sequence during posting.
       */
      while (newEmployeesBeforePost.hasNext()){
         EmpEOImpl emp =
            (EmpEOImpl)newEmployeesBeforePost.next();
         emp.setDeptId(newDeptId);
      }
      closeNewProductRowSet();
   }
}
```

After implementing this change, the sample in Observing the Post Ordering Problem First Hand runs without encountering any database constraint violations.

```
// In DeptEOImpl.java
RowSet newEmployeesBeforePost = null;
public void postChanges(TransactionEvent transactionEvent) {
   /* Only bother to update references if Department is a NEW one */
   if (getPostState() == STATUS_NEW) {
   /*
```

```
       * Get a rowset of employees related
       * to this new department before calling super
       */
      newEmployeesBeforePost = (RowSet)getEmpEO();
      }
      super.postChanges(transactionEvent);
   }
```

Advanced Entity Association Techniques

This section describes several advanced techniques for working with associations between entity objects.

Modifying Association SQL Clause to Implement Complex Associations

When you need to represent a more complex relationship between entities than one based only on the equality of matching attributes, you can modify the association's SQL clause to include more complex criteria. For example, sometimes the relationship between two entities depends on effective dates. A `Product` may be related to a `Supplier`, but if the name of the supplier changes over time, each row in the `SUPPLIERS` table might include additional `EFFECTIVE_FROM` and `EFFECTIVE_UNTIL` columns that track the range of dates in which that product row is (or was) in use. The relationship between a `Product` and the `Supplier` with which it is associated might then be described by a combination of the matching `SupplierId` attributes and a condition that the product's `RequestDate` lie between the supplier's `EffectiveFrom` and `EffectiveUntil` dates.

You can set up this more complex relationship in the overview editor for the association. First, add any additional necessary attribute pairs on the Relationship page, which in this example would include one (`EffectiveFrom`, `RequestDate`) pair and one (`EffectiveUntil`, `RequestDate`) pair. Then, on the Query page you can edit the **Where** field to change the WHERE clause to be:

```
(:Bind_SupplierId = Product.SUPPLIER_ID) AND
(Product.REQUEST_DATE BETWEEN :Bind_EffectiveFrom
                                 AND :Bind_EffectiveUntil)
```

For more information about creating associations, see Creating and Configuring Associations.

Exposing View Link Accessor Attributes at the Entity Level

When you create a **view link** between two entity-based view objects, on the View Link Properties page, you have the option to expose **view link accessor** attributes both at the view object level as well as at the entity object level. By default, a view link accessor is exposed only at the view object level of the destination view object. By selecting the appropriate **In Entity Object: *SourceEntityName*** or **In Entity Object:*DestinationEntityName*** checkbox, you can opt to have JDeveloper include a view link attribute in either or both of the source or destination entity objects. This can provide a handy way for an entity object to access a set of related view rows, especially when the query to produce the rows depends only on attributes of the current row.

What You May Need to Know About Custom Entity Object Methods

Custom methods that you implement in the entity object class must not be dependent on the return type of an application module. At runtime, in specific cases, methods that execute with such a dependency may throw a `ClassCastException` because the returned application module does not match the expected type. It is therefore recommended that custom methods that you implement should not have code to get a specific application module implementation or view object implementation as shown below.

```
((MyAM)getTransaction().getRootApplicationModule()).getMyVO
```

Specifically, the above code fails with a `ClassCastException` in the following scenarios:

- When your code uses the entity object in the context of a different view object, other that the view object that you reference in the method. Because your application may map more than one view object definition to the same same entity object, the ADF Business Components runtime does not guarantee that methods with dependencies on the view object will execute consistently.
- When you manually nest an application module under a **root application module**. In this case, the nested application modules share the same `Transaction` object and there is no guarantee that the expected application module type is returned with the above code.
- When the ADF Business Components framework implementation changes with releases. For example, in previous releases, the framework created an internal root application module in order to control declarative transactions that the application defined using **ADF task flows**.

Working Programmatically with Custom Data Sources and the Framework Base Class ProgrammaticEntityImpl

ADF Business Components supports programmatic entity objects that you can create to interact with a custom data source.

The framework base class `oracle.jbo.server.ProgrammaticEntityImpl` lets you take control of performing create/delete/update/lock/rollback operations for each row in a custom data source when you generate an `EntityObjectImpl` class for the entity object in your ADF Model project. At different phases of the entity populate, commit, or rollback lifecycle, the framework will call these hook points and the framework base implementation class gives the application developer control to interact with the custom data source and perform these operations.

> **Note:**
>
> Prior to the `ProgrammaticEntityImpl` base class, applications extended from the base class `oracle.jbo.server.EntityImpl` and overrode a number of lifecycle methods for custom behavior. Using the programmatic entity base class means integration with a custom data source is accomplished by the application developer without needing to understand the entire entity lifecycle.

To work with programmatic entity objects in the ADF Model project, you select the **Programmatic** option in the Create Entity Object wizard. Then entity object Java classes that you generate in the wizard will by default extend from the framework base class `oracle.jbo.server.ProgrammaticEntityImpl` instead of extending from the classic style framework class `oracle.jbo.server.EntityImpl`.

> **Note:**
>
> In order to ensure this behavior when creating an entity object, you must de-select the feature in the ADF Business Components Preferences dialog that enables extending from the base class `oracle.jbo.server.EntityImpl`. The option in the ADF Business Components-View Objects page of the Tools-Preferences dialog is **Classic Programmatic View** (de-select to enable extending from `ProgrammaticEntityImpl`).

How to Create an Entity Object Class Extending ProgrammaticEntityImpl

To create a programmatic entity object that extends `oracle.jbo.server.ProgrammaticEntityImpl`, you use the Create Entity Object wizard and select the **Programmatic** data source option.

Before you begin:

You must disable classic style programmatic entity object generation. In the Tools-Preferences dialog, de-select the option **Classic Programmatic View** on the ADF Business Components-View Objects page. If you leave this option selected (default), JDeveloper will generate entity object Java classes that extend `oracle.jbo.server.EntityImpl`. For details about classic mode, see Using Classic Style Programmatic View Objects for Alternative Data Sources.

To create programmatic entity objects extending ProgrammaticEntityImpl:

1. In the Applications window, right-click the project in which you want to create the entity object and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Entity Object**, and click **OK**.
3. In the Create Entity Object wizard, in the Name page, provide a name and package for the entity object. For the data source, select **Programmatic**.

4. In the Attributes page, click **New** one or more times to define the entity object attributes your programmatic entity object requires.
5. In the Attribute Settings page, adjust any setting you may need to for the attributes you defined.
6. In the Java page, select **Generate Entity Object Class** to enable a custom entity object class (`ProgrammaticEntityImpl`) to contain your code.
7. Click **Finish** to create the entity object.

   In your entity object's custom Java class, override the methods described in Key Framework Methods to Override for ProgrammaticEntityImpl Based Entity Objects to implement your custom data retrieval strategy.

Key Framework Methods to Override for ProgrammaticEntityImpl Based Entity Objects

The generated `EntityObjectImpl.java` that you generate for a programmatic entity object has the following methods that you must override.

- `postDataProvider(int operationType , ArrayList retAttrNames)`

  This method will be called during doDML execution. By default, the framework throws an Exception from the base implementation. Possible values of `operationType` argument are `EntityImpl.DML_INSERT` ,`EntityImpl.DML_UPDATE` or `EntityImpl.DML_DELETE`. Based on the operation type, applications should insert/update/delete the row from custom data source (or secondary cache, if maintaining). The `retAttrNames` argument contains the list of attribute names whose value the application should return back after row has been updated/ inserted.

- `getRowFromDataSource(HashMap[String , Object] origPrimaryKeyMap)`

  Applications should override this API to return the latest row data from custom data source. During entity fault-in, commit or re-populate, the framework needs to know the current row data to handle a multiple user access use case. The origPrimaryKeyMap argument will contain the original primary key information, even if the application has modified any of the key attributes.

- `lockDataProvider(boolean lock)`

  Applications should override this API to lock/unlock the corresponding row in custom data source. Similar to the database behavior, the framework will try to ensure the locking of custom row `DataProvider` to avoid multiple users committing simultaneously. In case the row is already locked, the application should throw `oracle.jbo.AlreadyLockedException` exception.

- `rollbackDataProvider()`

  If custom `DataSource` is also maintaining intermediate caching, applications can override this API to perform a rollback. The framework will invoke this API if any Exception occurs during the commit/postChanges phase.

- `commitDataProvider(ProgrammaticEntityImpl.CommitActionType commitActionType)`

  If custom `DataSource` is also maintaining intermediate caching, applications should merge the cache with original data by overriding this API. Possible values for `commitActionType` argument are:

  - `CommitActionType.DELETE` - Delete the row from cache and original custom DS
  - `CommitActionType.MERGE` - Merge the row from cache to original custom DS
  - `CommitActionType.IGNORE` - Ignore this cached row and perform NO action for original row

Other Useful Protected APIs

- `getPrimaryKeyMap(boolean orig)`

  Based on `orig` argument, this API returns the values map of the Primary key. If `orig` is TRUE, it will return the primary key values as read from the data source, else the current primary key values.

- `getChangedAttributeMap()`

  This API return the HashMap of all the changed attributes.

What You May Need to Know About Programmatic Entity Object Triggers

You can use triggers defined in the Groovy scripting language in place of overridden methods of `ProgrammaticEntityObjectImpl.java` to perform CUD operations on the custom datasource. Triggers can be called from various programmatic entity object lifecycle points.

The application allows you to call triggers that are defined in Groovy script in place of Java hook points. These triggers interact with a custom data source and perform operations such as creation, updation and deletion of data. They can be called from the various programmatic entity object lifecycle points. Although the option of subclassing the framework class, namely `ProgrammaticEntityImpl` and overriding certain methods to define implementations specific to a custom datasource remains, in order for the trigger to execute, the Java hook points should not be defined. Alternatively, if Java hook points are defined, then the triggers shouldn't exist for the Java hook points to execute. Note that if Java hook points as well as triggers are defined, then the triggers will not execute.

Specifically, the programmatic entity object triggers are:

`InsertData`

This trigger is used to create a new record in the custom datasource. It is invoked in place of the `postDataProvider()` method of `ProgrammaticEntityObjectImpl.java` during an insert operation. Use this trigger to optionally retrieve a map of attribute names and their associated values after performing the insert operation. Use this trigger to perform the insert operation in the custom data source and subsequently populate attribute values in the entity object.

The following code sample illustrates the usage of this trigger. The code sample utilizes these context specific keywords:

- `dmlFilter.key` — Returns an `oracle.jbo.Key` containing the key values of the object to be inserted.
- `dmlFilter.changeMap` – Returns a map containing the name and value pairs of attributes that were changed during the insert operation.

- returnMap - The map that is to be populated with attribute values from the data source after performing the insert operation. The map is pre-populated with keys corresponding to attribute names marked with RetrievedOnInsert=true.

```
@TriggerExpression(triggerType="InsertData", name="InsertData_Rule_0")
def InsertData_Rule_0_ValidationRuleScript_Trigger()
{
   def keyValue = dmlFilter.key.keyValues[0]
   def newEmp = new model.data.EmpObject()
   if (dmlFilter.changeMap.size() > 0)
   {
      def mapIter = dmlFilter.changeMap.keySet().iterator()
      while(mapIter.hasNext())
      {
         def attrName = mapIter.next()
         newEmp.setAttribute(attrName, dmlFilter.changeMap.get(attrName))
      }
   }
   model.data.DataCenter.getInstance().getEmpData().add(newEmp)

   if(returnMap.size() > 0)
   {
      def retMapIter = returnMap.keySet().iterator()
      while (retMapIter.hasNext())
      {
         String attrName = retMapIter.next()
         returnMap.put(attrName, newEmp.getAttribute(attrName))
      }
   }
}
```

UpdateData

This trigger is used to update an existing record in the custom datasource. It is invoked in place of the postDataProvider() method of ProgrammaticEntityObjectImpl.java during an update operation. You can optionally use this trigger to retrieve a map of name and value pairs of attributes after performing the update operation. This trigger populates the entity object with the returned name and value pairs of these attributes.

The following code sample illustrates the usage of this trigger. The code sample utilizes these context specific keywords:

- dmlFilter.key - Returns an oracle.jbo.Key containing the key values of the object to be updated.
- dmlFilter.changeMap - Returns a map containing the names and values of the attributes that were changed during the update operation.
- returnMap - The map that is to be populated with attribute values from the datasource after performing the update operation. The map is pre-populated with keys corresponding to attribute names marked with RetrievedOnUpdate=true

```
@TriggerExpression(triggerType="UpdateData", name="UpdateData_Rule_0")
def UpdateData_Rule_0_ValidationRuleScript_Trigger()
{
   def keyValue = dmlFilter.key.keyValues[0]
   def empData = model.data.DataCenter.getInstance().getEmpData()
   model.data.EmpObject empToUpdate = null
   for (emp in empData)
   {
      if (emp.empno.equals(keyValue))
```

```
            {
               //Found the EmpObject to update.
               empToUpdate = emp
               break
            }
         }
         if (dmlFilter.changeMap.size() > 0)
         {
            def mapIter = dmlFilter.changeMap.keySet().iterator()
            while(mapIter.hasNext())
            {
               def attrName = mapIter.next()
               empToUpdate.setAttribute(attrName, dmlFilter.changeMap.get(attrName))
            }
         }

         if(returnMap.size() > 0)
         {
            def retMapIter = returnMap.keySet().iterator()
            while (retMapIter.hasNext())
            {
               String attrName = retMapIter.next()
               returnMap.put(attrName, empToUpdate.getAttribute(attrName))
            }
         }
      }
```

`DeleteData`

This trigger is used to delete an existing record in the custom datasource. It is invoked in place of the `postDataProvider()` method of the `ProgrammaticEntityObjectImpl.java` class during a delete operation.

The following code sample illustrates the usage of this trigger. This code utilizes this context specific keyword:

- `dmlFilter.key` - Returns an `oracle.jbo.Key` containing the key values of object to be deleted.

```
@TriggerExpression(triggerType="DeleteData", name="DeleteData_Rule_0")
def DeleteData_Rule_0_ValidationRuleScript_Trigger()
{
   def keyValue = dmlFilter.key.keyValues[0]
   def empData = model.data.DataCenter.getInstance().getEmpData()
   def iter = empData.iterator()
   while (iter.hasNext())
   {
      def emp = iter.next();
      if (emp.empno.equals(keyValue))
      {
         //Found the EmpObject to delete
         iter.remove()
         break;
      }
   }
}
```

Defining Triggers for Programmatic Entity Objects

ADF Business Components allows you to define and apply triggers in a programmatic entity object’s lifecycle. This process is similar to the process to define triggers in normal entity objects. You can use Groovy script to implement business rules that are executed in response to entity-level triggers.

To add a trigger for a programmatic entity object:

1. In the Applications Navigator, double-click the entity object you want to add a trigger to.
2. In the overview editor, click the **Business Rules** navigation tab.
3. On the Business Rules page, select the Entity-Level Triggers node, and click the **Create New Trigger** icon.
4. Select the appropriate trigger point from the **Type** dropdown list.
5. Enter a Groovy expression.

When you create a trigger, a `<trigger>` tag is added to the entity object's XML file, and the `.bcs` file associated with the view object is populated .

Creating Custom, Validated Data Types Using Domains

Encapsulate common validation logic in custom data types, called as ADF Domains, which simplifies application maintenance and puts validation in a single place.

When you find yourself repeating the same sanity-checking validations on the values of similar attributes across multiple entity objects, you can save yourself time and effort by creating your own data types that encapsulate this validation. For example, imagine that across your business domain layer there are numerous entity object attributes that store strings that represent email addresses. One technique you could use to ensure that end users always enter a valid email address everywhere one appears in your business domain layer is to:

- Use a basic `String` data type for each of these attributes
- Add an attribute-level method validator with Java code that ensures that the `String` value has the format of a valid email address for each attribute

However, these approaches can become tedious quickly in a large application. Fortunately, ADF Business Components offers an alternative that allows you to create your own `EmailAddress` data type that represents an email address. After centralizing all of the sanity-checking regarding email address values into this new custom data type, you can use the `EmailAddress` as the type of every attribute in your application that represents an email address. By doing this, you make the intention of the attribute values more clear to other developers and simplify application maintenance by putting the validation in a single place. ADF Business Components calls these developer-created data types **domains**.

Domains are Java classes that extend the basic data types like `String`, `Number`, and `Date` to add constructor-time validation to ensure the candidate value passes relevant sanity checks. They offer you a way to define custom data types with cross-cutting behavior such as basic data type validation, formatting, and custom metadata properties in a way that is inherited by any entity objects or view objects that use the domain as the Java type of any of their attributes.

> **Note:**
>
> The example in this section refers to the `oracle.summit.model.domains` package in the `SummitADF_Examples` application workspace.

How to Create a Domain

To create a domain, use the Create Domain wizard. This wizard is available from the New Gallery in the **ADF Business Components** category.

Before you begin:

It may be helpful to have an understanding of using domains. For more information, see Creating Custom, Validated Data Types Using Domains.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create a domain:

1. In the Applications window, right-click the project for which you want to create a domain and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Domain**, and click **OK**.
3. In the Create Domain wizard, on the Name page, specify a name for the domain and a package in which it will reside. To create a domain based on a simple Java type, leave **Domain for an Oracle Object Type** unselected.
4. Click **Next**.
5. On the Settings page, indicate the base type for the domain and the database column type to which it will map.

   For example, if you were creating a domain called `ShortEmailAddress` to hold eight-character short email addresses, you would set the base type to `String` and the **Database Column Type** to `VARCHAR2(8)`. You can set other common attribute settings on this panel as well.
6. Click **Finish**.

What Happens When You Create a Domain

When you create a domain, JDeveloper creates its XML document in the subdirectory of your project's source path that corresponds to the package name you chose. For example, if you created the `ShortEmailAddress` domain in the `summit.model.domains` package, JDeveloper would create the `ShortEmailAddress.xml` file in the `./summit/model/domains` subdirectory. A domain always has a corresponding Java class, which JDeveloper creates in the `common` subpackage of the package where the domain resides. This means it would create the `ShortEmailAddress.java` class in the `summit.model.domains.common` package. The domain's Java class is generated with the appropriate code to behave in a way that is identical to one of the built-in data types.

What You May Need to Know About Domains

Domains can be created as a variety of different types, and have different characteristics than standard attributes. The sections that follow describe some of the things you may need to know about when working with domains.

Domains as Entity and View Object Attributes

After you've created a domain in a project, it appears among the list of available data types in the **Attribute Type** dropdown list in the entity object and view object wizards and dialogs. To use the domain as the type of a given attribute, just pick it from the list.

> **Note:**
>
> The entity-mapped attributes in an entity-based view object inherit their data type from their corresponding underlying entity object attribute. Therefore, if the entity attribute uses a domain type, the matching view object attribute will as well. For transient or SQL-derived view object attributes, you can directly set the type to use a domain since it is not inherited from any underlying entity.

DataCreationException in Custom validate() Method

Typically, the only coding task you need to do for a domain is to write custom code inside the generated `validate()` method. Your implementation of the `validate()` method should perform your sanity checks on the candidate value being constructed, and throw a `DataCreationException` in the `oracle.jbo` package if the validation fails.

In order to throw an exception message that is translatable, you can create a message bundle class similar to the one shown in the following example. Create it in the same package as your domain classes themselves. The message bundle returns an array of {*MessageKeyString*,*TranslatableMessageString*} pairs.

> **Note:**
>
> There are additional formats available for resource bundles, such as XLIFF. For more information, see Working with Resource Bundles.

```
package oracle.summit.model.domains;

import java.util.ListResourceBundle;

public class ErrorMessages extends ListResourceBundle {
  public static final String INVALID_SHORTEMAIL = "30002";
  public static final String INVALID_EVENNUMBER = "30003";
  private static final Object[][] sMessageStrings = new String[][] {
      { INVALID_SHORTEMAIL,
        "A valid short email address has no @-sign or dot."},
      { INVALID_EVENNUMBER,
        "Number must be even."}
    };

  /**
   * Return String Identifiers and corresponding Messages
   * in a two-dimensional array.
   */
  protected Object[][] getContents() {
    return sMessageStrings;
  }
}
```

String Domains and String Value Aggregation

Since `String` is a base JDK type, a domain based on a `String` aggregates a `private mData String` member field to hold the value that the domain represents. Then, the class implements the `DomainInterface` expected by the ADF runtime, as well as the `Serializable` interface, so the domain can be used in method arguments or return types of the custom client interfaces of Oracle ADF components.

The following example shows the `validate()` method for a simple `ShortEmailAddress` domain class. It tests to make sure that the `mData` value does not contains an at-sign or a dot, and if it does, then the method throws `DataCreationException` referencing an appropriate message bundle and message key for the translatable error message.

```
public class ShortEmailAddress implements DomainInterface, Serializable {
  private String mData;
  // . . .
  protected void validate() {
  /**Implements domain validation logic and throws a JboException on error. */
    int atpos = mData.indexOf('@');
    int dotpos = mData.lastIndexOf('.');
    if (atpos > -1 || dotpos > -1) {
      throw new DataCreationException(ErrorMessages.class,
      ErrorMessages.INVALID_SHORTEMAIL,null,null);
    }
  }
  // . . .
}
```

Simple Domains and Built-In Types

Other simple domains based on a built-in type in the `oracle.jbo.domain` package extend the base type, as shown in the following example. It illustrates the `validate()` method for a simple Number-based domain called `EvenNumber` that represents even numbers.

```
public class EvenNumber extends Number {
  // . . .
  /**
   * Validates that value is an even number, otherwise
   * throws a DataCreationException with a custom
   * error message.
   */
  protected void validate() {
    if (getValue() % 2 == 1) {
      throw new DataCreationException(ErrorMessages.class,
      ErrorMessages.INVALID_EVENNUMBER,null,null);
    }
  }
  // . . .
}
```

Simple Domains As Immutable Java Classes

When you create a simple domain based on one of the basic data types, it is an *immutable* class. That means that once you've constructed a new instance of it like this:

```
ShortEmailAddress email = new ShortEmailAddress("emailaddress1");
```

You cannot change its value. If you want to reference a different short email address, you just construct another one:

```
ShortEmailAddress email = new ShortEmailAddress("emailaddress2");
```

This is not a new concept because it's the same way that `String`, `Number`, and `Date` classes behave, among others.

Creating Domains for Oracle Object Types When Useful

Oracle Database supports the ability to create user-defined types in the database. For example, you could create a type called `POINT_TYPE` using the following DDL statement:

```
create type point_type as object (
   x_coord number,
   y_coord number
);
```

If you use user-defined types like `POINT_TYPE`, you can create domains based on them, or you can reverse-engineer tables containing columns of object type to have JDeveloper create the domain for you. You can use the Create Domain wizard to create Oracle object type domains manually.

To manually create an Oracle object type domain:

1. In the Applications window, right-click the project for which you want to create a domain and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Domain**, and click **OK**.
3. In the Create Domain wizard, on the Name page, select the **Domain for an Oracle Object Type** checkbox, then select the object type for which you want to create a domain from the **Available Types** list.
4. Click **Next**.
5. On the Settings page, use the **Attribute** dropdown list to switch between the multiple domain properties to adjust the settings as appropriate.
6. Click **Finish**.

To reverse-engineer an Oracle object type domain:

In addition to manually creating object type domains, when you use the Business Components from Tables wizard and select a table containing columns of an Oracle object type, JDeveloper creates domains for those object types as part of the reverse-engineering process. For example, imagine you created a table like this with a column of type POINT_TYPE:

```
create table interesting_points(
  id number primary key,
  coordinates point_type,
  description varchar2(20)
);
```

If you create an entity object for the INTERESTING_POINTS table in the Business Components from Tables wizard, then you get both an InterestingPoints entity object and a PointType domain. The latter is generated, based on the POINT_TYPE object type, because it was required as the data type of the Coordinates attribute of the InterestingPoints entity object.

Unlike simple domains, object type domains are mutable. JDeveloper generates getter and setter methods into the domain class for each of the elements in the object type's structure. After changing any domain properties, when you set that domain as the value of a view object or entity object attribute, it is treated as a single unit. Oracle ADF does not track which domain properties have changed, only that a domain-valued attribute value has changed.

> **Note:**
>
> Domains based on Oracle object types are useful for working programmatically with data whose underlying type is an oracle object type. They can also simplify passing and receiving structure information to stored procedures. However, support for working with object type domains in the **ADF binding** layer is not complete, so it is not straightforward to use object domain-valued attributes in declaratively databound user interfaces.

Domains Packaged in the Common JAR

When you create an ADF Library JAR for your business components, as described in How to Package a Component into an ADF Library JAR, the domain classes and message bundle files in the *.common subdirectories of your project's source path get packaged into the *CSCommon.jar. They are classes that are common to both the middle-tier application server and to an eventual remote client you might need to support.

Custom Domain Properties and Attributes in Entity and View Objects

You can define custom metadata properties on a domain. Any entity object or view object attribute based on that domain inherits those custom properties as if they had been defined on the attribute itself. If the entity object or view object attribute defines the same custom property, its setting takes precedence over the value inherited from the domain.

Inherited Restrictive Properties of Domains in Entity and View Objects

JDeveloper enforces the declarative settings you impose at the domain definition level: they cannot be made *less* restrictive for the entity object or view object for an attribute based on the domain type. For example, if you define a domain to have its **Updatable** property set to **While New**, then when you use your domain as the Java type of an entity object attribute, you can set **Updatable** to be **Never** (more restrictive) but you cannot set it to be **Always**. Similarly, if you define a domain to be **Persistent**, you cannot make it transient later. When sensible for your application, set declarative properties for a domain to be as lenient as possible, so you can later make them more restrictive as needed.

Creating New History Types

Use history types to track time-specific data. JDeveloper provides out-of-the-box ADF history types and also allows you to create custom history types.

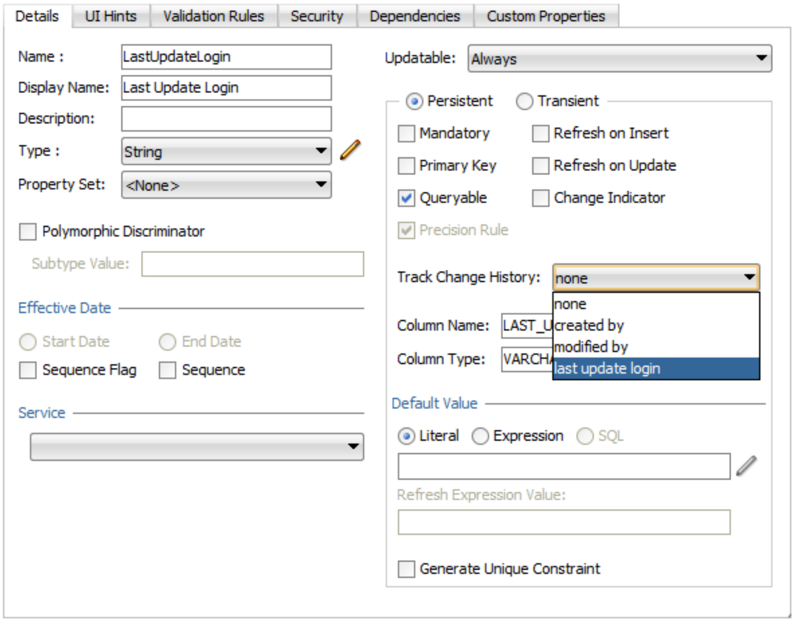
History types are used to track data specific to a point in time. JDeveloper ships with a number of history types, but you can also create your own. For information on the standard history types and how to use them, see How to Track Created and Modified Dates Using the History Column.

How to Create New History Types

You are not limited to the history types provided: you can add or remove custom history types using the History Types page in the Preferences dialog, and then write custom Java code to implement the desired behavior. The code to handle custom history types should be written in your application-wide entity base class for reuse.

Figure 4-17 shows a custom type called `last update login` with type ID of `11`. Assume that `last_update_login` is a foreign key in the `FND_LOGINS` table.

Figure 4-17 New History Types in the Overview Editor



Name : LastUpdateLogin
Display Name: Last Update Login
Description:
Type : String
Property Set: <None>
□ Polymorphic Discriminator
Subtype Value:
Updatable: Always
● Persistent ○ Transient
□ Mandatory □ Refresh on Insert
□ Primary Key □ Refresh on Update
☑ Queryable □ Change Indicator
☑ Precision Rule
Track Change History: none
Column Name: LAST_U
Column Type: VARCHA
○ Start Date ○ End Date
□ Sequence Flag □ Sequence
● Literal ○ Expression ○ SQL
Refresh Expression Value:
□ Generate Unique Constraint

Before you begin:

It may be helpful to have an understanding of history types. For more information, see Creating New History Types.

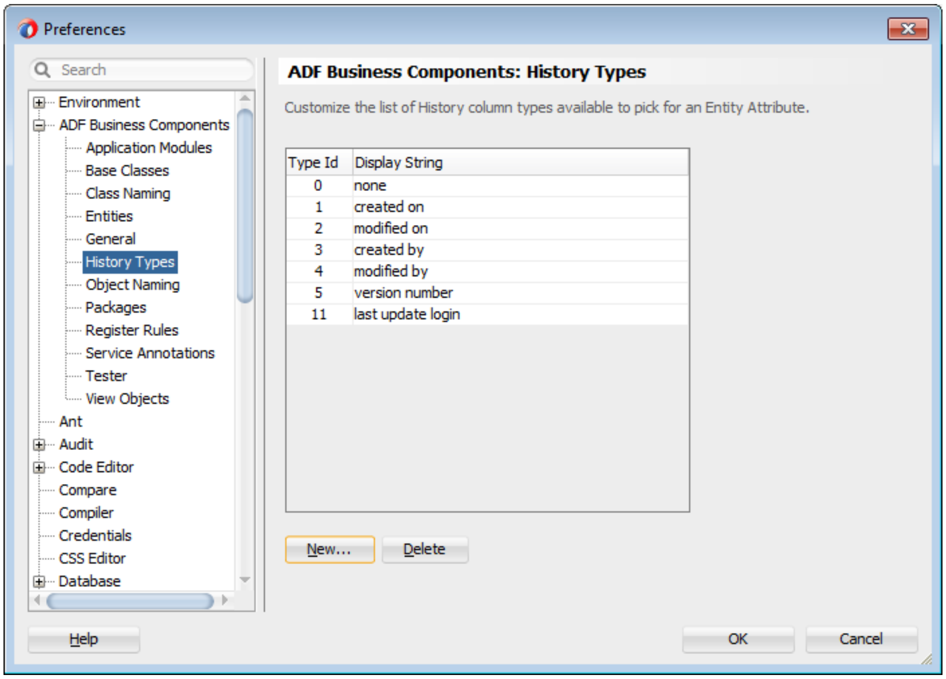
You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create a custom history type:

1. From the main menu, choose **Tools > Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and click **History Types**.
3. In the Preferences dialog, on the History Types page, click **New**.
4. In the New History Type dialog, enter a string value for the name (spaces are allowed) and a numerical ID.

   The **Type Id** must be an integer between 11 and 126. The numerical values 0-10 are reserved for internal use. The display string is displayed in the **Track Change History** dropdown list the next time you use the overview editor. Figure 4-18 shows the new history type in the Preferences dialog.

   Figure 4-18 Custom History Type in Preferences



ADF Business Components: History Types

Customize the list of History column types available to pick for an Entity Attribute.

Type Id	Display String
0	none
1	created on
2	modified on
3	created by
4	modified by
5	version number
11	last update login

5. Open the entity object's Java class file (or the extension class on which it is based) and add a definition similar to the following.

```
private static final byte LASTUPDATELOGIN_HISTORY_TYPE = 11;
```

6. Override the `getHistoryContextForAttribute(AttributeDefImpl attr)` method from the `EntityImpl` base class with code similar the following.

```
@Override
protected Object getHistoryContextForAttribute(AttributeDefImpl attr) {
    if (attr.getHistoryKind() == LASTUPDATELOGIN_HISTORY_TYPE) {
        // Custom History type logic goes here
    }
    else {
        return super.getHistoryContextForAttribute(attr);
        }
    }
```

How to Remove a History Type

Because they are typically used for auditing values over the life of an application, it is rare that you would want to remove a history type. However, in the event that you need to do so, perform the following tasks:

1. Remove the history type from the JDeveloper history types list in the Preferences dialog.
2. Remove any custom code you implemented to support the history type in the `getHistoryContextForAttribute` method in the entity object's Java class file (or the extension class on which it is based).
3. Remove all usages of the history type in the entity attribute metadata. Any attribute that you have defined to use this history type must be edited.

Before you begin:

It may be helpful to have an understanding of history types. For more information, see Creating New History Types.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To remove a history type from the JDeveloper history types list:

1. From the main menu, choose **Tools > Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and click **History Types**.
3. In the Preferences dialog, on the History Types page, select the history type that you want to remove and click **Delete**.

Basing an Entity Object on a PL/SQL Package API

The ADF framework allows you to use the PL/SQL API in combination with a database view. It allows client programs to read using the database view and write to the table using the PL/SQL API.

If you have a PL/SQL package that encapsulates insert, update, and delete access to an underlying table, you can override the default DML processing event for the entity object that represents that table to invoke the procedures in your PL/SQL API instead. Often, such PL/SQL packages are used in combination with a companion database view. Client programs read data from the underlying table using the database view, and "write" data back to the table using the procedures in the PL/SQL package.

For example, say you want to create a `Product` entity object based on such a combination of a view and a package.

Given the `S_PRODUCT` table in the Summit ADF schema, consider a database view named `PRODUCT_V`, created using the following DDL statement:

```
create or replace view product_v
as select id,name,image_id,short_desc from s_product;
```

In addition, consider the simple PRODUCTS_API package shown below that encapsulates insert, update, and delete access to the underlying S_PRODUCT table.

```
create or replace PACKAGE PRODUCTS_API as
  procedure insert_product(p_id number,
                           p_name varchar2,
                           p_short_desc varchar2,
                           p_longtext_id number,
                           p_image_id number,
                           p_suggested_whlsl_price number,
                           p_whlsl_units varchar2);
  procedure update_product(p_id number,
                           p_name varchar2,
                           p_short_desc varchar2,
                           p_longtext_id number,
                           p_image_id number,
                           p_suggested_whlsl_price number,
                           p_whlsl_units varchar2);
  procedure delete_product(p_id number);
end products_api;
```

To create an entity object based on this combination of database view and PL/SQL package, you would perform the following tasks:

1. Create a view-based entity object, as described in How to Create an Entity Object Based on a View.
2. Create a base class for the entity object, as described in How to Centralize Details for PL/SQL-Based Entities into a Base Class.
3. Implement the appropriate stored procedure calls, as described in How to Implement the Stored Procedure Calls for DML Operations.
4. Handle selecting and locking functionality, if necessary, as described in How to Add Select and Lock Handling.

Note:

The example in these sections refers to the oracle.summit.model.wrapplsql package in the SummitADF_Examples application workspace.

Although the example uses an table-based entity object rather than a view-based entity object, the configuration details are congruent.

How to Create an Entity Object Based on a View

To create an entity object based on a view, you use the Create Entity Object wizard.

Before you begin:

It may be helpful to have an understanding of how entity objects can use the PS/SQL API. For more information, see Basing an Entity Object on a PL/SQL Package API.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

You will need to launch the Create Entity Object wizard as described in How to Create Single Entity Objects Using the Create Entity Wizard, and proceed through the wizard with the exceptions noted in the following procedure.

To create an entity object based on a view:

1. On the Name page, give the entity a name.
2. In the Select Schema Object dialog, in the **Object Type** section, select the **Views** checkbox.

   This enables the display of the available database views in the current schema in when you click **Query**.
3. In the **Available Objects** list, select the desired database view.
4. On the Attribute Settings page, use the **Select Attribute** dropdown list to choose the attribute that will act as the primary key, and then select the **Primary Key** checkbox for that attribute.

   > **Note:**
   >
   > When defining the entity based on a view, JDeveloper cannot automatically determine the primary key attribute since database views do not have related constraints in the database data dictionary.

What Happens When You Create an Entity Object Based on a View

By default, an entity object based on a view performs all of the following directly against the underlying database view:

- `SELECT` statement (for `findByPrimaryKey()`)
- `SELECT FOR UPDATE` statement (for `lock()`), and
- `INSERT`, `UPDATE`, `DELETE` statements (for `doDML()`)

To use stored procedure calls, you will need to override the `doDML()` operations (as described in How to Centralize Details for PL/SQL-Based Entities into a Base Class), and possibly override the `lock()` and `findByPrimaryKey()` handling (as described in How to Implement the Stored Procedure Calls for DML Operations).

How to Centralize Details for PL/SQL-Based Entities into a Base Class

If you plan to have more than one entity object based on a PL/SQL API, it's a smart idea to abstract the generic details into a base framework extension class. In doing this, you'll be using several of the concepts described in Extending Business Components Functionality. Start by creating a `PLSQLEntityImpl` class that extends the base `EntityImpl` class that each one of your PL/SQL-based entities can use as their base class.

> **Note:**
>
> If you are already using an extended entity implementation class for your entity, you can extend it further with the PLSQLEntityImpl class. For example, if you have a framework extension class named zzEntityImpl, you would create a PLSQLEntityImpl class that extends the zzEntityImpl class.

As shown below, you'll override the doDML() method of the base class to invoke a different helper method based on the operation.

```
// In PLSQLEntityImpl.java
protected void doDML(int operation, TransactionEvent e) {
  // super.doDML(operation, e);
  if (operation == DML_INSERT)
    callInsertProcedure(e);
  else if (operation == DML_UPDATE)
    callUpdateProcedure(e);
  else if (operation == DML_DELETE)
    callDeleteProcedure(e);
}
```

In the PLSQLEntityImpl.java base class, you can write the helper methods so that they perform the default processing like this:

```
// In PLSQLEntityImpl.java
/* Override in a subclass to perform nondefault processing */
protected void callInsertProcedure(TransactionEvent e) {
  super.doDML(DML_INSERT, e);
}
/* Override in a subclass to perform nondefault processing */
protected void callUpdateProcedure(TransactionEvent e) {
  super.doDML(DML_UPDATE, e);
}
/* Override in a subclass to perform nondefault processing */
protected void callDeleteProcedure(TransactionEvent e) {
  super.doDML(DML_DELETE, e);
}
```

After putting this infrastructure in place, when you base an entity object on the PLSQLEntityImpl class, you can use the **Source > Override Methods** menu item to override the callInsertProcedure(), callUpdateProcedure(), and callDeleteProcedure() helper methods and perform the appropriate stored procedure calls for that particular entity.

> **Note:**
>
> If you do not override these helper methods in a subclass, they will perform the default processing as defined in the superclass. You only need to override the operations in the doDML() method that you want to provide alternative processing for.

To simplify the task of implementing these calls, you could add the `callStoredProcedure()` helper method (described in Invoking Stored Procedures and Functions) to the `PLSQLEntityImpl` class as well. This way, any PL/SQL-based entity objects that extend this class can leverage the helper method.

How to Implement the Stored Procedure Calls for DML Operations

To implement the stored procedure calls for DML operations, you will need to create a custom Java class for the entity object and override the operations in it.

Before you begin:

It may be helpful to have an understanding of entity objects that are based on a PL/SQL package API. For more information, see Basing an Entity Object on a PL/SQL Package API.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To create the custom Java class with the override methods:

1. In the Applications window, double-click the entity object.
2. In the overview editor, click the **Java** navigation tab, and then click the **Edit Java options** icon.
3. In the Select Java Options dialog, click **Classes Extend**.
4. In the Override Base Classes dialog, in the **Row** field, enter the package and class of the `PLSQLEntityImpl` class, or click **Browse** to search and select it.
5. Select **Generate Entity Object Class**, and click **OK**.
6. In the Applications window, double-click the generated entity object class.
7. From the main menu, choose **Source > Override Methods**.
8. In the Override Methods dialog, select the `callInsertProcedure()`, `callUpdateProcedure()`, and `callDeleteProcedure()` methods, and click **OK**.
9. In the source editor, enter the necessary code to override these procedures.

The following example shows some sample code that you would write in these overridden helper methods to invoke insert, update, and delete procedures.

```
// In ProductImpl.java
protected void callInsertProcedure(TransactionEvent e) {
   callStoredProcedure("products_api.insert_product(?,?,?,?,?,?,?)",
      new Object[] { getId(), getName(), getShortDesc(), getLongtextId(),
            getImageId(), getSuggestedWhlslPrice(), getWhlslUnits() });
}
protected void callUpdateProcedure(TransactionEvent e) {
   callStoredProcedure("products_api.update_product(?,?,?,?,?,?)",
      new Object[] { getId(), getName(), getShortDesc(), getLongtextId(),
            getImageId(), getSuggestedWhlslPrice(), getWhlslUnits() });
}
protected void callDeleteProcedure(TransactionEvent e) {
   callStoredProcedure("products_api.delete_product(?)",
      new Object[] { getId() });
}
```

At this point, if you create a default entity-based view object called ProductView for the Product entity object and add an instance of it to a AppModule application module you can quickly test inserting, updating, and deleting rows from the ProductView view object instance in the Oracle ADF Model Tester.

Often, overriding just the insert, update, and delete operations will be enough. The default behavior that performs the SELECT statement for findByPrimaryKey() and the SELECT FOR UPDATE statement for the lock() against the database view works for most basic kinds of views.

However, if the view is complex and does not support SELECT FOR UPDATE or if you need to perform the findByPrimaryKey() and lock() functionality using additional stored procedures APIs, then you can use the technique described in How to Add Select and Lock Handling.

How to Add Select and Lock Handling

You can handle the lock() and findByPrimaryKey() functionality of an entity object by invoking stored procedures if necessary. Imagine that the PRODUCTS_API package were updated to contain the two additional procedures shown here.

```
/* Added to PRODUCTS_API package */
procedure lock_product(p_id number,
                       p_name OUT varchar2,
                       p_short_desc OUT varchar2,
                       p_longtext_id OUT number,
                       p_image_id OUT number,
                       p_suggested_whlsl_price OUT number,
                       p_whlsl_units OUT varchar2);
procedure select_product(p_id number,
                       p_name OUT varchar2,
                       p_short_desc OUT varchar2,
                       p_longtext_id OUT number,
                       p_image_id OUT number,
                       p_suggested_whlsl_price OUT number,
                       p_whlsl_units OUT varchar2);
```

Both the lock_product and select_product procedures accept a primary key attribute as an IN parameter and return values for the remaining attributes using OUT parameters.

To add select and lock handling, you will need to perform the following tasks:

1. Update the base class to handle lock and select, as described in Updating PLSQLEntityImpl Base Class to Handle Lock and Select.
2. Update the entity object implementation class to implement the lock and select behaviors, as described in Implementing Lock and Select for the Product Entity.
3. Override the lock() method in the entity object implementation class to refresh the entity object after a RowInconsistentException has occurred, as described in Refreshing the Entity Object After RowInconsistentException.

Updating PLSQLEntityImpl Base Class to Handle Lock and Select

You can extend the PLSQLEntityImpl base class to handle the lock() and findByPrimaryKey() overrides using helper methods similar to the ones you added for insert, update, delete. At runtime, both the lock() and findByPrimaryKey()

operations invoke the lower-level entity object method called doSelect(boolean lock). The lock() operation calls doSelect() with a true value for the parameter, while the findByPrimaryKey() operation calls it passing false instead.

The following example shows the overridden doSelect() method in PLSQLEntityImpl to delegate as appropriate to two helper methods that subclasses can override as necessary.

```
// In PLSQLEntityImpl.java
protected void doSelect(boolean lock) {
  if (lock) {
    callLockProcedureAndCheckForRowInconsistency();
  } else {
    callSelectProcedure();
  }
}
```

The two helper methods are written to just perform the default functionality in the base PLSQLEntityImpl class:

```
// In PLSQLEntityImpl.java
/* Override in a subclass to perform nondefault processing */
protected void callLockProcedureAndCheckForRowInconsistency() {
  super.doSelect(true);
}
/* Override in a subclass to perform nondefault processing */
protected void callSelectProcedure() {
  super.doSelect(false);
}
```

Notice that the helper method that performs locking has the name callLockProcedureAndCheckForRowInconsistency(). This reminds you that you need to perform a check to detect at the time of locking the row whether the newly selected row values are the same as the ones the entity object in the entity cache believes are the current database values.

To assist subclasses in performing this old-value versus new-value attribute comparison, you can add one final helper method to the PLSQLEntityImpl class like this:

```
// In PLSQLEntityImpl
protected void compareOldAttrTo(int attrIndex, Object newVal) {
  if ((getPostedAttribute(attrIndex) == null && newVal != null) ||
      (getPostedAttribute(attrIndex) != null && newVal == null) ||
      (getPostedAttribute(attrIndex) != null && newVal != null &&
       !getPostedAttribute(attrIndex).equals(newVal))) {
    throw new RowInconsistentException(getKey());
  }
}
```

Implementing Lock and Select for the Product Entity

With the additional infrastructure in place in the base PLSQLEntityImpl class, you can override the callSelectProcedure() and callLockProcedureAndCheckForRowInconsistency() helper methods in the entity object implementation class (for example, ProductImpl). Because the select_product and lock_product procedures have OUT arguments, as described in How to Call Other Types of Stored Procedures, you need to use a JDBC CallableStatement object to perform these invocations.

The example below shows the code you would use to invoke the `select_product` procedure for the `ProductImpl` entity object implementation class to select a row by primary key. It's performing the following basic steps:

1. Creating a `CallableStatement` for the PLSQL block to invoke.
2. Registering the `OUT` parameters and types, by one-based bind variable position.
3. Setting the `IN` parameter value.
4. Executing the statement.
5. Retrieving the possibly updated column values.
6. Populating the possibly updated attribute values in the row.
7. Closing the statement.

```
// In ProductImpl.java
protected void callSelectProcedure() {
   String stmt = "begin products_api.select_product(?,?,?,?,?,?,?);end;";
   // 1. Create a CallableStatement for the PLSQL block to invoke
   CallableStatement st = getDBTransaction().createCallableStatement(stmt, 0);
   try {
      // 2. Register the OUT parameters and types
      st.registerOutParameter(2, VARCHAR2);
      st.registerOutParameter(3, VARCHAR2);
      st.registerOutParameter(4, NUMBER);
      st.registerOutParameter(5, NUMBER);
      st.registerOutParameter(6, NUMBER);
      st.registerOutParameter(7, VARCHAR2);
      // 3. Set the IN parameter value
      st.setObject(1, getId());
      // 4. Execute the statement
      st.executeUpdate();
      // 5. Retrieve the possibly updated column values
      String possiblyUpdatedName = st.getString(2);
      String possiblyUpdatedShortDesc = st.getString(3);
      String possiblyUpdatedLongTextId = st.getString(4);
      String possiblyUpdatedImageId = st.getString(5);
      String possiblyUpdatedSuggestedPrice = st.getString(6);
      String possiblyUpdatedWhlslUnits = st.getString(7);
      // 6. Populate the possibly updated attribute values in the row
      populateAttribute(NAME, possiblyUpdatedName, true, false,
                        false);
      populateAttribute(SHORTDESC, possiblyUpdatedShortDesc, true,
                        false, false);
      populateAttribute(LONGTEXTID, possiblyUpdatedLongTextId, true,
                        false, false);
      populateAttribute(IMAGEID, possiblyUpdatedImageId, true, false,
                        false);
      populateAttribute(SUGGESTEDWHLSLPRICE, possiblyUpdatedSuggestedPrice,
                        true, false, false);
      populateAttribute(WHLSLUNITS, possiblyUpdatedWhlslUnits, true,
                        false, false);
   } catch (SQLException e) {
      throw new JboException(e);
   } finally {
      if (st != null) {
         try {
            // 7. Closing the statement
            st.close();
         } catch (SQLException e) {
         }
      }
   }
}
```

The following example shows the code to invoke the `lock_product` procedure. It's doing basically the same steps as those above, with just the following two interesting differences:

- After retrieving the possibly updated column values from the `OUT` parameters, it uses the `compareOldAttrTo()` helper method inherited from the `PLSQLEntityImpl` to detect whether or not a `RowInconsistentException` should be thrown as a result of the row lock attempt.
- In the `catch (SQLException e)` block, it is testing to see whether the database has thrown the error:

  ```
  ORA-00054: resource busy and acquire with NOWAIT specified
  ```

  and if so, it again throws the ADF Business Components `AlreadyLockedException` just as the default entity object implementation of the `lock()` functionality would do in this situation.

With these methods in place, you have and entity object that wraps the PL/SQL package (in this case, a `Product` entity object with the `PRODUCTS_API` package) for all of its database operations. Due to the clean separation of the data querying functionality of view objects and the data validation and saving functionality of entity objects, you can now leverage this entity object in any way you would use a normal entity object. You can build as many different view objects as necessary that use this entity object as their entity usage.

```
// In ProductsImpl.java
protected void callLockProcedureAndCheckForRowInconsistency() {
   String stmt = "begin products_api.lock_product(?,?,?,?,?,?,?);end;";
   CallableStatement st =
      getDBTransaction().createCallableStatement(stmt, 0);
   try {
      st.registerOutParameter(2, VARCHAR2);
      st.registerOutParameter(3, VARCHAR2);
      st.registerOutParameter(4, NUMBER);
      st.registerOutParameter(5, NUMBER);
      st.registerOutParameter(6, NUMBER);
      st.registerOutParameter(7, VARCHAR2);
      st.setObject(1, getId());
      st.executeUpdate();
      String possiblyUpdatedName = st.getString(2);
      String possiblyUpdatedShortDesc = st.getString(3);
      String possiblyUpdatedLongTextId = st.getString(4);
      String possiblyUpdatedImageId = st.getString(5);
      String possiblyUpdatedSuggestedPrice = st.getString(6);
      String possiblyUpdatedWlhslUnits = st.getString(7);
      compareOldAttrTo(NAME, possiblyUpdatedName);
      compareOldAttrTo(SHORTDESC, possiblyUpdatedShortDesc);
      compareOldAttrTo(LONGTEXTID, possiblyUpdatedLongTextId);
      compareOldAttrTo(IMAGEID, possiblyUpdatedImageId);
      compareOldAttrTo(SUGGESTEDWHLSLPRICE, possiblyUpdatedSuggestedPrice);
      compareOldAttrTo(WHLSLUNITS, possiblyUpdatedWlhslUnits);
   } catch (SQLException e) {
      if (Math.abs(e.getErrorCode()) == 54) {
         throw new AlreadyLockedException(e);
      } else {
```

```
            throw new JboException(e);
         }
      } finally {
         if (st != null) {
            try {
               st.close();
            } catch (SQLException e) {
            }
         }
      }
   }
```

Refreshing the Entity Object After RowInconsistentException

You can override the `lock()` method to refresh the entity object after a `RowInconsistentException` has occurred. The following example shows code that can be added to the entity object implementation class to catch the `RowInconsistentException` and refresh the entity object.

```
// In the entity object implementation class
@Override
public void lock() {
  try {
    super.lock();
  }
  catch (RowInconsistentException ex) {
    this.refresh(REFRESH_UNDO_CHANGES);
    throw ex;
  }
}
```

Basing an Entity Object on a Join View or Remote DBLink

Some types of schema do not support the `RETURNING` clause. So disable this clause in the ADF entity object. The entity object then implements `Refresh on Insert`and `Refresh on Update`.

If you need to create an entity object based on either of the following:

- Synonym that resolves to a remote table over a `DBLINK`
- View with `INSTEAD OF` triggers

Then you will encounter the following error if any of its attributes are marked as **Refresh on Insert** or **Refresh on Update**:

```
JBO-26041: Failed to post data to database during "Update"
## Detail 0 ##
ORA-22816: unsupported feature with RETURNING clause
```

These types of schema objects do not support the `RETURNING` clause, which by default the entity object uses to more efficiently return the refreshed values in the same database roundtrip in which the `INSERT` or `UPDATE` operation was executed.

How to Disable the Use of the RETURNING Clause

Because some types of schema objects do not support the `RETURNING` clause, you might need to disable the `RETURNING` clause in your entity object. The following procedures explains how to do that.

Before you begin:

It may be helpful to have an understanding of the types of schema objects don't support the `RETURNING` clause. For more information, see Basing an Entity Object on a Join View or Remote DBLink.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

To disable the use of the RETURNING clause for an entity object of this type:

1. Enable a custom entity definition class for the entity object.
2. In the custom entity definition class, override the `createDef()` method to call `setUseReturningClause(false)`.
3. If the **Refresh on Insert** attribute is the primary key of the entity object, you must specify some other attribute in the entity as an alternate unique key by setting the **Unique Key** property on it.

What Happens at Runtime: Refresh Behavior With Disabled RETURNING Clause

At runtime, when you have disabled the use of the `RETURNING` clause as described in How to Disable the Use of the RETURNING Clause,, the entity object implements the **Refresh on Insert** and **Refresh on Update** behavior using a separate `SELECT` statement to retrieve the values to refresh after insert or update as appropriate.

Using Inheritance in Your Business Domain Layer

ADF Business Components supports inheritance to allow you to create new components by extending existing ones.

Inheritance is a powerful feature of object-oriented development that can simplify development and maintenance when used appropriately. As shown in Creating Extended Components Using Inheritance, ADF Business Components supports using inheritance to create new components that extend existing ones in order to add additional properties or behavior or modify the behavior of the parent component. Inheritance can be useful in modeling the different kinds of entities in your reusable business domain layer.

Note:

The example in this section is an extension of the oracle.summit.model.polymorphic package in the SummitADF_Examples workspace.

Understanding When Inheritance Can Be Useful

Your application's database schema might contain tables where different logical kinds of business information are stored in rows of the same table. These tables will typically have one column whose value determines the kind of information stored in each row. For example, an application's S_CUSTOMER table stores information about both domestic and international customers in the same table. It contains a CUSTOMER_TYPE_CODE column whose value determines what kind of S_CUSTOMER the row represents.

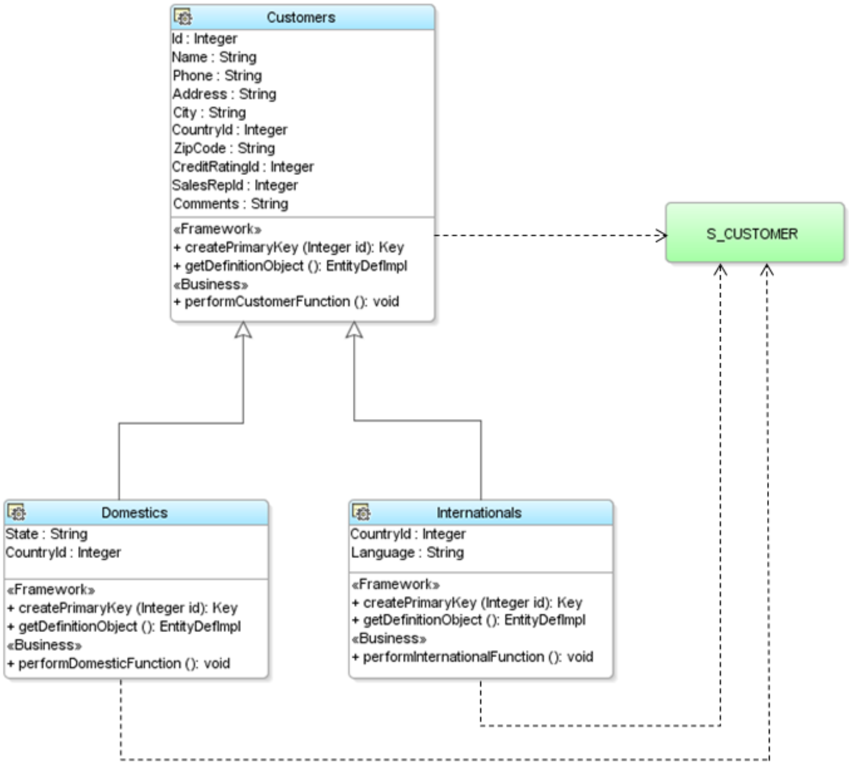
While the Summit ADF sample application implementation doesn't contain this differentiation, it's reasonable to assume that revisions of the application might require:

- Managing additional database-backed attributes that are specific to domestic customers or specific to international customers
- Implementing common behavior for all users that is different for domestic or international customers
- Implementing new functionality that is specific to only domestic or only international customers

Figure 4-19 shows what the business domain layer would look like if you created distinct Customers, Domestics, and Internationals entity objects to allow distinguishing the different kinds of business information in a more formal way inside your application. Since domestic and international are special *kinds* of customers, their corresponding entity objects would extend the base Customers entity object. This base Customers entity object would contain all of the attributes and methods common to all types of users. The performCustomerFunction() method in the figure represents one of these common methods.

Then, for the Domestics and Internationals entity objects you can add specific additional attributes and methods that are unique to that kind of user. For example, Domestics has an additional State attribute of type String to track the state in which the domestic customer is located. There is also a performDomesticFunction() method that is specific to domestic customers. Similarly, the Internationals entity object has an additional Language attribute to track whether the customer speaks English. The performInternationalFunction() is a method that is specific to international customers.

Figure 4-19 Distinguishing Customers, Domestics, and Internationals Using Inheritance



By modeling these different kinds of customers as distinct entity objects in an inheritance hierarchy in your domain business layer, you can simplify having them share common data and behavior and implement the aspects of the application that make them distinct.

How to Create Entity Objects in an Inheritance Hierarchy

To create entity objects in an inheritance hierarchy, you use the Create Entity Object wizard to create each entity.

To create entity objects in an inheritance hierarchy, you will perform the following tasks:

1. Identify the discriminator column and values, as described in Identifying the Discriminator Column and Distinct Values.
2. Identify the subset of attributes for each entity object, as described in Identifying the Subset of Attributes Relevant to Each Kind of Entity.
3. Create the base entity object, as described in Creating the Base Entity Object in an Inheritance Hierarchy.
4. Create the subtype entity objects, as described in Creating a Subtype Entity Object in an Inheritance Hierarchy.

Identifying the Discriminator Column and Distinct Values

Before creating entity objects in an inheritance hierarchy based on a table containing different kinds of information, you should first identify which column in the table is used to distinguish which kind of row it is.

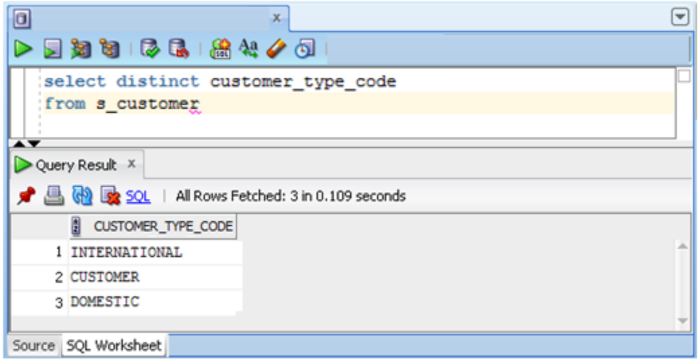
For example, in a `S_CUSTOMER` table, this might be a `CUSTOMER_TYPE_CODE` column. Since it helps partition or "discriminate" the rows in the table into separate groups, this column is known as the **discriminator column**.

Next, determine the valid values that the discriminator column takes on in your table. You might know this, or you could execute a simple SQL statement in the JDeveloper **SQL Worksheet** to determine the answer. To access the worksheet:

1. With the application open in JDeveloper, choose **Window > Database > Databases** from the main menu.
2. Expand the workspace node, and select the connection.
3. Right-click the database connection, and choose **Open SQL Worksheet**.

Figure 4-20 shows the results of performing a `SELECT DISTINCT` query in the SQL Worksheet on the `CUSTOMER_TYPE_CODE` column in the `S_CUSTOMER` table. It confirms that the rows are partitioned into two groups based on the `CUSTOMER_TYPE_CODE` discriminator values: `DOMESTIC` and `INTERNATIONAL`.

Figure 4-20 Using the SQL Worksheet to Find Distinct Discriminator Column Values



```
select distinct customer_type_code
from s_customer
```

Query Result

SQL | All Rows Fetched: 3 in 0.109 seconds

	CUSTOMER_TYPE_CODE
1	INTERNATIONAL
2	CUSTOMER
3	DOMESTIC

Identifying the Subset of Attributes Relevant to Each Kind of Entity

Once you know how many different kinds of business entities are stored in the table, you will also know how many entity objects to create to model these distinct items. You'll typically create one entity object per kind of item. Then, to help determine which entity should act as the base of the hierarchy, you need to determine which subset of attributes is relevant to each kind of item.

For example, assume you determine that all of the attributes except `State` and `Language` are relevant to all users, and that:

- `State` is specific to domestic customers

- `Language` is specific to international customers.

This information leads you to determine that the `Customers` entity object should be the base of the hierarchy, with the `Domestics` and `Internationals` entity objects each extending `Customers` to add their specific attributes.

Creating the Base Entity Object in an Inheritance Hierarchy

To create the base entity object in an inheritance hierarchy, you use the Create Entity Object wizard.

Before you begin:

It may be helpful to have an understanding of entity objects in an inheritance hierarchy. For more information, see Using Inheritance in Your Business Domain Layer.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

You will also need to determine the discriminator column and values, as described in Identifying the Discriminator Column and Distinct Values, and determine the attributes for each entity object, as described in Identifying the Subset of Attributes Relevant to Each Kind of Entity.

To create the base entity object

1. In the Applications window, right-click the project to which you want to add the entity object and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Entity Object**, and click **OK**.
3. In the Create Entity Object wizard, on the Name Page, provide a name and package for the entity, and select the schema object on which the entity will be based.

   In this example, name the entity object `Customers` and base it on the `S_CUSTOMER` table.
4. On the Attributes page, select the attributes in the **Entity Attributes** list that are not relevant to the base entity object (if any) and click **Remove** to remove them.

   In this example, you would remove the `State` and `Language` attributes from the list.
5. On the Attribute Settings page, use the **Select Attribute** dropdown list to choose the attribute that will act as the discriminator for the family of inherited entity objects and select the **Discriminator** checkbox to identify it as such. Importantly, you must also supply a **Default Value** for this discriminator attribute to identify rows of this base entity type.

   In this example, you would select the `CustomerTypeCode` attribute, mark it as a discriminator attribute, and set its **Default Value** to the value "`CUSTOMER`".

> **Note:**
>
> Leaving the **Default Value** blank for a discriminator attribute is legal. A blank default value means that a row with the discriminator column value `IS NULL` will be treated as this base entity type.

6. Then click **Finish**.

Creating a Subtype Entity Object in an Inheritance Hierarchy

To create a subtype entity object in an inheritance hierarchy, you use the Create Entity Object wizard.

Before you begin:

It may be helpful to have an understanding of entity objects in an inheritance hierarchy. For more information, see Using Inheritance in Your Business Domain Layer.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

You will also need to perform the following tasks:

1. Determine the discriminator column and values, as described in Identifying the Discriminator Column and Distinct Values.
2. Determine the attributes for each entity object, as described in Identifying the Subset of Attributes Relevant to Each Kind of Entity.
3. Create the parent entity object from which your new entity object will extend, as described in Creating the Base Entity Object in an Inheritance Hierarchy.
4. Make sure that the parent entity has a discriminator attribute already identified.

   If it does not, use the overview editor to set the **Discriminator** property on the appropriate attribute of the parent entity before creating the inherited child.

To create the new subtype entity object in the hierarchy:

1. In the Applications window, right-click the project to which you want to add the entity object and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Entity Object**, and click **OK**.
3. In the Create Entity Object wizard, on the Name Page, provide a name and package for the entity, and click the **Browse** button next to the **Extends** field to select the parent entity from which the entity being created will extend.

   In this example, you would name the new entity `Domestics` and select the `Customers` entity object in the **Extends** field.
4. On the Attributes page, the **Entity Attributes** list displays the attributes from the underlying table that are not included in the base entity object. Select the attributes you do not want to include in this entity object and click **Remove**.

   In this example, because you are creating the `Domestics` entity you would remove the `Language` attribute and leave the `State` attribute.

5. Click **Override** to select the discriminator attribute so that you can customize the attribute metadata to supply a distinct **Default Value** for the `Domestics` entity subtype.

   In this example, you would override the `CustomerTypeCode` attribute.

6. On the Attribute Settings page, use the **Select Attribute** dropdown list to select the discriminator attribute. Change the **Default Value** field to supply a distinct default value for the discriminator attribute that defines the entity subtype being created.

   In this example, you would select the `CustomerTypeCode` attribute and change its **Default Value** to the value "`DOMESTIC`".

7. Click **Finish**.

> **Note:**
>
> You can repeat the same steps to define the `Internationals` entity object that extends `Customers` to add the additional `Language` attribute and overrides the **Default Value** of the `CustomerTypeCode` discriminator attribute to have the value "`INTERNATIONAL`".

How to Add Methods to Entity Objects in an Inheritance Hierarchy

To add methods to entity objects in an inheritance hierarchy, enable the custom Java class for the entity object and use the source editor to add the method. Methods that are common to all entity objects in the hierarchy are added to the base entity, while subtype-specific methods are added to the subtype. You can also override methods from the base entity object in the subtypes as necessary.

Adding Methods Common to All Entity Objects in the Hierarchy

To add a method that is common to all entity objects in the hierarchy, you add the method to the implementation class of the base entity object.

Before you begin:

It may be helpful to have an understanding of entity objects in an inheritance hierarchy. For more information, see Using Inheritance in Your Business Domain Layer.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

You will also need to perform the following tasks:

1. Create the base entity object and subtypes in the hierarchy, as described in How to Create Entity Objects in an Inheritance Hierarchy.
2. Create a custom Java implementation class for the base entity object, as described in Generating Custom Java Classes for an Entity Object.

To add a method common to all entity objects in a hierarchy:

1. In the Applications window, double-click the base entity object implementation class (for example, `CustomersImpl.java`).
2. In the source editor, add the method.

   For example, you could add the following method to the `CustomersImpl` class for the base `Customers` entity object:

   ```
   // In CustomersImpl.java
   public void performCustomerFunction() {
     System.out.println("## performCustomerFunction as Customer");
   }
   ```

Because this is the base entity object class, the methods you implement here are inherited by all subtype entity objects in the hierarchy.

Overriding Common Methods in a Subtype Entity Object

To override a method in a subtype entity object that is common to all entity objects in the hierarchy, you modify the common method inherited from the base entity object in the implementation class of the subtype entity object.

Before you begin:

It may be helpful to have an understanding of entity objects in an inheritance hierarchy. For more information, see Using Inheritance in Your Business Domain Layer.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

You will also need to perform the following tasks:

1. Create the base entity object and subtypes in the hierarchy, as described in How to Create Entity Objects in an Inheritance Hierarchy.
2. Create the common method in the base entity object, which your subtype entity object will override, as described in Adding Methods Common to All Entity Objects in the Hierarchy.
3. Create a a custom Java implementation class for the subtype entity object, as described in Generating Custom Java Classes for an Entity Object.

To override a method in a subtype entity object:

1. In the Applications window, double-click the subtype entity object implementation class (for example, `DomesticsImpl.java`).
2. With the subtype entity object implementation class open in the source editor, choose **Source > Override Methods** from the main menu.
3. In the Override Methods dialog, select the method you want to override (for example, the `performCustomerFunction()` method), and click **OK**.
4. In the source editor, customize the overridden method's implementation.

   For example, you could override the `performCustomerFunction()` method in the `DomesticsImpl` class for the `Domestics` subtype entity object and change the implementation to look like this:

   ```
   // In DomesticsImpl.java
   public void performCustomerFunction() {
   ```

```
  System.out.println("## performCustomerFunction as Domestics");
}
```

When working with instances of entity objects in a subtype hierarchy, sometimes you will process instances of multiple different subtypes. Because the `Domestics` and `Internationals` entity objects are special kinds of `Customers`, you can write code that works with all of them using the more generic `CustomersImpl` type that they all have in common. When doing this generic kind of processing of classes that might be one of a *family* of subtypes in a hierarchy, Java will always invoke the most specific override of a method available.

This means that invoking the `performCustomerFunction()` method on an instance of `CustomersImpl` that happens to really be the more specific `DomesticsImpl` subtype, will the result in printing out the following:

```
## performCustomerFunction as Domestics
```

instead of the default result that regular `CustomersImpl` instances would get:

```
## performCustomerFunction as Customer
```

Adding Methods Specific to a Subtype Entity Object

To add a method that is specific to a subtype entity object in the hierarchy, you simply add the method in the implementation class of the subtype using the source editor.

Before you begin:

It may be helpful to have an understanding of entity objects in an inheritance hierarchy. For more information, see Using Inheritance in Your Business Domain Layer.

You may also find it helpful to understand additional functionality that can be added using other entity object features. For more information, see Additional Functionality for Entity Objects.

You will also need to perform the following tasks:

1. Create the base entity object and subtypes in the hierarchy, as described in How to Create Entity Objects in an Inheritance Hierarchy.
2. Create a custom Java implementation class for the subtype entity object, as described in Generating Custom Java Classes for an Entity Object.

To add a method specific to a subtype entity object:

1. In the Applications window, double-click the subtype entity object implementation class (for example, `InternationalsImpl.java`).
2. In the source editor, add the method.

   For example, you could add a `performInternationalFunction()` method to the `InternationalsImpl` class for the subtype `Internationals` entity object:

   ```
   // In InternationalsImpl.java
   public void performInternationalFunction() {
     System.out.println("## performInternationalFunction called");
   }
   ```

What You May Need to Know About Using Inheritance

When using inheritance, you can also introduce a new base entity, find subtype entities using a primary key, and create view objects with polymorphic entity usages.

Introducing a New Base Entity

For example, where the `Customers` entity object corresponds to a concrete kind of row in the `S_CUSTOMERS` table, it also plays the role of the base entity in the inheritance hierarchy. In other words, all of its attributes were common to all entity objects in the hierarchy. A situation might arise, however, where the `Customers` entity object required a property that was specific to customers, but not common to domestic or international customers.

In this case, you can introduce a new entity object (for example, `BaseCustomers`) to act as the base entity in the hierarchy. It would have all of the attributes common to all `Customers`, `Domestics`, and `Internationals` entity objects. Then each of the three entities that correspond to concrete rows that appear in the table could have some attributes that are inherited from `BaseCustomers` and some that are specific to the individual subtype. In the `BaseCustomers` type, so long as you mark the `CustomerTypeCode` attribute as a discriminator attribute, you can just leave the **Default Value** blank (or some other value that does *not* occur in the `CUSTOMER_TYPE_CODE` column in the table). Because you will not use instances of the `BaseCustomers` entity in the application, it doesn't matter what its discriminator default value is.

Subtype Entity Objects and the findByPrimaryKey() Method

When you use the `findByPrimaryKey()` method on an entity definition, it only searches the entity cache for the entity object type on which you call it. For example, this means that if you call `CustomersImpl.getDefinitionObject()` to access the entity definition for the `Customers` entity object when you call `findByPrimaryKey()` on it, you will only find entities in the cache that happen to be customers. Sometimes this is exactly the behavior you want.

However, if you want to find an entity object by primary key allowing the possibility that it might be a subtype in an inheritance hierarchy, then you can use the `findByPKExtended()` method from the `EntityDefImpl` class instead.

For example, if you have created subtypes of the `Customers` entity object, this alternative finder method would find an entity object by primary key whether it is a customer, domestic, or international. You can then use the Java `instanceof` operator to test which type you found, and then cast the `CustomersImpl` object to the more specific entity object type to work with features specific to that subtype.

View Objects with Polymorphic Entity Usages

When you create an entity-based view object with an entity usage corresponding to a base entity object in an inheritance hierarchy, you can configure the view object to query rows corresponding to multiple different subtypes in the base entity's subtype hierarchy. Each row in the view object will use the appropriate subtype entity object as the entity row part, based on matching the value of the discriminator attribute. See How to Create a Subtype View Object with a Polymorphic Entity Usage, for specific instructions on setting up and using these view objects.

5

Defining SQL Queries Using View Objects

This chapter describes how to create ADF view objects to create SQL queries that join, filter, sort, and aggregate data for use in an Oracle ADF application. It describes how view objects map their SQL-derived attributes to database table columns and static data sources, such as a flat file.
This chapter includes the following sections:

About View Objects

Use Oracle ADF view objects to encapsulate SQL queries and build data models of ADF application modules.

A **view object** is an **Oracle Application Development Framework** (Oracle ADF) component that encapsulates a SQL query and simplifies working with its results. There are several types of view objects that you can create in your data model project:

- Entity-based view objects when data updates will be performed or just to read data
- Non-entity backed view objects for cases not supported by entity objects (view objects with no entity usage definition are always read-only)
- Static data view objects for data defined by the view object itself
- Programmatically populated view objects (see Using Programmatic View Objects for Alternative Data Sources)

An **entity-based view object** can be configured to support updatable rows when you create view objects that map their attributes to the attributes of one or more existing entity objects. The mapped entity object is saved as an entity usage in the view object definition. In this way, entity-based view objects cooperate automatically with entity objects to enable a fully updatable data model. The entity-based view object usage queries just the data needed for the client-facing task and relies on its mapped entity objects and their entity cache of rows to automatically validate and save changes made to its view rows. An entity-based view object encapsulates a SQL query, it can be linked into master-detail hierarchies, and it can be used in the data model of an **application module**. The backing entity cache manages updates to the queried data so that every view object usage based on the same entity object points to the entity cache of rows rather than store duplicate data in the view object usage.

In contrast to entity-based view objects, *entity-less view objects* require you to write the query using the SQL query language. Non-entity backed view objects do not pick up entity-derived default values, they do not reflect pending changes, and they do not reflect updated reference information. The Create View Object wizard and overview editor for entity-based view objects, on the other hand, simplify this task by helping you to construct the SQL query declaratively. In addition, because entity-based view objects manage queried data using the entity cache, they have better performance over view objects with no entity usage which require special runtime handling of updates to their view object row cache. For these reasons, it is almost always preferable to create an entity-mapped view object, even when you want to create a view object just to read data.

There remain a few situations where it is still preferable to create a non-entity-mapped view object to read data, including SQL-based validation, Unions, and Group By queries. In this case, it is worth noting, that view objects with no entity usage definition are always read-only.

As an alternative to creating view objects that specify a SQL statement at design time, you can create entity-based view objects that contain no SQL statements. This capability of the **ADF Business Components** design time and runtime is known as **declarative SQL mode**. The business component developer who works with the wizard or editor for a view object in declarative SQL mode, requires no knowledge of SQL. In declarative SQL mode, the runtime query statement is based solely on the usage of attributes in the databound UI component.

When a view object has one or more underlying entity usages, you can create new rows, and modify or remove queried rows. The entity-based view object coordinates with underlying entity objects to enforce business rules and to permanently save the changes to the database. In addition, entity-based view objects provide these capabilities that do not exist with entity-less view objects:

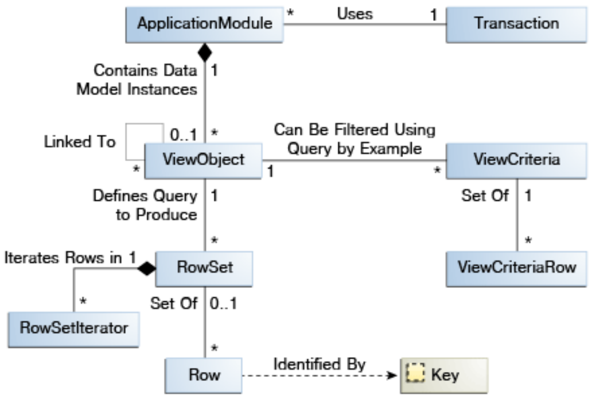
- Changes in cache (updates, inserts, deletes) managed by entities survive the view object's execution boundary.
- Changes made to relevant entity object attributes through other view objects in the same transaction are immediately reflected.
- Attribute values of new rows are initialized to the values from the underlying entity object attributes.
- Changes to foreign key attribute values cause reference information to get updated.
- Validation for row (entity) level is supported.
- Composition features, including validation, locking, ordered-updates are supported.
- Support for effective dating, change indicator, and business events.

View Object Use Cases and Examples

This chapter helps you understand these view object concepts as illustrated in Figure 5-1:

- You define a view object by providing a SQL query (either defined explicitly or declaratively).
- You use view object instances in the context of an application module that provides the database transaction for their queries.
- You can link a view object to one or more others to create master-detail hierarchies.
- At runtime, the view object executes your query and produces a set of rows (represented by a `RowSet` object).
- Each row is identified by a corresponding row key.
- You iterate through the rows in a row set using a **row set iterator**.
- You can filter the row set a view object produces by applying a set of Query-by-Example criteria rows.

Figure 5-1 A View Object Defines a Query and Produces a Row Set of Rows

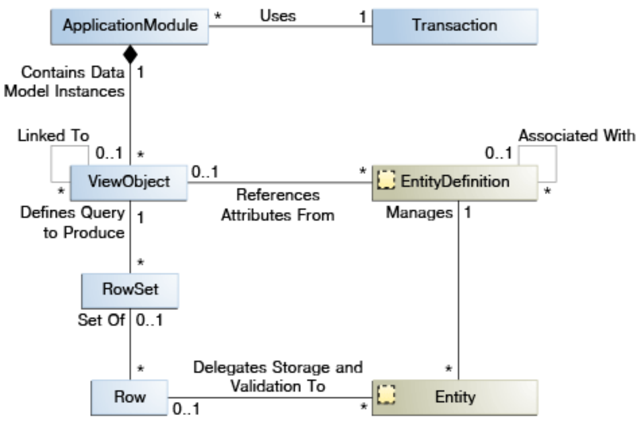


This chapter explains how instances of entity-based view objects contained in the data model of your application module enable clients to search for, update, insert, and delete **business services layer** information in a way that combines the full data shaping power of SQL with the clean, object-oriented encapsulation of reusable domain business objects. And all without requiring a line of code.This chapter helps you to understand these entity-based view object concepts as illustrated in Figure 5-2:

- You define an updatable view object by referencing attributes from one or more entity objects.
- You can use multiple, associated entity objects to simplify working with reference information.
- You can a define **view link** based on underlying **entity associations**.
- You use your entity-based view objects in the context of an application module that provides the transaction.

- At runtime, the view row delegates the storage and validation of its attributes to underlying entity objects.

Figure 5-2 View Objects and Entity Objects Collaborate to Enable an Updatable Data Model



Additional Functionality for View Objects

You may find it helpful to understand other **Oracle ADF** features before you start working with view objects. Following are links to other functionality that may be of interest.

- For additional information about using Groovy script wherever expressions are supported in view object definitions, see Using Groovy Scripting Language with Business Components.
- For details about using the interactive Oracle ADF Model Tester to validate view object query results, see Testing View Instance Queries.
- For details about the role of the entity cache plays in a transaction involving entity-based view objects, see What Happens at Runtime: How View Objects and Entity Objects Cooperate.
- For details about creating a data model consisting of view object instances, see Implementing Business Services with Application Modules.
- For a quick reference to the most common code that you will typically write, use, and override in your custom view object classes, see Most Commonly Used ADF Business Components Methods.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Populating View Object Rows from a Single Database Table

ADF Business Components view objects are utilized to retrieve data from a data source such as a database table using SQL queries.

View objects provide the means to retrieve data from a data source. In the majority of cases, the data source will be a database and the mechanism to retrieve data is the

SQL query. ADF Business Components can work with JDBC to pass this query to the database and retrieve the result.

When view objects use a SQL query, query columns map to view object attributes in the view object. The definition of these attributes, saved in the view object's XML definition file, reflect the properties of these columns, including data types and precision and scale specifications.

> **Performance Tip:**
>
> If the query associated with the view object contains query parameters whose values change from execution to execution, use bind variables. Using bind variables in the query allows the query to reexecute without needing to reparse the query on the database. You can add bind variables to the view object in the Query page of the overview editor for the view object. For more information, see See Working with Bind Variables.

Using the same Create View Object wizard, you can create view objects that either map to the attributes of existing entity objects or not. Only entity-based view objects automatically coordinate with mapped entity objects to enforce business rules and to permanently save data model changes. Additionally, you can disable the Updatable feature for entity-based view objects and work entirely declaratively to query read-only data. Alternatively, you can use the wizard or editor's custom SQL mode to work directly with the SQL query language, but the view object you create will not support the transaction features of the entity-based view object.

When you create entity-based view objects, you have the option to keep the view object definition entirely declarative and maintain a customizable view object. Or, you may switch to custom SQL query editing to create queries that entity objects alone cannot express, including Unions and Group By queries. Additionally, custom SQL view objects are useful in SQL-based validation queries used by the view object-based Key Exists validator. It is worth noting that, by definition, using custom SQL mode to define a SQL query means the view object is read only.

For information about the differences between entity-based view objects and entity-less view objects, see About View Objects.

How to Create an Entity-Based View Object

Creating an entity-based view object is the simplest way to create a view object. It is even easier than creating a custom SQL view object, since you don't have to type in the SQL statement yourself. An entity-based view object also offers significantly more runtime functionality than its custom SQL counterpart.

In an entity-based view object, the view object and entity object play cleanly separated roles:

- The view object is the data *source*: it retrieves the data using SQL.
- The entity object is the data *sink*: it handles validating and saving data changes.

Because view objects and entity objects have cleanly separated roles, you can build different view objects — projecting, filtering, joining, sorting the data in whatever way your user interfaces require, application after application — without any changes to the reusable entity object. In fact, it is possible that the development team responsible for the core business services layer of entity objects might be completely separate from another team responsible for the specific application modules and view objects needed to support the end-user environment. This relationship is enabled by metadata that the entity-based view object encapsulates. The metadata specifies how the `SELECT` list columns are related to the attributes of one or more underlying entity objects.

Your entity-based view object may be based on more than one database table. To use database joins to add multiple tables to the view object, see Working with Multiple Tables in Join Query Results.

Creating a View Object with All the Attributes of an Entity Object

When you want to allow the client to work with *all* of the attributes of an underlying entity object, you can use the Create Default View Object dialog to quickly create the view object from an entity object that you select in the Applications window. To create the default view object, select the entity object, right-click and choose **New Default View Object**. When you do not want the view object to contain all the attributes, you can use the Create View Object wizard and select only the attributes that you need, as described in Creating an Entity-Based View Object from a Single Table.

Before you begin:

It may be helpful to have an understanding of entity-based view objects. For more information, see How to Create an Entity-Based View Object.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Either create the desired entity objects yourself, as described in How to Create Multiple Entity Objects and Associations from Existing Tables or consult the developer responsible for creating entity objects and let them know the data that you expect to query.

To create a default entity-based view object:

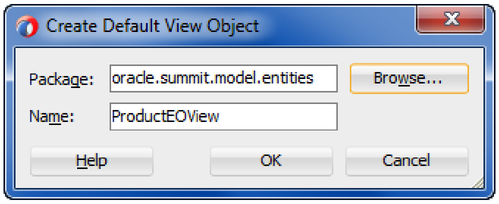
1. In the Applications window, right-click the entity object and choose **New Default View Object**.

   This context menu option lets you create a view object based on a single entity object that you select. If you need to add additional entity objects to the view object definition, you can use the Entity Objects page of the view object overview editor after you create the view object.

2. In the Create Default View Object dialog, provide a package and component name for the new view object.

   In the Create Default View Object dialog you can click **Browse** to select the package name from the list of existing packages. For example, in Figure 5-3, clicking **Browse** locates `oracle.summit.model.entities` package on the classpath for the `Model` project of the application.

Figure 5-3 Shortcut to Creating a Default View Object for an Entity Object



Package: oracle.summit.model.entities

Name: ProductEOView

The new entity-based view object created will be identical to one you could have created with the Create View Object wizard. By default, it will have a single entity usage referencing the entity object you selected in the Applications window, and will include all of its attributes. It will initially have neither a `WHERE` nor `ORDER BY` clause, and you may want to use the overview editor for the view object to:

- Remove unneeded attributes
- Refine its selection with a `WHERE` clause
- Order its results with an `ORDER BY` clause
- Customize any of the view object properties

Creating an Entity-Based View Object from a Single Table

To create an entity-based view object, use the Create View Object wizard, which is available from the New Gallery.

Before you begin:

It may be helpful to have an understanding of entity-based view objects. See, see How to Create an Entity-Based View Object.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired entity objects, as described in How to Create Multiple Entity Objects and Associations from Existing Tables.

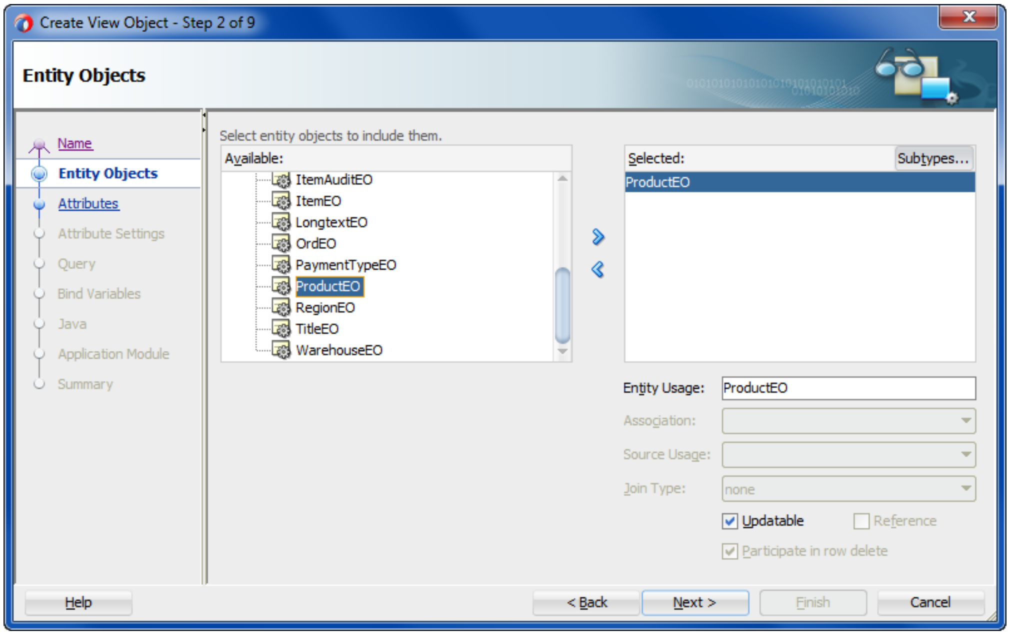
To create an entity-based view object from a single table:

1. In the Applications window, right-click the package of the data model project in which you want to create the view object and choose **New** and then **View Object**.
2. In the Create View Object wizard, on the Name page, enter a package name and a view object name. Keep the default setting **Entity** selected to indicate that you want this view object to manage data with its base entity object. Click **Next**.
3. On the Entity Objects page, select an entity object whose data you want to use in the view object. Click **Next**.

   An entry in this list is known as an **entity usage**, since it records the entity objects that the view object will be using. Each entry could also be thought of as an **entity reference**, since the view object references attributes from that entity. For information about working table joins to create additional entity usages, see Working with Multiple Tables in Join Query Results.

For example, Figure 5-4 shows the result after shuttling the `ProductEO` entity object into the **Selected** list.

Figure 5-4 Create View Object Wizard, Entity Objects Page



Create View Object - Step 2 of 9

Entity Objects

Select entity objects to include them.

Available:
- ItemAuditEO
- ItemEO
- LongtextEO
- OrdEO
- PaymentTypeEO
- ProductEO
- RegionEO
- TitleEO
- WarehouseEO

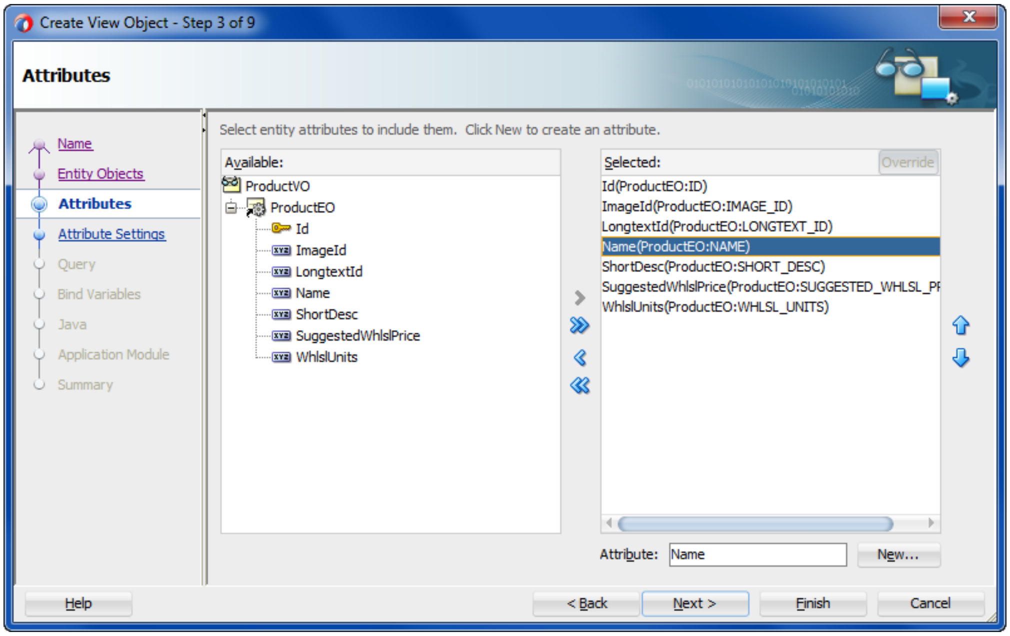
Selected:
- ProductEO

Entity Usage: ProductEO
Association:
Source Usage:
Join Type: none
☑ Updatable ☐ Reference
☑ Participate in row delete

4. On the Attributes page, select the attributes you want to include from each entity usage in the **Available** list and shuttle them to the **Selected** list. Click **Next**.

   For example, Figure 5-5 shows the attributes have been selected from the `ProductEO`.

Figure 5-5 Create View Object Wizard, Attributes Page



Create View Object - Step 3 of 9

Attributes

Select entity attributes to include them. Click New to create an attribute.

Available:
- ProductVO
  - ProductEO
    - Id
    - ImageId
    - LongtextId
    - Name
    - ShortDesc
    - SuggestedWhlslPrice
    - WhlslUnits

Selected:
- Id(ProductEO:ID)
- ImageId(ProductEO:IMAGE_ID)
- LongtextId(ProductEO:LONGTEXT_ID)
- Name(ProductEO:NAME)
- ShortDesc(ProductEO:SHORT_DESC)
- SuggestedWhlslPrice(ProductEO:SUGGESTED_WHLSL_PF
- WhlslUnits(ProductEO:WHLSL_UNITS)

Attribute: Name

5. On the Attribute Settings page, optionally, use the **Select Attribute** dropdown list to switch between the view object attributes in order to change their names or any of their initial settings.

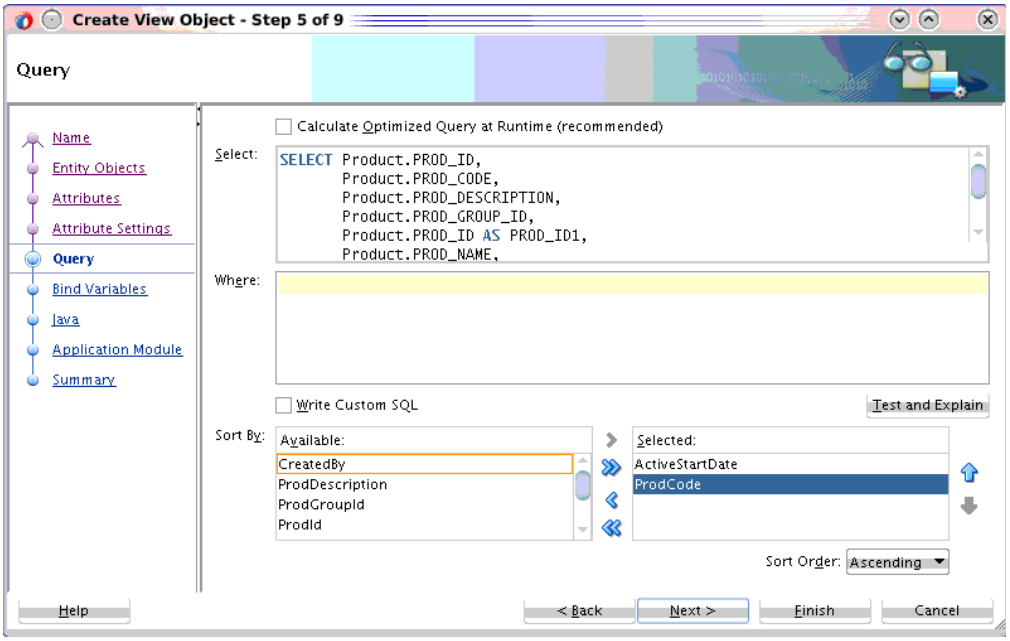
   See about any of the attribute settings, press F1 or click **Help**.

6. On the Query page, deselect **Calculate Optimized Query at Runtime** . Optionally add a `WHERE` clause and use the `Sort By` panel to shuffle entries from Available to Selected to add a sort criteria. JDeveloper automatically generates the SELECT statement based on the entity attributes you've selected.

   Do not include the `WHERE` keywords in the **Where** field values. The view object adds those keywords at runtime when it executes the query.

   For example, Figure 5-6 shows the `Sort By` clause, where the entries in the Selected column indicate the sort criteria.

Figure 5-6 Create View Object Wizard, Query Page



□ Calculate Optimized Query at Runtime (recommended)

Select:

```
SELECT  Product.PROD_ID,
        Product.PROD_CODE,
        Product.PROD_DESCRIPTION,
        Product.PROD_GROUP_ID,
        Product.PROD_ID AS PROD_ID1,
        Product.PROD_NAME,
```

Where:

□ Write Custom SQL

Sort By:

Available: CreatedBy, ProdDescription, ProdGroupId, ProdId

Selected: ActiveStartDate, ProdCode

Sort Order: Ascending

7. Click **Finish**.

What Happens When You Create an Entity-Based View Object

When you create a view object, JDeveloper creates the XML document file that represents the view object's declarative settings and saves it in the directory that corresponds to the name of its package. For example, the view object `ProductVO`, added to the `views` package, will have the XML file `./views/ProductVO.xml` created in the project's source path.

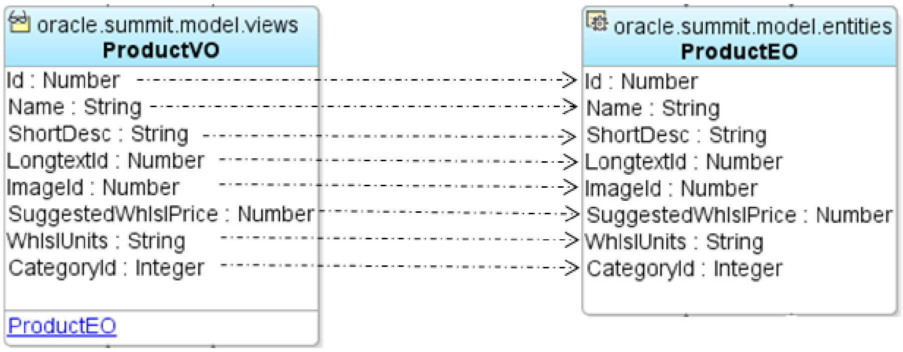
To view the view object settings, select the desired view object in the Applications window and open the Structure window. The Structure window displays the list of XML definitions, including the SQL query, the name of the entity usage, and the properties of each attribute. To open the XML definition in the editor, right-click the corresponding node and choose **Go to Source**.

Note:

If you configure JDeveloper preferences to generate default Java classes for ADF Business Components, the wizard will also create an optional custom view object class (for example, ProductVOImpl.java) and/or a custom view row class (for example, ProductVORowImpl.java). For details about setting preferences, see How to Customize Model Project Properties for ADF Business Components.

Figure 5-7 depicts the entity-based view object ProductVO and the singe entity usage referenced in its query statement. The dotted lines represent the metadata captured in the entity-based view object's XML document that map SELECT list columns in the query to attributes of the entity objects used in the view object.

Figure 5-7 View Object Encapsulates a SQL Query and Entity Attribute Mapping Metadata



What You May Need to Know About Non-Updatable View Objects

When you use the Create View Object wizard to create an entity-based view object, by default the attributes of the view object will be updatable. When you want to make all the attributes of the view object read-only, you can deselect **Updatable** when you add the entity object in the wizard. Later you may decide to convert the view object to one that permits updates to its SQL-mapped table columns. However, this cannot be accomplished by merely changing the attribute's **Updatable** property. You must delete the read-only view object and recreate the entity-based view object so that the intended attributes are updatable.

How to Edit a View Object

After you've created a view object, you can edit any of its settings in the overview editor for the view object.

> **Performance Tip:**
>
> How you configure the view object to fetch data plays a large role in the runtime performance of the view object. For information about the tuning parameters that you can edit to optimize performance, see What You May Need to Know About Optimizing View Object Runtime Performance.

Before you begin:

It may be helpful to have an understanding of view objects. For more information, see Populating View Object Rows from a Single Database Table.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To edit a view object definition:

1. In the Applications window, double-click the view object that you want to edit.
2. In the overview editor, click the desired navigation tab.

   The pages of the view object overview editor let you adjust the SQL query, change the attribute names, add named bind variables, add UI controls hints, control Java generation options, and edit other settings.

Overriding the Inherited Properties from Underlying Entity Object Attributes

One interesting aspect of entity-based view objects is that each attribute that relates to an underlying entity object attribute inherits that attribute's properties. Figure 5-8 shows the Details section of the view object editor's Attributes page with an inherited attribute selected. You can see that fields like the Java attribute type and the query column type are disabled and their values are inherited from the related attribute of the underlying entity object to which this view object is related. Some properties like the attribute's data type are inherited and cannot be changed at the view object level.

Other properties like `Queryable` and `Updatable` are inherited but can be overridden as long as their overridden settings are more restrictive than the inherited settings. For example, the attribute from underlying entity object might have an **Updatable** setting of **Always**. As shown Figure 5-8, the Details section of the Attributes page of the view object overview editor allows you to set the corresponding view object attribute to a more restrictive setting like **While New** or **Never**. However, if the attribute in the underlying entity object had instead an **Updatable** setting of **Never**, then the editor would not allow the view object's related attribute to have a less restrictive setting like **Always**.

Customizing View Object Attribute Display in the Overview Editor

When you edit view objects in the overview editor, you can customize the Attributes page of the overview editor to make better use of the attributes table displayed for the view object.

Customization choices that you make for the attributes table include the list of attribute properties to display as columns in the attributes table, the order that the columns appear (from left to right) in the attributes table, the sorting order of the columns, and the width of the columns. The full list of columns that you can choose to display correspond to the properties that you can edit for the attribute.

For example, you can add the **Updatable** property as a column to display in the attributes table when you want to quickly determine which attributes of your view object are updatable. Or, you can add the attributes' **Label** property as a column and see the same description as the end user. Or, you might want to view the list of attributes based on their entity usages. In this case, you can display the **Entity Usage** column and sort the entire attributes table on this column.

When you have set up the attributes table with the list of columns that you find most useful, you can apply the same set of columns to the attributes table displayed for other view objects by right-clicking the attributes table and choose **Apply to All View Objects**.

Before you begin:

It may be helpful to have an understanding of view objects. For more information, see Populating View Object Rows from a Single Database Table.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

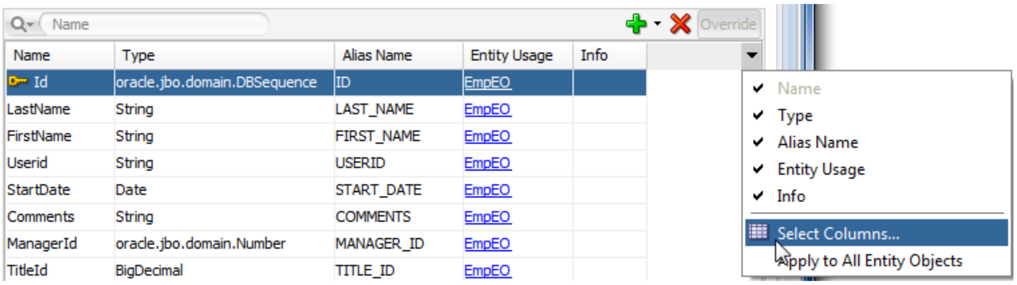
To customize the attributes table display:

1. In the Applications window, double-click the view object for which you want to customize the attributes table display.

2. In the overview editor, click the **Attributes** navigation tab.

3. In the Attributes page, click the dropdown menu icon to the right of the attribute column headers (just below the attributes table's button bar) and choose **Select Columns**.

Figure 5-9 Changing the Attribute Columns to DIsplay in the Overview Editor



Name	Type	Alias Name	Entity Usage	Info
Id	oracle.jbo.domain.DBSequence	ID	EmpEO	
LastName	String	LAST_NAME	EmpEO	
FirstName	String	FIRST_NAME	EmpEO	
Userid	String	USERID	EmpEO	
StartDate	Date	START_DATE	EmpEO	
Comments	String	COMMENTS	EmpEO	
ManagerId	oracle.jbo.domain.Number	MANAGER_ID	EmpEO	
TitleId	BigDecimal	TITLE_ID	EmpEO	

4. In the Select Columns dialog, perform any of the following actions:

   a. Click the left/right shuttle buttons to change the list of visible columns in the attributes table of the overview editor. The overview editor displays only those columns corresponding to the attribute properties that appear the **Selected** list.

   b. Click one of the **Move Selection** buttons to change the position of the columns in the attributes table of the overview editor. The overview editor displays the attribute properties arranged from left to right starting with the property at the top of the **Selected** list.

5. Click **OK**.

6. On the Attributes page of the overview editor, perform any of the following actions:

   a. Select any column header and drag to change the position of the column in the attributes table of the overview editor.

   b. Click any column header to sort all columns in the attributes table by the selected column.

      This feature is particularly useful when you want to focus on a particular column. For example, in the case of an entity-based view object, you can click the **Entity Usage** column header to group attributes in the attributes table by their underlying entity objects.

   c. Click any column header border and drag to adjust the width of the attributes table's column.

   d. Click the dropdown list to the right of the column headers and select among the list of displayed columns to change the visibility of a column in the current attributes table display.

      This feature lets you easily hide columns when you want to simplify the attributes table display in the current view object overview editor.

7. To extend the changes in the columns (including column list, column order, column sorting, and column width) to all other view object overview editors, click the

dropdown menu to the right of the column headers and choose **Apply to All View Objects**.

This feature allows you to easily compare the same attributes across view objects. The overview editor will apply the column selections (and order) that you make in the Select Columns dialog and the current attributes table's column sorting and column widths to all view objects that you edit. View objects that are currently displayed in an open overview editor are not updated with these settings; you must close the open view object overview editor and then reopen the view object to see these settings applied.

Modifying the Order of Attributes in the View Object Source File

After you create a view object definition, you may decide to change the order of the attributes queried by the view object. This view object editing feature allows you to easily change the order that the attributes will appear in the attributes table displayed on the Attributes page of the view object overview editor. Because this feature acts on specific attributes and alters the XML definition of the current view object, it does not apply to other view objects that you may edit. Alternatively, you can sort the display of attributes on the Attribute page of the view object overview editor without affecting the source file by clicking any column header in the overview editor's attributes table.

Before you begin:

It may be helpful to have an understanding of view objects. For more information, see Populating View Object Rows from a Single Database Table.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To modify the order of attributes in the view object source file:

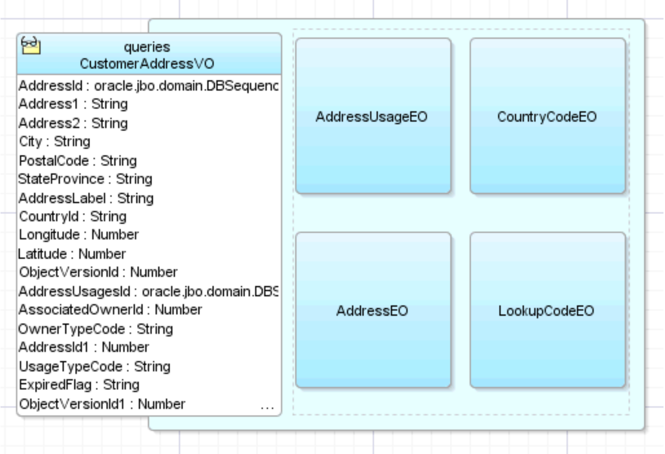
1. In the Applications window, double-click the view object that you want to modify.
2. In the overview editor, click the **Attributes** navigation tab and then click **Set Source Order**.
3. In the Set Source Order dialog, select the attribute you want to reposition and click one of the **Move Selection** buttons.
4. Click **OK**.

   This feature has no affect on other view objects that you may edit; it only affects the current view object.

How to Show View Objects in a Business Components Diagram

JDeveloper's UML diagramming lets you create a Business Components diagram to visualize your business services layer. In addition to supporting entity objects, JDeveloper's UML diagramming allows you to drop view objects onto diagrams as well to visualize their structure and entity usages. For example, if you create a new Business Components Diagram in the `oracle.summit.model` package, and drag the `CustomerAddressVO` view object from the Applications window onto the diagram, its entity usages would display, as shown in Figure 5-10. When viewed as an expanded node, the diagram shows a compartment containing the view objects entity usages.

Figure 5-10 View Object and Its Entity Usages in a Business Components Diagram



Before you begin:

It may be helpful to have an understanding of view objects. For more information, see Populating View Object Rows from a Single Database Table.

You may also find it helpful to understand how to create an entity diagram, see Creating a Diagram of Entity Objects for Your Business Layer.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To create a business components diagram that models existing view objects:

1. In the Applications window, right-click the package in the data model project in which you want to create the business component diagram and choose **New** and then **Business Components Diagram**.
2. In the Create Business Components Diagram dialog, enter the name of the diagram and enter the package name in which the diagram will be created. Select any additional diagram features.
3. Click **OK**.
4. To add existing view objects to the diagram, select them in the Applications window and drop them onto the diagram surface.

Working with View Objects in Declarative SQL Mode

Create entity-based view objects as a no-SQL alternative and utilize ADF Business Components’ declarative SQL mode in design time and runtime.

At runtime, when ADF Business Components works with JDBC to pass a query to the database and retrieve the result, the mechanism to retrieve the data is the SQL query. As an alternative to creating view objects that specify a SQL statement at design time, you can create entity-based view objects that contain no SQL statements. This capability of the ADF Business Components design time and runtime is known as **declarative SQL mode**. When the data model developer works with the wizard or editor for a view object in declarative SQL mode, they require no knowledge of SQL. In declarative SQL mode, the ADF Business Components runtime generates the SQL query statements based on metadata that you must define for the view object, as follows:

- Generates `SELECT` and `FROM` lists based on the rendered web page's databound UI components' usage of one or more entity objects' attributes

  Specifying the runtime query statement based solely on databound UI component attribute usage is an optimization that you control at the level of each view object attribute by changing the attribute's `IsSelected` property setting. By default, the property setting is `IsSelected=true` for each attribute that you add to the view object in declarative SQL mode. The default setting specifies the added attribute will be selected in the SQL statement regardless of whether or not the attribute is exposed in the UI by a databound component. For details about changing the property setting to optimize the runtime query statement, see How to Create Declarative SQL View Objects.

- In the case of ADF RESTful web services, generates a SELECT clause based on the list of attributes specified using the URL query parameter fields.

  SQL SELECT statements executed by the ADF REST resource’s backing view object are based at runtime on how the view object was created. Only view objects that you create with declarative SQL mode enabled support optimized SQL SELECT statements formed exclusively by the list of attributes named by the query parameter fields. The SELECT statement executed by non-declarative view objects will contain all attributes of the view object definition. To gain this runtime optimization, it is therefore recommended that ADF Business Components developers create view objects for ADF REST resources using only declarative SQL mode.

- Generates a `WHERE` clause based on a **view criteria** that you add to the view object definition
- Generates an `ORDERBY` clause based on a sort criteria that you add to the view object definition.
- Augments the `WHERE` clause to support table joins based on named view criteria that you add to the view object definition
- Augments the `WHERE` clause to support master-detail view filtering based on a view criteria that you add to either the source or destination of a view link definition

Additionally, the SQL statement that a declarative SQL mode view object generates at runtime will be determined by the SQL platform specified in the Business Components page of the Project Properties dialog.

> **Note:**
>
> Currently, the supported platforms for runtime SQL generation are SQL92 (ANSI) style and Oracle style. For information about setting the SQL platform for your project, see How to Initialize the Data Model Project With a Database Connection.

Declarative SQL mode selection is supported in JDeveloper as the default setting for all view objects that you create in the Create View Object wizard. The wizard allows you to override the declarative SQL mode setting for any view object you create when you want to create custom SQL at design time.

When you work with custom SQL, the view object definitions you create at design time always contain the entire SQL statement based on the SQL platform required by your application module's defined database connection. Thus the capability of SQL independence does not apply to view objects that you create in custom SQL mode. For information about using the wizard and editor to customize view objects when SQL is desired at design time, see Populating View Object Rows from a Single Database Table.

How to Create Declarative SQL View Objects

All view objects that you create in JDeveloper rely on the same design time wizard and editor. However, when you enable declarative SQL mode, the wizard and editor change to support customizing the view object definition without requiring you to display or enter any SQL. For example, the Query page of the Create View Object wizard with declarative SQL mode enabled lacks the **Generated SQL** field present in normal mode.

Additionally, in declarative SQL mode, since the wizard and editor do not allow you to enter the `WHERE` clause, you provide equivalent functionality by defining a view criteria and sort criteria (using the Sort By panel) respectively. In declarative SQL mode, these criteria appear in the view object metadata definition and will be converted at runtime to their corresponding SQL clause. When the databound UI component has no need to display filtered or sorted data, you may omit the view criteria or sort criteria from the view object definition.

Otherwise, after you enable declarative SQL mode, the basic procedure to create a view object with ensured SQL independence is the same as you would follow to create any entity-based view object. For example, you must still ensure that your view object encapsulates the desired entity object metadata to support the intended runtime query. As with any entity-based view object, the columns of the runtime-generated `FROM` list must relate to the attributes of one or more of the view object's underlying entity objects. In declarative SQL mode, you automatically fulfill this requirement when working with the wizard or editor when you add or remove the attributes of the entity objects on the view object definition.

If you prefer to optimize the declarative SQL query so that the `SELECT` and `FROM` clauses of the SQL query statement are based solely on whether or not the attributes you add to the view object are rendered at runtime by a databound UI component, then you must disable the **Selected in Query** checkbox (sets `IsSelected=false` for the view object definition) for all added attributes. By default, the `IsSelected` property is `true` for any attribute that you add to the view object in declarative SQL mode. The default setting means the added attribute will be selected in the SQL statement regardless of whether or not the attribute is exposed by a databound UI component. When you create a new view object in declarative SQL mode, you can use the Attribute Settings page of the Create View Object wizard to change the setting for each attribute. If you need to alter this setting after you generate the view object, you can use the Properties window to change the **Selected in Query** setting for one or more attributes that you select in the Attributes page of the view object editor.

> **Performance Tip:**
>
> A view object instance configured to generate SQL statements dynamically will requery the database during page navigation if a subset of all attributes with the same list of key entity objects is used in the subsequent page navigation. Thus performance can be improved by activating a superset of all the required attributes to eliminate a subsequent query execution.

Before you begin:

It may be helpful to have an understanding of declarative SQL mode. For more information, see How to Create Declarative SQL View Objects.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To create declarative SQL-based view objects:

1. In the Applications window, right-click the package in the data model project in which you want to create the view objects and choose **New** and then **View Object**.
2. In the Create View Object wizard, on the Name page, enter a package name and a view object name. Keep the default setting **Entity** selected to indicate that you want this view object to manage data with its base entity object. Click **Next**.

   Any other choice for the data selection will disable declarative SQL mode in the Create View Object wizard.
3. On the Entity Objects page, select the entity object whose data you want to use in the view object. Click **Next**.

   When you want to create a view object that joins entity objects, you can add secondary entity objects to the list. To create more complex entity-based view objects, see How to Create Joins for Entity-Based View Objects.
4. On the Attributes page, select at least one attribute from the entity usage in the **Available** list and shuttle it to the **Selected** list. Attributes you do not select will not be eligible for use in view criteria and sort criteria. Click **Next**.

   You should select any attribute that you intend to customize (in the Attribute Settings page) or any attribute that you intend to use in a view criteria or sort criteria (in the Query page). Additionally, the tables that appear in the `FROM` list of the runtime-generated query will be limited to the tables corresponding to the attributes of the entity objects you select.
5. On the Attribute Settings page, use the **Select Attribute** dropdown list to switch between the view object attributes and deselect **Selected in Query** for each attribute that you want to defer adding to the SQL statement until runtime.

   By default, the **Selected in Query** checkbox is enabled for all view object attributes that you add in declarative SQL mode. This default setting will generate a SQL statement with all added attributes selected. When you deselect the checkbox for an attribute, the `IsSelected` property is set to `false` and whether or not the attribute is selected will be determined at runtime by the databound UI component's usage of the attribute.
6. Optionally, change the attribute names or any of their initial settings. Click **Next**.

7. On the Query page, select **Calculate Optimized Query at Runtime** if it is not already displayed. The wizard changes to declarative SQL mode.

   The Create View Object wizard enables declarative SQL mode by default. The default mode allows you to create entity-based view objects that rely on no SQL in the design time. Declarative SQL mode is an alternative to custom SQL mode, which lets you create SQL statements directly in the Create View Object wizard. Deselecting **Calculate Optimized Query at Runtime** enables custom SQL mode.

8. Optionally, define **Where** and **Sort By** criteria (Using the Sort Panel) to filter and sort the data as required. At runtime, ADF Business Components automatically generates the corresponding SQL statements based on the criteria you create.

   Click **Edit** next to the **Where** field to define the view criteria you will use to filter the data. The view criteria you enter will be converted at runtime to a `WHERE` clause that will be enforced on the query statement. For information about specifying view criteria, see Working with Named View Criteria.

   In the **Sort By** panel select the desired attribute in the **Available** list and shuttle it to the **Selected** list. Add additional attributes to the **Selected** list when you want the results to be sorted by more than one column. Arrange the selected attributes in the list according to their sort precedence. Then for each sort attribute, assign whether the sort should be performed in ascending or descending order by selecting **Ascending** or **Descending** in **Sort Order**. Assigning the sort order to each attribute ensures that attributes ignored by the UI component still follow the intended sort order.

9. Click **Finish**.

How to Filter Declarative SQL-Based View Objects When Table Joins Apply

When you create an entity-based view object you can reference more than one entity object in the view object definition. In the case of view objects you create in declarative SQL mode, whether the base entity objects are activated from the view object definition will depend on the requirements of the databound UI component at runtime. If the UI component displays attribute values from multiple entity objects, then the SQL generated at runtime will contain a `JOIN` operation to query the appropriate tables.

Just as with any view object that you create, it is possible to filter the results from table joins by applying named view criteria. In the case of normal mode view objects, all entity objects and their attributes will be referenced by the view object definition and therefore will be automatically included in the view object's SQL statement. However, by delaying the SQL generation until runtime with declarative SQL mode, there is no way to know whether the view criteria should be applied.

> **Note:**
>
> In declarative SQL mode, you can define a view criteria to specify the `WHERE` clause (optional) when you create the view object definition. This type of view criteria when it exists by default will be applied at runtime. For a description of this usage of the view criteria, see How to Create Declarative SQL View Objects.

Because the UI component may not display sufficient attributes to cause a SQL `JOIN` for a view object with multiple entity objects defined in declarative SQL mode, named view criteria that you define to filter query results should be applied conditionally at runtime. In other words, named view criteria that you create for declarative SQL-based view objects need not be applied as required, automatic filters. To support declarative SQL mode, named view criteria that you apply to a view object created in declarative SQL mode can be set to apply only on the condition that the UI component is bound to the attributes referenced by the view criteria. The named view criteria once applied will, however, support the UI component's need to display a filtered result set.

Before you begin:

It may be helpful to have an understanding of SQL independence at runtime. For more information, see Working with View Objects in Declarative SQL Mode.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

- Create the view object with declarative SQL mode enabled, as described in How to Create Declarative SQL View Objects.
- Create a view criteria to filter the results from table joins, as described in How to Create Named View Criteria Declaratively.

  You will use the Edit View Criteria dialog to create the named view criteria by selecting one or more attributes from the joined entity objects. You then enable its conditional usage by setting **AppliedIfJoinSatisfied** in the Properties window.

To define a view criteria to filter only when the join is satisfied:

1. In the Applications window, double-click the declarative SQL view object that supports table joins.
2. In the overview editor, click the **View Criteria** navigation tab.
3. In View Criteria page, select the view criteria you created to filter the declarative SQL view object.

   The join view criteria must refer only to attributes from the joined entity objects.
4. In the Properties window, when you have selected one or more attributes from the joined entity objects, select **true** from the **AppliedIfJoinSatisfied** dropdown list.

   The property value **true** means you want the view criteria to be applied only on the condition that the UI component requires the attributes referenced by the view criteria. The default value **false** means that the view criteria will automatically be applied at runtime. In the case of declarative SQL mode-based view objects, the value **true** ensures that the query filter will be appropriate to needs of the view object's databound UI component.

How to Filter Master-Detail Related View Objects with Declarative SQL Mode

Just as with normal mode view objects, you can link view objects that you create in declarative SQL mode to other view objects to form master-detail hierarchies of any complexity. The steps to create the view links are the same as with any other entity-based view object, as described in How to Create a Master-Detail Hierarchy

Based on Entity Associations. However, in the case of view objects that you create in declarative SQL mode, you can further refine the view object results in the Source SQL or Destination SQL dialog for the view link by selecting a previously defined view criteria in the Create View Link wizard or the overview editor for the view link.

Before you begin:

It may be helpful to have an understanding of SQL independence at runtime. For more information, see Working with View Objects in Declarative SQL Mode.

You may also find it helpful to understand functionality that can be added using other view object features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

1. Create the master and detail view objects with declarative SQL mode enabled, as described in How to Create Declarative SQL View Objects.
2. Define the desired view criteria for either the source (master) view object or the destination (detail) view object, as described in How to Filter Declarative SQL-Based View Objects When Table Joins Apply.
3. Create the view link, as described in How to Create a Master-Detail Hierarchy Based on Entity Associations.

To filter a view link source or view link destination:

1. In the Applications window, double-click the view link you created to form the master-detail hierarchy.
2. In the overview editor, click the **Query** navigation tab.
3. In the Query page, expand the **Source** or **Destination** section and from the **View Criteria** dropdown list, select the desired view criteria.

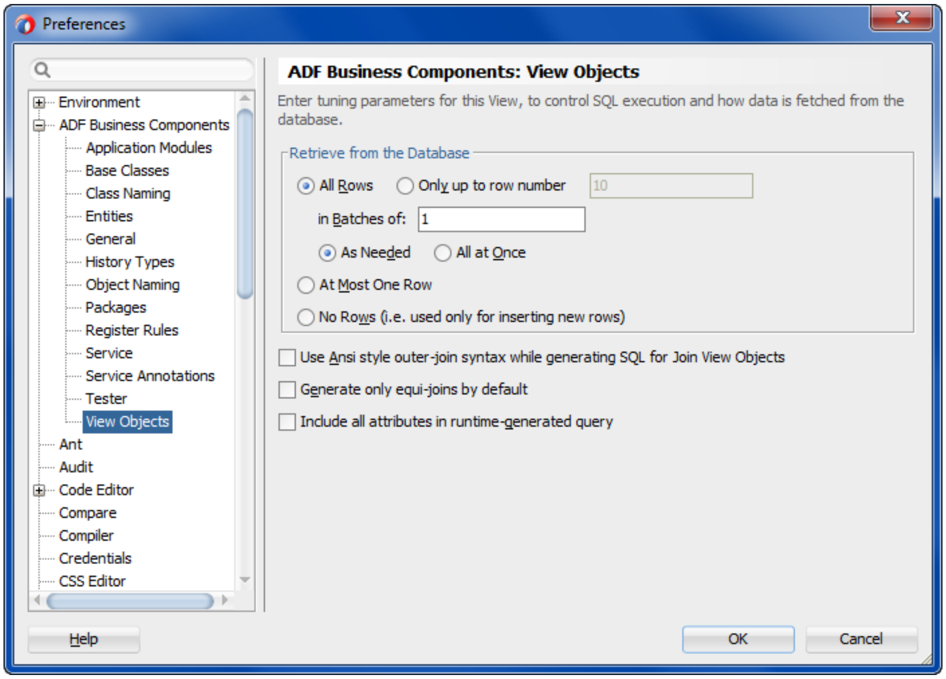
   The dropdown list will be empty if no view criteria exist for the view object.

   > **Tip:**
   >
   > If the overview editor does not display a dropdown list for view criteria selection, then the view objects you selected for the view link were not created in declarative SQL mode. For view objects created in normal or custom SQL mode, you must edit the `WHERE` clause to filter the data as required.

How to Support Programmatic Execution of Declarative SQL Mode View Objects

Typically, when you define a declarative SQL mode view object, the attributes that get queried at runtime will be determined by the requirements of the databound UI component as it is rendered in the web page. This is the runtime-generation capability that makes view objects independent of the design time database's SQL platform. However, you may also need to execute the view object programmatically without exposing it to an ADF binding in the UI. In this case, you can enable the **Include all attributes in runtime-generated query** option to ensure that a programmatically executed view object has access to all of the entity attributes. Figure 5-11 shows the global preference **Include all attributes in runtime-generated query** set to enabled.

Figure 5-11 Preferences Dialog with Declarative SQL Mode Enabled



ADF Business Components: View Objects

Enter tuning parameters for this View, to control SQL execution and how data is fetched from the database.

Retrieve from the Database

● All Rows ○ Only up to row number 10

in Batches of: 1

● As Needed ○ All at Once

○ At Most One Row

○ No Rows (i.e. used only for inserting new rows)

□ Use Ansi style outer-join syntax while generating SQL for Join View Objects

□ Generate only equi-joins by default

□ Include all attributes in runtime-generated query

> **Note:**
>
> Be careful to limit the use of the **Include all attributes in runtime-generated query** option to programmatically executed view objects. If you expose the view object with this setting enabled to a databound UI component, the runtime query will include all attributes.

The **Include all attributes in runtime-generated query** option can be specified as a global preference setting or as a setting on individual view objects. Both settings may be used in these combinations:

- Enable the global preference so that every view object you create includes all attributes in the runtime query statement.
- Enable the global preference, but disable the setting on view objects that will not be executed programmatically and therefore should not include all attributes in the runtime query statement.
- Disable the global preference (default), but enable the setting on view objects that will be executed programmatically and therefore should include all attributes in the runtime query statement.

Forcing Attribute Queries for All Declarative SQL Mode View Objects

You can enable the global preference to force attribute queries for all declarative SQL mode view objects as the default mode, or you can leave the option disabled and enable the option directly in the overview editor for a specific view object.

Before you begin:

It may be helpful to have an understanding of how the **Include all attributes in runtime-generated query** option supports programmatic execution of declarative SQL mode view objects. For more information, see How to Support Programmatic Execution of Declarative SQL Mode View Objects.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To set the global preference to include all attributes in the query:

1. In the main menu, choose **Tools** and then **Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and select **View Objects**.
3. Select **Include all attributes in runtime-generated query** to force all attributes of the view object's underlying entity objects to participate in the query and click **OK**.

   Enabling this option sets a flag in the view object definition but you will still need to add entity object selections and entity object attribute selections to the view object definition.

Forcing Attribute Queries for Specific Declarative SQL Mode View Objects

When you want to force all attributes for a specific view object to participate in the view object query, you can specify this in the **Tuning** section of the General page of the overview editor. The overview editor only displays the **Include all attributes in runtime-generated query** option if you have created the view object in declarative SQL mode.

Before you begin:

It may be helpful to have an understanding of how the **Include all attributes in runtime-generated query** option supports programmatic execution of declarative SQL mode view objects. For more information, see How to Support Programmatic Execution of Declarative SQL Mode View Objects.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the view object in the Create View Object wizard and be sure that you have enabled declarative SQL mode, as described in How to Create Declarative SQL View Objects.

To set the view object-specific preference to include all attributes in the query:

1. In the Applications window, double-click the declarative SQL view object.

2. In the overview editor, click the **General** navigation tab.

   You can verify that the view object was created in declarative SQL mode in the overview editor. In the overview editor, click the **Query** navigation tab and then in the Query page, verify that the **Mode** dropdown list shows the selection **Declarative**.

3. In the General page, expand the **Tuning** section and select **Include all attributes in runtime-generated query**.

   Enabling this option forces all attributes of the view object's underlying entity objects to participate in the query. When enabled, it sets a flag in the view object definition but you will still need to add entity object selections and entity object attribute selections to the view object definition.

What Happens When You Create a View Object in Declarative SQL Mode

When you create the view object in declarative SQL mode, three properties get added to the view object's metadata: `SelectListFlags`, `FromListFlags`, and `WhereFlags`. Properties that are absent in declarative SQL mode are the normal mode view object's `SelectList`, `FromList`, and `Where` properties, which contain the actual SQL statement (or, for custom SQL mode, the `SQLQuery` element). The following example shows the three view object metadata flags that get enabled in declarative SQL mode to ensure that SQL will be generated at runtime instead of specified as metadata in the view object's definition.

```
<ViewObject
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="CustomerCardStatus"
  SelectListFlags="1"
  FromListFlags="1"
  WhereFlags="1"
   ...
```

Similar to view objects that you create in either normal or custom SQL mode, the view object metadata also includes a `ViewAttribute` element for each attribute that you select in the Attribute page of the Create View Object wizard. However, in declarative SQL mode, when you "select" attributes in the wizard (or add an attribute in the overview editor), you are not creating a `FROM` or `SELECT` list in the design time. The attribute definitions that appear in the view object metadata only determine the list of potential entities and attributes that will appear in the runtime-generated statements. For information about how ADF Business Components generates these SQL lists, see What Happens at Runtime: Declarative SQL Mode Queries.

The following example shows the additional features of declarative SQL mode view objects, including the optional declarative `WHERE` clause (`DeclarativeWhereClause` element) and the optional declarative `ORDERBY` clause (`SortCriteria` element).

```
<DeclarativeWhereClause>
    <ViewCriteria
        Name="CustomerStatusWhereCriteria"
        ViewObjectName="oracle.summit.model.views.CustomerCardStatus"
        Conjunction="AND"
        Mode="3"
        AppliedIfJoinSatisfied="false">
        <ViewCriteriaRow
            Name="vcrow60">
            <ViewCriteriaItem
                Name="CardTypeCode"
                ViewAttribute="CardTypeCode"
                Operator="STARTSWITH"
                Conjunction="AND"
                Required="Optional">
            <ViewCriteriaItemValue
                Value=":cardtype"
                IsBindVarValue="true"/>
            </ViewCriteriaItem>
        </ViewCriteriaRow>
    </ViewCriteria>
    </DeclarativeWhereClause>
    <SortCriteria>
       <Sort
        Attribute="CustomerId"/>
       <Sort
        Attribute="CardTypeCode"/>
    </SortCriteria>
```

What Happens at Runtime: Declarative SQL Mode Queries

At runtime, when a declarative SQL mode query is generated, ADF Business Components determines which attributes were defined from the metadata ViewCriteria element and SortCriteria element. It then uses these attributes to generate the WHERE and Sort By clauses. Next, the runtime generates the FROM list based on the tables corresponding to the entity usages defined by the metadata ViewAttribute elements. Finally, the runtime builds the SELECT statement based on the attribute selection choices the end user makes in the UI. As a result, the view object in declarative SQL mode generates all SQL clauses entirely at runtime. The runtime-generated SQL statements will be based on the platform that appears in the project properties setting. Currently, the runtime supports SQL92 (ANSI) style and Oracle style platforms.

Note that the binding style of SQL queries will be determined by the SQL flavor chosen for the application. In practice, all queries must use the same binding style (named or positional) or SQL validation errors may result. To avoid this issue, application developers must ensure that all ADF applications that they deploy to the same managed server all use a single value for their chosen SQL platform. For more information, see How to Initialize the Data Model Project With a Database Connection.

What You May Need to Know About Working Programmatically with Declarative SQL Mode View Objects

As a convenience to developers, the view object implementation API allows individual attributes to be selected and deselected programmatically. This API may be useful in combination with the view objects you create in declarative SQL mode and intend to execute programmatically. The following example shows how to call selectAttributeDefs() on the view object when you want to add a subset of attributes to those already configured with SQL mode enabled.

```
ApplicationModule am = Configuration.createRootApplicationModule(amDef, config);
ViewObjectImpl vo = (ViewObjectImpl) am.findViewObject("CustomerVO");
vo.resetSelectedAttributeDefs(false);
vo.selectAttributeDefs(new String[] {"FirstName, "LastName"});
vo.executeQuery();
```

The call to `selectAttributeDefs()` adds the attributes in the array to a private member variable of `ViewObjectImpl`. A call to `executeQuery()` transfers the attributes in the private member variable to the actual select list. It is important to understand that these `ViewObjectImpl` attribute calls are not applicable to the client layer and are only accessible inside the `Impl` class of the view object on the middle tier.

Additionally, you might call `unselectAttributeDefs()` on the view object when you want to deselect a small subset of attributes after *enabling* the **Include all attributes in runtime-generated query** option. Alternatively, you can call `selectAttributeDefs()` on the view object to select a small subset of attributes after *disabling* the **Include all attributes in runtime-generated query** option.

> **Caution:**
>
> Be careful not to expose a declarative SQL mode view object executed with this API to the UI since only the value of the **Include all attributes in runtime-generated query** option will be honored.

Creating View Objects Populated With Static Data

Create ADF Business Components static data view objects to access a small set of static data, and avoid unnecessary querying of the database.

ADF Business Components lets you create view objects in your data model project with rows that you populate at design time. Typically, you create static data view objects when you have a small amount of data to maintain and you do not expect that data to change frequently. The decision whether to use a lookup table from the database or whether to use a static data view object based on a list of hardcoded values depends on the size and nature of the data. The static data view object is useful when you have no more than 100 entries to list. Any larger number of rows should be read from the database with a conventional table-based view object. The static data view object has the advantage of being easily translatable since attribute values are stored in a resource bundle. However, all of the rows of a static data view object will be retrieved at once and therefore, using no more than 100 entries yields the best performance.

> **Best Practice:**
>
> When you need to create a view object to access a small list of static data, you should use the static data view object rather than query the database. The static data view object is ideal for lists not exceeding 100 rows of data. Because the Create View Object wizard saves the data in a resource message file, these data are easily translatable.

Static data view objects are useful as an LOV data source when it is not desirable to query the database to supply the list of values. Suppose your order has the following statuses: open, closed, pending. You can create a static data view object with these values and define an LOV on the static data view object's status attribute. Because the wizard stores the values of the status view object in a translatable resource file, the UI will display the status values using the resource file corresponding to the application's current locale.

How to Create Static Data View Objects with Data You Enter

You use the Create View Object wizard to create static data view objects. The wizard lets you define the desired attributes (columns) and enter as many rows of data as necessary. The wizard displays the static data table as you create it.

> **Note:**
>
> Because the data in a static data view object does not originate in database tables, the view object will be read-only.

You can also use the Create View Object wizard to create the attributes based on data from a comma-separated value (CSV) file format like a spreadsheet file.

Before you begin:

It may be helpful to have an understanding of static data view objects. For more information, see Creating View Objects Populated With Static Data.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To manually create attributes for a static data view object:

1. In the Applications window, right-click the package in the data model project in which you want to create the static data view object and choose **New** and then **View Object**.
2. In the Create View Object wizard, on the Name page, enter a package name and a view object name. Select **Static list** to indicate that you want to supply static data for this view object. Click **Next**.
3. On the Attributes page, click **New** to add an attribute that corresponds to the columns in the static list table. In the New View Object Attribute dialog, enter a name and select the attribute type. Click **OK** to return to the wizard, and click **Next**.
4. On the Attribute Settings page, do nothing and click **Next**.
5. On the Static List page, click the **Add** button to enter the data directly into the wizard page. The attributes you defined will appear as the columns for the static data table.
6. On the Application Module pages, do nothing and click **Next**.
7. On the Summary page, click **Finish**.

How to Create Static Data View Objects with Data You Import

Using the Import feature of the Create View Object wizard, you can create a static data view object with attributes based on data from a comma-separated value (CSV) file format like a spreadsheet file. The wizard will use the first row of a CSV flat file to identify the attributes and will use the subsequent rows of the CSV file for the data for each attribute. For example, if your application needs to display choices for international currency, you might define the columns Symbol, Country, and Description in the first row and then add rows to define the data for each currency type, as shown in Figure 5-12.

Figure 5-12 Sample Data Ready to Import from CSV Flat File

	A	B	C
1	Symbol	Country	Description
2	USD	United States of America	Dollars
3	CNY	P.R. China	Yuan Renminbi
4	EUR	Europe	Euro
5	JPY	Japan	Yen

Before you begin:

It may be helpful to have an understanding of static data view objects. For more information, see Creating View Objects Populated With Static Data.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To create attributes of a static data view object based on a flat file:

1. In the Applications window, right-click the project in which you want to create the static data view object and choose **New** and then **View Object**.
2. In the Create View Object wizard, on the Name page, enter a package name and a view object name. Select **Static list** to indicate that you want to supply static data for this view object. Click **Next**.
3. On the Attributes page, if the CSV flat file does not define column names in the first row of the file, click **New** to add an attribute that corresponds to the column names in the static data table. In the New View Object Attribute dialog, enter a name and select the attribute type. Click **OK** to return to the wizard, and click **Next**.

   The attributes you add must match the order of the data columns defined by the flat file. If you create fewer attributes than columns, the wizard will ignore extra columns during import. Conversely, if you create more attributes than columns, the wizard will define extra attributes with value null.
4. On the Attribute Settings page, do nothing and click **Next**.
5. On the Static List page, click **Import** to locate the CSV file and display the data in the wizard. Verify the data and edit the values as needed.

   If you created the attribute names yourself and the first row of the CSV file displays the column names in the first row, the column names will be displayed in the wizard as data and should be deleted. To edit an attribute value, double-click in the value field.
6. Optionally, click the **Add** button or **Remove** button to change the number of rows of data. Click **Next**.

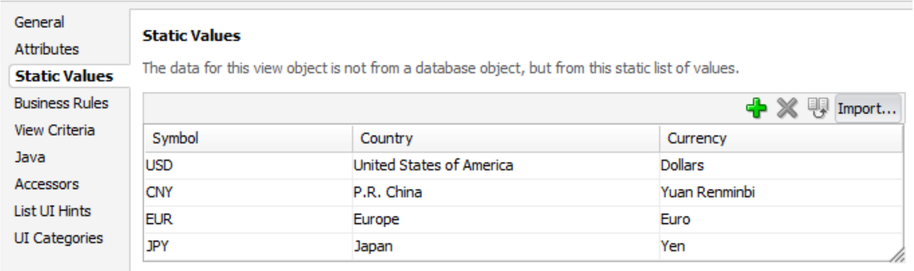
   To enter values for the attributes of a new row, double-click in the value field.
7. On the Application Module page, do nothing and click **Next**.

8. On the Summary page, click **Finish**.

What Happens When You Create a Static Data View Object

When you create a static data view object, the overview editor for the view object displays the rows of data that you defined in the wizard. You can use the editor to define additional data, as shown in Figure 5-13.

Figure 5-13 Static Values Page Displays Data



Static Values

The data for this view object is not from a database object, but from this static list of values.

Symbol	Country	Currency
USD	United States of America	Dollars
CNY	P.R. China	Yuan Renminbi
EUR	Europe	Euro
JPY	Japan	Yen

The generated XML definition for the static data view object contains one transient attribute for each column of data. For example, if you import a CSV file with data that describes international currency, your static data view object might contain a transient attribute for `Symbol`, `Country`, and `Description`, as shown in the following example.

```
<ViewObject
...
<!-- Transient attribute for first column -->
  <ViewAttribute
    Name="Symbol"
    IsUpdateable="false"
    IsSelected="false"
    IsPersistent="false"
    PrecisionRule="true"
    Precision="255"
    Type="java.lang.String"
    ColumnType="VARCHAR2"
    AliasName="Symbol"
    SQLType="VARCHAR"/>
<!-- Transient attribute for second column -->
  <ViewAttribute
    Name="Country"
    IsUpdateable="false"
    IsPersistent="false"
    PrecisionRule="true"
    Precision="255"
    Type="java.lang.String"
    ColumnType="VARCHAR"
    AliasName="Country"
    SQLType="VARCHAR"/>
<!-- Transient attribute for third column -->
  <ViewAttribute
    Name="Description"
    IsUpdateable="false"
    IsPersistent="false"
    PrecisionRule="true"
    Precision="255"
    Type="java.lang.String"
    ColumnType="VARCHAR"
    AliasName="Description"
    SQLType="VARCHAR"/>
  <StaticList
    Rows="4"
    Columns="3"/>
<!-- Reference to file that contains static data -->
  <ResourceBundle>
    <PropertiesBundle
      PropertiesFile="model.ModelBundle"/>
  </ResourceBundle>
</ViewObject>
```

Because the data is static, the overview editor displays no Query page and the generated XML definition for the static data view object contains no query statement. Instead, the `<ResourceBundle>` element in the XML definition references a resource bundle file. The following example shows the reference to the file as `PropertiesFile="model.ModelBundle"`. The resource bundle file describes the rows of data and also lets you localize the data. When the default resource bundle type is used, the file `ModelBundle.properties` appears in the data model project, as shown in the following example.

```
model.ViewObj.SL_0_0=USD
model.ViewObj.SL_0_1=United States of America
model.ViewObj.SL_0_2=Dollars
model.ViewObj.SL_1_0=CNY
model.ViewObj.SL_1_1=P.R. China
model.ViewObj.SL_1_2=Yuan Renminbi
model.ViewObj.SL_2_0=EUR
model.ViewObj.SL_2_1=Europe
model.ViewObj.SL_2_2=Euro
model.ViewObj.SL_3_0=JPY
model.ViewObj.SL_3_1=Japan
model.ViewObj.SL_3_2=Yen
```

How to Edit Static Data View Objects

When you need to make changes to the static list table, double-click the view object in the Applications window to open the overview editor for the view object. You can add and delete attributes (columns in the static list table), add or delete rows (data in the static list table), sort individual rows, and modify individual attribute values. The editor will update the view object definition file and save the modified attribute values in the message bundle file. For information about localizing message bundles, see Working with Resource Bundles.

What You May Need to Know About Static Data View Objects

The static data view object has a limited purpose in the application module's data model. Unlike entity-based view objects, static data view objects will not be updatable. You use the static data view object when you want to display read-only data to the end user and you do not want to create a database table for the small amount of data the static list table contains.

Adding Calculated and Transient Attributes to a View Object

ADF Business Components view objects can include SQL-calculated attributes and transient attributes that do not map to any entity object attributes.

In addition to having attributes that map to underlying entity objects, your view objects can include calculated attributes that don't map to any entity object attribute value. The two kinds of calculated attributes are known as:

- **SQL-calculated attributes**, when their value is retrieved as an expression in the SQL query's SELECT list
- **Transient attributes,** when their value is not retrieved as part of the query

A view object can include an entity-mapped attribute which itself is a transient attribute at the entity object level.

How to Add a SQL-Calculated Attribute

You use the overview editor for the view object to add a SQL-calculated attribute.

Before you begin:

It may be helpful to have an understanding of calculated attributes. For more information, see Adding Calculated and Transient Attributes to a View Object.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

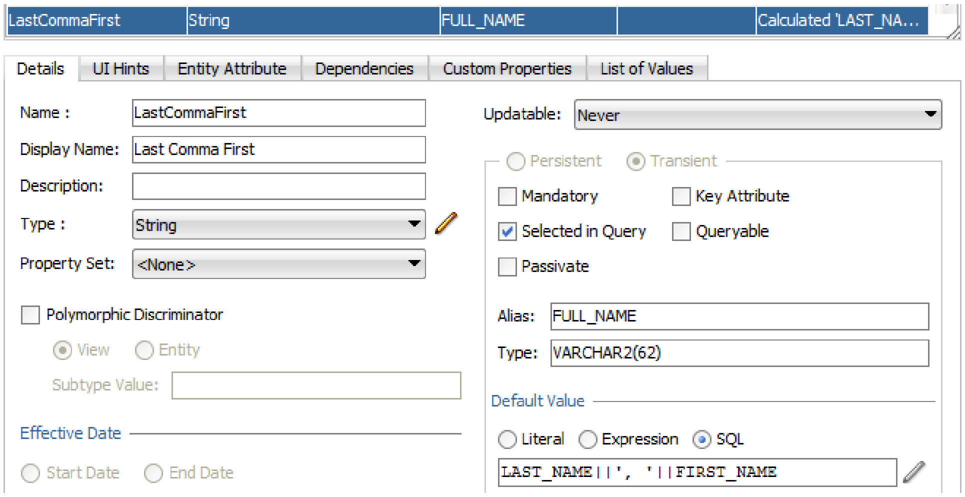
To add a SQL-calculated attribute to a view object:

1. In the Applications window, double-click the view object for which you want to define a SQL-calculated attribute.
2. In the overview editor, click the **Attributes** navigation tab and then click the **Create new attribute** button.
3. In the New View Object Attribute dialog, enter a name for the attribute.
4. In the overview editor, in the Attributes page, select the new attribute.
5. Click the **Details** tab, set the Java type to an appropriate value.

   For example, a calculated attribute that concatenates a first name and a last name would have the type `String`, as shown in Figure 5-14.
6. In the **Default Value** section, select **SQL** and provide a SQL expression in the expression field.

   For example, to change the order of first name and last name, you could write the expression `LAST_NAME||', '||FIRST_NAME`, as shown in Figure 5-14.

Figure 5-14 New SQL-Calculated Attribute



LastCommaFirst	String	FULL_NAME		Calculated 'LAST_NA...

Name : LastCommaFirst

Display Name: Last Comma First

Description:

Type : String

Property Set: <None>

☐ Polymorphic Discriminator

● View ○ Entity

Subtype Value:

○ Start Date ○ End Date

Updatable: Never

○ Persistent ● Transient

☐ Mandatory ☐ Key Attribute

☑ Selected in Query ☐ Queryable

☐ Passivate

Alias: FULL_NAME

Type: VARCHAR2(62)

○ Literal ○ Expression ● SQL

LAST_NAME||', '||FIRST_NAME

7. Consider changing the SQL column alias to match the name of the attribute.
8. Verify the database query column type and adjust the length (or precision/scale) as appropriate.

What Happens When You Add a SQL-Calculated Attribute

When you add a SQL-calculated attribute in the overview editor for the view object, JDeveloper updates the XML document for the view object to reflect the new attribute. The entity-mapped attribute's `<ViewAttribute>` tag looks like the sample shown in the following example. The entity-mapped attribute inherits most of it properties from the underlying entity attribute to which it is mapped.

```
<ViewAttribute
   Name="LastName"
   IsNotNull="true"
   EntityAttrName="LastName"
   EntityUsage="EmpEO"
   AliasName="LAST_NAME" >
</ViewAttribute>
```

Whereas, in contrast, a SQL-calculated attribute's `<ViewAttribute>` tag looks like sample shown in the following example. As expected, the tag has no `EntityUsage` or `EntityAttrName` property, and includes datatype information along with the SQL expression.

```
<ViewAttribute
   Name="LastCommaFirst"
   IsUpdatable="false"
   IsPersistent="false"
   PrecisionRule="true"
   Type="java.lang.String"
   ColumnType="VARCHAR2"
   AliasName="FULL_NAME"
   SQLType="VARCHAR" >
   Precision="62"
   Expression="LAST_NAME||', '||FIRST_NAME">
</ViewAttribute>
```

What You May Need to Know About SQL-Calculated Attributes

The view object includes the SQL expression for your SQL-calculated attribute in the `SELECT` list of its query at runtime. The database is the one that evaluates the expression, and it returns the result as the value of that column in the query. The value is reevaluated each time you execute the query.

How to Add a Transient Attribute

Transient attributes are often used to provide subtotals or other calculated expressions that are not stored in the database.

Before you begin:

It may be helpful to have an understanding of transient attributes. For more information, see Adding Calculated and Transient Attributes to a View Object.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

Transient attributes that you define may be evaluated using the Groovy Expression Language. Groovy lets you insert expressions and variables into strings. The expression is saved as part of the view object definition. For more information, see Using Groovy Scripting Language With Business Components.

You should be familiar with the limitations of using transient attributes. For more information, see What You May Need to Know About View Object Queries with Primary Keys Defined by Transient Attributes.

You will need to complete this task:

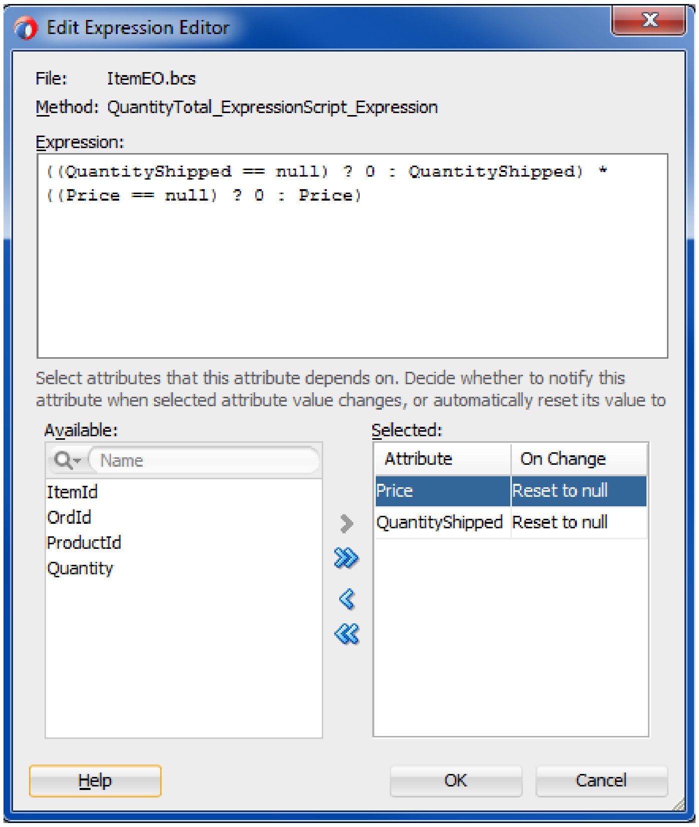
> Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To add a transient attribute to a view object:

1. In the Applications window, double-click the view object for which you want to define a transient attribute.
2. In the overview editor, click the Attributes navigation tab and then click the **Create new attribute** button.
3. In the New View Object Attribute dialog, enter a name for the attribute and select the Java attribute type from the **Type** dropdown, then click **OK**.
4. On the Attributes page of the overview editor, click the Details tab and select the **Transient** option.
5. If the transient attribute's default value is to be calculated by an expression, under Default Value, select **Expression** checkbox and click the icon beside to open the Edit Expression Editor dialog.
6. In the Edit Expression Editor dialog, enter a default value expression that calculates the default value of the attribute.

   Transient attribute expressions may derive the value from persistent attributes that are defined by the view object. If you need to refer to an entity attribute, that attribute must be added to the view object definition.

Figure 5-15 Edit Expression Editor



File: ItemEO.bcs

Method: QuantityTotal_ExpressionScript_Expression

Expression:

```
((QuantityShipped == null) ? 0 : QuantityShipped) *
((Price == null) ? 0 : Price)
```

Select attributes that this attribute depends on. Decide whether to notify this attribute when selected attribute value changes, or automatically reset its value to

Available:

ItemId
OrdId
ProductId
Quantity

Selected:

Attribute	On Change
Price	Reset to null
QuantityShipped	Reset to null

7. Specify the attributes on which this attribute is dependent. Move these attributes from Available to Selected.

8. Click **OK** to save the expression that you entered in the Edit Expression Editor dialog.

9. You can optionally provide a condition for when to recalculate the expression in the Refresh Expression Value field. The procedure to define the recalculation expression is the same as the procedure to define the default value expression. The recalculation expression if evaluated as true, recalculates the default value expression.

   For example, the following Refresh Expression Value Groovy expression causes the attribute to be recalculated when either the `Country` attribute or the `RegionId` attribute are changed:

   ```
   return (adf.object.isAttributeChanged("Country") ||
   adf.object.isAttributeChanged("RegionId"));
   ```

> **Note:**
>
> When either the value expression or the optional recalculate expression that you define references an attribute from the base entity object, you must define this as a dependency in the Edit Expression Editor dialog. Locate each attribute in the Available list and shuttle it to the Selected list.

How to Add a Transient Attribute Defined by an Entity Object

A view object can include an entity-mapped attribute which itself is a transient attribute at the entity object level.

Before you begin:

It may be helpful to have an understanding of transient attributes. For more information, see Adding Calculated and Transient Attributes to a View Object.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To add a transient attribute from an entity object to an entity-based view object:

1. In the Applications window, double-click the view object for which you want to add a transient attribute based on an entity usage.
2. In the overview editor, click the **Attributes** navigation tab and then click the **Create new attribute** button and choose **Add Attribute from Entity** to view the list of available entity-derived attributes.
3. In the Attributes dialog, move the desired transient attribute from the **Available** list into the **Selected** list.
4. Click **OK**.

How to Add a Validation Rule to a Transient Attribute

Attribute-level validation rules are triggered for a particular view object transient attribute when either the end user or the program code attempts to modify the attribute's value. Since you cannot determine the order in which attributes will be set, attribute-level validation rules should be used only when the success or failure of the rule depends exclusively on the candidate value of that single attribute.

The process for adding a validation rule to a view object transient attribute is similar to the way you create any declarative validation rule, and is done using the Add Validation Rule dialog. You can open this dialog from the overview editor for the view object by clicking the **Add Validation Rule** button in the Validation Rules section of the Attributes page. You must first select the transient attribute from the attributes list and the transient attribute must be defined as updatable. Validation rules cannot be defined for read-only transient attributes.

Before you begin:

It may be helpful to have an understanding of attribute UI hints. For more information, see Defining UI Hints for View Objects.

You may also find it helpful to understand the different types of validation rules you can define. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To add a validation rule for a transient attribute:

1. In the Applications window, double-click the desired view object.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the transient attribute, and then click the **Details** tab and verify that **Updatable** displays **Always**.

   Validation rules for transient attributes must be updatable. The value **Never** specifies a read-only attribute.
4. In the Attributes page, click the **Validation Rules** tab and then click the **Add Validation Rule** icon.
5. In the Add Validation Rule dialog, select the type of validation rule desired from the **Type** dropdown list.
6. In the **Rule Definition** tab, use the dialog settings to configure the new rule.

   The controls will change depending on the kind of validation rule you select. For more information about the different validation rules, see Using the Built-in Declarative Validation Rules.
7. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails. For more information, see Creating Validation Error Messages.
8. Click **OK**.

What Happens When You Add a Transient Attribute

When you add a transient attribute in the overview editor for a view object, JDeveloper updates the XML document for the view object to reflect the new attribute. A transient attribute's <ViewAttribute> tag in the XML is similar to the SQL-calculated one, but it lacks an Expression property.

When you base a transient attribute on a Groovy expression, a <TransientExpression> tag is created within the appropriate attribute. The following example shows XML code for a Groovy expression. The Groovy expression is added for the SalesRepName attribute of the OrdVO view object. The XML definition shows that the .bcs file where this Groovy expression script resides in is part of this XML definition: CodeSourceName=”OrdVORow”. Therefore, the .bcs file name is OrdVORow.bcs. There is also an operations.xml file, which in this example is OrdVOOperations.xml; this operations.xml file has an URI which points the user to the .bcs file.

```
<ViewAttribute
    Name="SalesRepName"
    IsUpdateable="false"
    IsSelected="false"
    IsPersistent="false"
    PrecisionRule="true"
    Type="java.lang.String"
    ColumnType="CHAR"
    AliasName="VIEW_ATTR"
    SQLType="VARCHAR">
    <TransientExpression
       Name="ExpressionScript"
       trustMode="untrusted"
       CodeSourceName="OrdVORow"/>
  </ViewAttribute>
```

What You May Need to Know About Transient Attributes and Calculated Values

A transient attribute is a placeholder for a data value. If you change the **Updatable** property of the transient attribute to **Always**, the end user can enter a value for the attribute. If you want the transient attribute to display a calculated value, then you'll typically leave the **Updatable** property set to **Never** and write a Groovy Language expression on the Attribute page of the overview editor for the view object.

Alternatively, if you want to write Java code to calculate the transient attribute, you need to enable a custom view row class and choose to generate accessor methods, in the Java dialog that you open by clicking the **Edit** button on the Java page of the overview editor for the view object. Then you would write Java code inside the accessor method for the transient attribute to return the calculated value. The following example shows the `CustomerVORowImpl.java` view row class contains the Java code to return a calculated value in the `getFirstDotLast()` method.

```
// In CustomerVORowImpl.java
public String getFirstDotLast() {
  // Commented out this original line since we're not storing the value
  // return (String) getAttributeInternal(FIRSTDOTLAST);
  return getFirstName().substring(0,1)+". "+getLastName();
}
```

What You May Need to Know About View Object Queries with Primary Keys Defined by Transient Attributes

In general, because a transient attribute will force reevaluation of the primary key attribute with each access, defining the primary key with a transient attribute may not be suitable for all use cases. In particular, Oracle recommends that you avoid using a transient attribute to define the primary key of any view object that will be bound to an **ADF Faces** component that may produce multiple queries, such as an ADF Tree component. In such situations, the performance of the application will be degraded by the need to reevaluate the transient attribute as the primary key.

Additionally, you should be aware that when your programmatic view object query relies on transient attributes for it primary key, it is possible for the user to receive a null pointer exception when they scroll the UI out of the view object's cached rows. In this case, since the view object query is not generated from a database table, your view object implementation must override the `ViewObjectImpl` classes' `retrieveByKey()` method to return the rows (or return an empty array when no rows are found).

Overriding this method will allow **ADF Business Components** to execute findByKey() to first find the requested rows from the cache. When that fails (because the primary key is a transient attribute), ADF Business Components will execute your retrieveByKey() override to perform the operations you defined to retrieve the rows that match the key coming in. The default implementation of this method tries to issue a database query to get the row(s) from the database:

```
protected Row[] retrieveByKey(ViewRowSetImpl rs, Key key,
                                  int maxNumOfRows, boolean skipWhere)
```

The method has these arguments:

maxNumOfRows is the maxNumOfRows you passed into the call to findByKey(). It may be 1 .. *n* or -1. *n* means that it's looking for *n* many rows whose key matches the one that got passed in. -1 means match all rows. Note that it is possible for the view object to have more than one row that matches the key when the key is a partial key and the view object is based on multiple entity objects.

skipWhere controls whether findByKey() should apply the same WHERE clause as the base view object. If the base view object has a WHERE clause DEPTNO = 10, if skipWhere is false, you're supposed to apply the same WHERE clause when looking for the row(s) from the backing store. If skipWhere is true, then don't bother with the WHERE clause from the base view object.

Limiting View Object Rows Using Effective Date Ranges

You can define an ADF view object to query data in a particular date range and limit view rows to fall in the purview of this date range.

Applications that need to query data over a specific date range can generate **date-effective row sets**. To define a date-effective view object you must create an entity-based view object that is based on an date-effective entity object. User control over the view object's effective date usage is supported by metadata on the view object at design time. At runtime, ADF Business Components generates the query filter that will limit the view rows to an effective date.

How to Create a Date-Effective View Object

Whether or not the query filter for an effective date will be generated depends on the value of the **Effective Dated** property displayed in the Properties window for the view object (to view the property, click the **General** tab in the overview editor for the view object and expand the **Name** section in the Properties window).

The overview editor for the view object does not display the date-effective query clause in the WHERE clause. You can use the Test Query dialog to view the clause. A typical query filter for effective dates looks like this:

```
(:Bind_SysEffectiveDate BETWEEN CustomerVO.EFFECTIVE_START_DATE AND
CustomerVO.EFFECTIVE_END_DATE)
```

At runtime, the bind value for the query can be obtained from a property of the **root application module** or can be assigned directly to the view object. In order to set the effective date for a transaction, use code similar to the following snippet:

```
am.setProperty(ApplicationModule.EFF_DT_PROPERTY_STR, new
Date("2008-10-01));
```

If you do not set `EFF_DT_PROPERTY_STR` on the application module, the current date is used in the query filter, and the view object returns the effective rows filtered by the current date.

The view object has its own transient attribute, `SysEffectiveDate`, that you can use to set the effective date for view rows. This transient attribute is generated in the view object by JDeveloper when you set the view object to be date-effective. Otherwise, the `SysEffectiveDate` attribute value for new rows and defaulted rows is derived from the application module. ADF Business Components propagates the effective date from the view row to the entity object during DML operations only.

Before you begin:

It may be helpful to have an understanding of data-effective row sets. For more information, see Limiting View Object Rows Using Effective Date Ranges.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

1. Create an effective dated entity object, as described in How to Store Data Pertaining to a Specific Point in Time.
2. Use the Create View Object wizard to create the entity-based view object, as described in How to Create an Entity-Based View Object.

   The view object you create should be based on the effective dated entity object you created. In the Attributes page of the wizard, be sure to add the date-effective attributes that specify the start date and end date on the entity object to the **Selected** list for the view object.

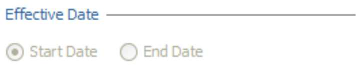
To enable effective dates for a view object using the SysEffectiveDate attribute:

1. In the Applications window, double-click the view object you created based on the effective dated entity object.
2. In the overview editor, click the **General** navigation tab.
3. In the Properties window, expand the **Name** section, and verify that the **Effective Dated** dropdown menu displays **True**.

   If the **Name** section is not displayed in the Properties window, click the **General** navigation tab in the overview editor to set the proper focus.
4. In the overview editor, click the **Attributes** navigation tab and select the attribute for the start date, and then click the **Details** tab and verify that **Effective Date** is enabled and that **Start** is selected, as shown in Figure 5-16.

   Verify that the attribute for the end date is also enabled correctly, as shown in the figure. Note that these fields appear grayed out to indicate that they cannot be edited for the view object.

Figure 5-16 View Object Overview Editor Displays Effective Date Setting



No additional steps are required once you have confirmed that the view object has inherited the desired attributes from the date-effective entity object.

How to Create New View Rows Using Date-Effective View Objects

Creating (inserting) date-effective rows is similar to creating or inserting ordinary view rows. The start date and end date can be specified as follows:

- The user specifies the effective date on the application module. The start date is set to the effective date, and the end date is set to end of time.

  End of time is defined for ADF Business Components as December 31st, 4712.

- The user specifies values for the start date and the end date (advanced).

In either case, during entity validation, the new row is checked to ensure that it does not introduce any gaps or overlaps. During post time, ADF Business Components will acquire a lock on the previous row to ensure that the gap or overlaps are not created upon the row insert.

How to Update Date-Effective View Rows

Date-effective rows are updated just as non date-effective rows are updated, using a `Row.setAttribute()` call. However, for the desired operation to take effect, an effective date mode must be set on the row before the update. ADF Business Components supports various modes to initiate the row update.

To set the update mode, invoke the `Row.setEffectiveDateMode(int mode)` method with one of the following mode constants defined by the `oracle.jbo.Row` class.

- `CORRECTION` (Correction Mode)

  The effective start date and effective end dates remain unchanged. The values of the other attributes may change. This is the standard row update behavior.

- `UPDATE` (Update Mode)

  The effective end date of the latest row will be set to the effective date. All user modifications to the row values are reverted on this row. A new row with the modified values is created. The effective start date of the new row is set to the effective date plus one day, and the effective end date is set to end of time. The new row will appear after the transaction is posted to the database.

- `OVERRIDE` (Update Override Mode)

  The effective end date of the modified row will be set to the effective date. The effective start date of the next row is set to effective date plus one day and the effective end date of the next row is set to end of time.

- `CHANGE_INSERT` (Change Insert Mode)

  Similar to update mode, but change insert mode operates on a past row not the latest row. The effective end date of the modified row should be set to the effective date. All user modifications to the row values are reverted on this row. A new row with the modified values will be created. The effective start date of the new row is set to effective date plus one day, and the effective end date is set to effective start date of the next row minus one day. The new row will appear after the transaction is posted to the database.

How to Delete Date-Effective View Rows

ADF Business Components supports various modes to initiate the row deletion. You can mark view rows for deletion by using API calls like `RowSet.removeCurrentRow()` or `Row.remove()`.

To set the deletion mode, invoke the `Row.setEffectiveDateMode(int mode)` method with one of the following mode constants defined by the `oracle.jbo.Row` class.

- `DELETE` (Delete Mode)

  The effective end date of the row is set to the effective date. The operation for this row is changed from delete to update. All rows with the same noneffective date key values and with an effective start date greater than the effective date are deleted.

- `NEXT_CHANGE` (Delete Next Change Mode)

  The effective end date of the row is set to the effective end date of the next row with the same noneffective date key values. The operation for this row is changed from delete to update. The next row is deleted.

- `FUTURE_CHANGE` (Delete Future Change Mode)

  The effective end date of the row is set to the end of time. The operation for this row is changed from delete to update. All future rows with the same noneffective date key values are deleted.

- `ZAP` (Zap Mode)

  All rows with the same non-effective date key values are deleted.

The effective date mode constants are defined on the row interface as well.

What Happens When You Create a Date-Effective View Object

When you create a date-effective view object, the view object inherits the transient attribute `SysEffectiveDate` from the entity object to store the effective date for the row. Typically, the insert/update/delete operations modify the transient attribute while Oracle ADF decides the appropriate values for effective start date and effective end date.

The query displayed in the overview editor for the date-effective view object does not display the `WHERE` clause needed to filter the effective date range. To view the full query for the date-effective view object, including the `WHERE` clause, edit the query and click **Test and Explain** in the Query page of the overview editor. The following sample shows a typical query and query filter for effective dates:

```
SELECT OrdersVO.ORDER_ID,        OrdersVO.CREATION_DATE,
       OrdersVO.LAST_UPDATE_DATE
FROM ORDERS OrdersVO
WHERE (:Bind_SysEffectiveDate BETWEEN OrdersVO.CREATION_DATE AND
                                      OrdersVO.LAST_UPDATE_DATE)
```

The following example shows sample XML entries that are generated when you create an date-effective view object.

```
<ViewObject
...
```

```
<!-- Property that enables date-effective view object. -->
  IsEffectiveDated="true">
  <EntityUsage
    Name="Orders1"
    Entity="model.OrdersDatedEO"
    JoinType="INNER JOIN"/>
<!-- Attribute identified as the start date -->
  <ViewAttribute
    Name="CreationDate"
    IsNotNull="true"
    PrecisionRule="true"
    IsEffectiveStartDate="true"
    EntityAttrName="CreationDate"
    EntityUsage="Orders1"
    AliasName="CREATION_DATE"/>
<!-- Attribute identified as the end date -->
  <ViewAttribute
    Name="LastUpdateDate"
    IsNotNull="true"
    PrecisionRule="true"
    IsEffectiveEndDate="true"
    EntityAttrName="LastUpdateDate"
    EntityUsage="Orders1"
    AliasName="LAST_UPDATE_DATE"/>
<!-- The SysEffectiveDate transient attribute -->
  <ViewAttribute
    Name="SysEffectiveDate"
    IsPersistent="false"
    PrecisionRule="true"    Type="oracle.jbo.domain.Date"
    ColumnType="VARCHAR2"
    AliasName="SysEffectiveDate"
    Passivate="true"
    SQLType="DATE"/>
</ViewObject>
```

What You May Need to Know About Date-Effective View Objects and View Links

Effective dated associations and view links allow queries to be generated that take the effective date into account. The effective date of the driving row is passed in as a bind parameter during the query execution.

While it is possible to create a noneffective dated association between two entities when using the Create Association wizard or Create View Link wizard, JDeveloper will by default make the association or link effective dated if one of the ends is effective dated. However, when the association or view link exists between an effective dated and a noneffective dated object, then at runtime ADF Business Components will inspect the effective dated nature of the view object or entity object before generating the query clause and binding the effective date. The effective date is first obtained from the driving row. If it is not available, then it is obtained from the property EFF_DT_PROPERTY_STR of the root application module. If you do not set EFF_DT_PROPERTY_STR for the application module, the current date is used in the query filter on the driving row and applied to the other side of the association or view link.

Working with Multiple Tables in Join Query Results

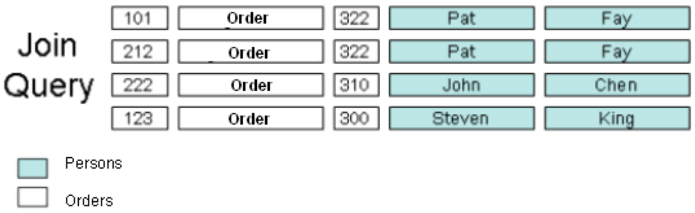
Use the Create View Object Wizard to define join queries declaratively that involves multiple tables.

Many queries you will work with will involve multiple tables that are related by foreign keys. In this scenario, you join the tables in a single view object query to show additional descriptive information in each row of the main query result. You use the Create View Object wizard to define the query using declarative options. Whether your view object is read-only or entity-based determines how you can define the join:

- When you work with entity-based view objects, the Create View Object wizard uses an existing association defined between the entities to automatically build the view object's join `WHERE` clause. You can declaratively specify the type of join you want to result from the entity objects. Inner join (equijoin) and outer joins are both supported.
- When you work with non-entity based view objects, you can use the SQL Builder dialog to build the view object's join `WHERE` clause. In this case, you must select the columns from the tables that you want to join.

Figure 5-17 illustrates the rows resulting from two tables queried by a view object that defines a join query. The join is a single flattened result.

Figure 5-17   Join Query Result



101	Order	322	Pat	Fay
212	Order	322	Pat	Fay
222	Order	310	John	Chen
123	Order	300	Steven	King

How to Create Joins for Entity-Based View Objects

It is extremely common in business applications to supplement information from a *primary* business domain object with secondary reference information to help the end user understand what foreign key attributes represent. Take the example of the `ItemEO` entity object. It contains foreign key attribute of type `Number` like:

- `ItemId`, representing the product to which the order item pertains

Showing an end user exclusively these "raw" numerical values is not very helpful. Ideally, reference information from the view object's related entity objects should be displayed to improve the application's usability. One typical solution involves performing a join query that retrieves the combination of the primary and reference information. This is equivalent to populating "dummy" fields in each queried row with reference information based on extra queries against the lookup tables.

When the end user can *change* the foreign key values by editing the data, this presents an additional challenge. Luckily, entity-based view objects support easily including reference information that's always up to date. The key requirement to leverage this feature is the presence of associations between the entity object that act as the view object's primary entity usage and the entity objects that contribute reference information.

To include reference entities in a join view object, use the Create View Object wizard. The Create View Object wizard lets you specify the type of join:

- **Inner Join**

  Select when you want the view object to return all rows between two or more entity objects, where each entity defines the same primary key column. The inner join view object will not return rows when a primary key value is missing from the joined entities.
- **Outer Join**

  Select when you want the view object to return all rows that exist in one entity object, even though corresponding rows do not exist in the joined entity object. Both left and right outer join types are supported. The left and right designation refers to the source (left) and destination (right) entity object named in an association. For details about changing the default inner join to an outer join, see How to Modify a Default Join Clause to Be an Outer Join When Appropriate. For details about cases where a matching outer entity row is not found (none exists), see What You May Need to Know About Outer Joins.

Both inner joins and outer joins are supported with the following options:

- **Reference**

  Select when you want the data from the entity object to be treated as reference information for the view object. Automatic lookup of the data is supported and attribute values will be dynamically fetched from the entity cache when a controlling key attribute changes. For details about how this setting affects runtime behavior, see What Happens at Runtime: View Row Creation.
- **Updatable**

  Deselect when you want to prevent the view object from modifying any entity attributes in the entity object. By default, the first entity object (primary) in the **Selected** list is updatable and subsequent entity objects (secondary) are not updatable. To understand how to create a join view object with *multiple* updatable entity usages, see How to Create a Subtype View Object with a Polymorphic Entity Usage.
- **Participate in row delete**

  Select when you have defined the entity as updatable and you want the action of removing rows in the UI to delete the participating reference entity object. This option is disabled for the primary entity and is used mainly on the outer joined entity. For example, while it may be possible to delete an order item, it should not be possible to delete the order when a remove row is called from the join view object. For details about how this setting affects view row deletion for various join types, see What You May Need to Know About Entity Based Joins and Participates in Row Delete and What You May Need to Know About Composition Associations and Joins.

Before you begin:

It may be helpful to have an understanding of how the type of view object effects joins. For more information, see Working with Multiple Tables in Join Query Results.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You may also find it helpful to understand Oracle Database features related to join queries. See the SQL Queries and Subqueries in the *Oracle Database SQL Language Reference*.

You will need to complete this task:

> Create the desired entity objects, as described in How to Create Multiple Entity Objects and Associations from Existing Tables.

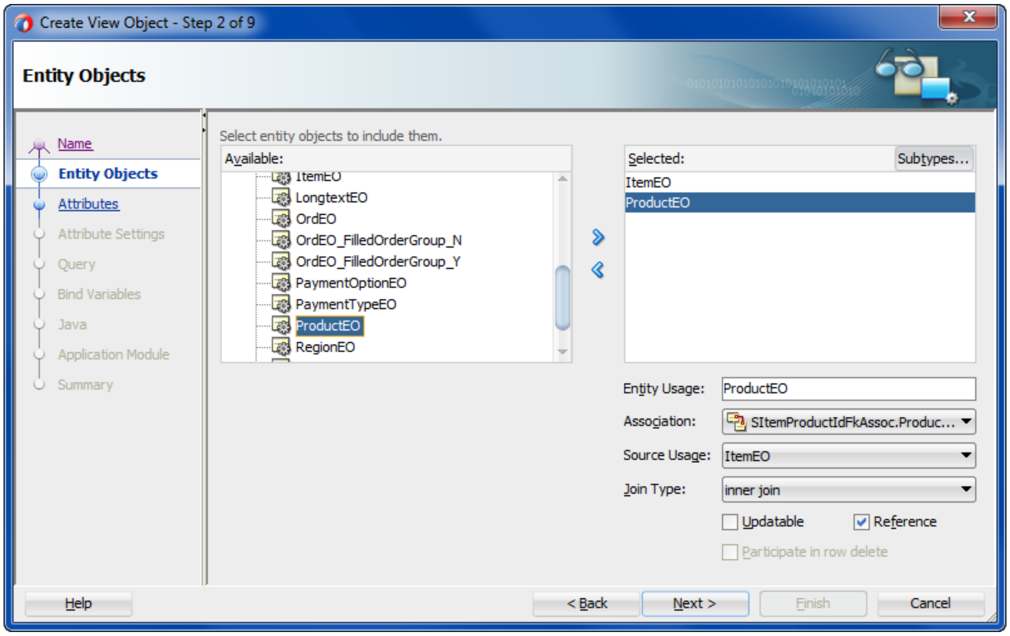
To create a view object that joins entity objects:

1. In the Applications window, right-click the package in the data model project in which you want to create the view object and choose **New** and then **View Object**.
2. In the Create View Object wizard, on the Name page, enter a package name and a view object name. Keep the default setting **Entity** enabled to indicate that you want this view object to manage data with its base entity object. Click **Next**.
3. In the Entity Objects page, the first entity usage in the **Selected** list is known as the *primary* entity usage for the view object. Select the primary entity object from the **Available** list and shuttle it to the **Selected** list.

   The list is not limited to a single, primary entity usage.
4. To add additional, secondary entity objects to the view object, select them in the **Available** list and shuttle them to the **Selected** list.

   The **Association** dropdown list shows you the name of the association that relates the selected secondary entity usage to the primary one. For example, Figure 5-18 shows the result of adding one secondary reference entity usage, `ProductEO`, in addition to the primary `ItemEO` entity usage. The association that relates to this secondary entity usage is `SItemProductIdFkAssoc.ProductEO`.

Figure 5-18 Create View Object Wizard, Entity Objects Page



Selected: ItemEO, ProductEO

Entity Usage: ProductEO

Association: SItemProductIdFkAssoc.Produc...

Source Usage: ItemEO

Join Type: inner join

☐ Updatable ☑ Reference

☐ Participate in row delete

5. Optionally, use the **Entity Usage** field to give a more meaningful name to the entity usage when the default name is not clear.

6. If you add multiple entity usages for the same entity, use the **Association** dropdown list to select which association represents that usage's relationship to the primary entity usage. Click **Next**.

   For each secondary entity usage, the **Reference** option is enabled to indicate that the entity provides reference information and that it is not the primary entity. The **Updatable** option is disabled. This combination represents the typical usage. However, when you want to create a join view object with multiple, updatable entity usages, see How to Create a Subtype View Object with a Polymorphic Entity Usage.

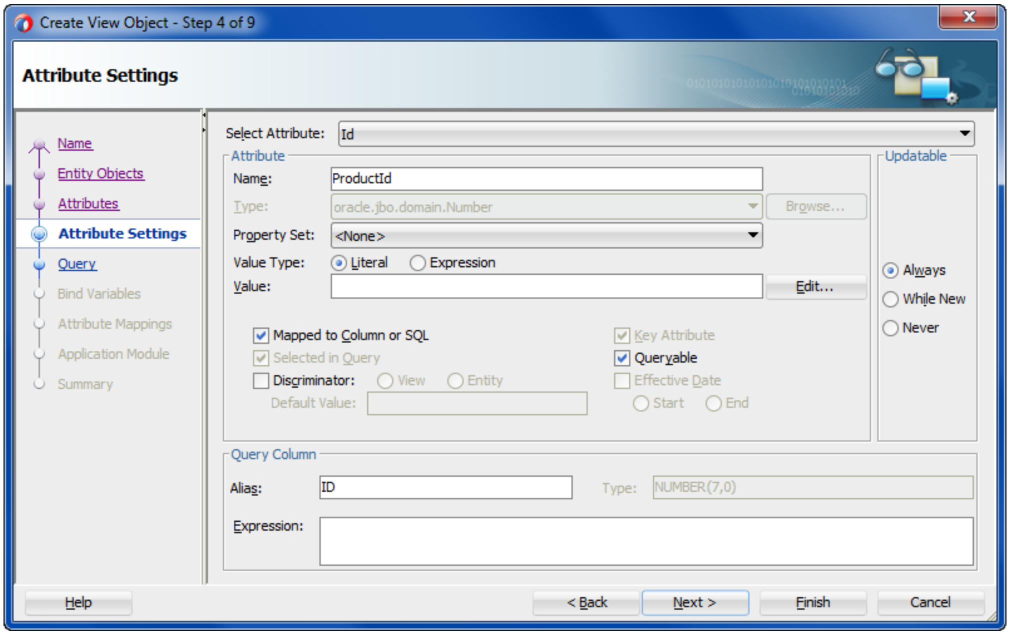
   Secondary entity usages that are updatable can also have the **Participate in row delete** option enabled. This will allow secondary entity attributes to appear `NULL` when the primary entity is displayed.

7. On the Attributes page, select the attributes you want each entity object usage to contribute to the view object. Click **Next**.

8. On the Attribute Settings page, you can rename an attribute when the names are not as clear as they ought to be.

   The same attribute name often results when the reference and secondary entity objects derive from the same table. Figure 5-19 shows the attribute `Id` in the **Select Attribute** dropdown list, which has been renamed to `ProductId` in the **Name** field.

Figure 5-19 Create View Object Wizard, Attribute Settings Page



Select Attribute: Id

Name: ProductId

Type: oracle.jbo.domain.Number

Property Set: <None>

Value Type: ● Literal ○ Expression

Value:

☑ Mapped to Column or SQL

☑ Selected in Query

□ Discriminator: ○ View ○ Entity

Default Value:

☑ Key Attribute

☑ Queryable

□ Effective Date

○ Start ○ End

Updatable: ● Always ○ While New ○ Never

Alias: ID

Type: NUMBER(7,0)

Expression:

9. Click **Finish**.

How to Modify a Default Join Clause to Be an Outer Join When Appropriate

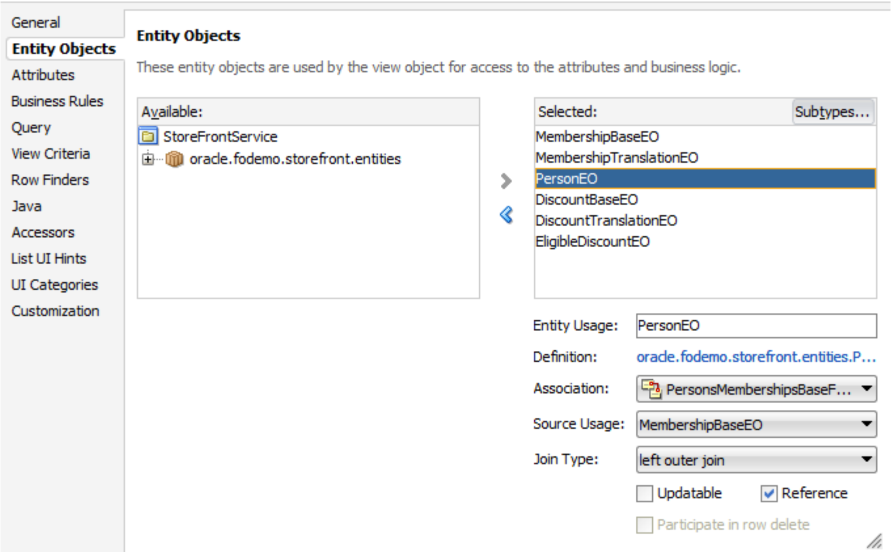
When you add a secondary entity usage to a view object, the entity usage is related to an entity usage that precedes it in the list of selected entities. This relationship is established by an entity association displayed in the **Association** dropdown list in the Entity Objects page of the overview editor for the view object. You use the **Association** dropdown list in the editor to select the entity association that relates the secondary entity usage to the desired preceding entity usage in the **Selected** list. The name of the preceding entity usage is identified in the **Source Usage** dropdown list.

When JDeveloper creates the `WHERE` clause for the join between the table for the primary entity usage and the tables for related secondary entity usages, by default it always creates inner joins. You can modify the default inner join clause to be a left or right outer join when appropriate. The left designation refers to the source entity object named in the selected association. This is the entity identified in the **Source Usage** dropdown list. The right designation refers to the current secondary entity usage that you have selected in the **Selected** list.

In the left outer join, you will include all rows from the left table (related to the entity object named in the **Source Usage** list) in the join, even if there is no matching row from the right table (related to the current secondary entity object selection). The right outer join specifies the reverse scenario: you will include all rows from the right table (related to the entity object named in the **Selected** list) in the join, even if there is no matching row from the left table (related to the current secondary entity object selection).

For example, assume that a person is not yet assigned a membership status. In this case, the `MembershipId` attribute will be `NULL`. The default inner join condition will not retrieve these persons from the `MEMBERSHIPS_BASE` table. Assuming that you want persons without membership status to be viewable and updatable through the `MembershipDiscountsVO` view object, you can use the Entity Objects page in the overview editor for the view object to change the query into an left outer join to the `MEMBERSHIPS_BASE` table for the possibly null `MEMBERSHIP_ID` column value. When you add the person entity to the view object, you would select the **left outer join** as the join type. As shown in Figure 5-20, the association `PersonsMembershipsBaseFkAssoc` identifies a source usage `MembershipBaseEO` on the left side of the join and the selected `PersonEO` entity usage on the right side. The view object `MembershipDiscountsVO` joins the rows related to both of these entity objects and defines a left outer join for `PersonEO` to allow the view object to return rows from the table related to `MembershipBaseEO` even if they do not have a match in the table related to `PersonEO`.

Figure 5-20   Setting an Outer Join to Return NULL Rows from Joined Entities



Entity Objects

These entity objects are used by the view object for access to the attributes and business logic.

Entity Usage: PersonEO

Definition: oracle.fodemo.storefront.entities.P...

Association: PersonsMembershipsBaseF...

Source Usage: MembershipBaseEO

Join Type: left outer join

☐ Updatable ☑ Reference

☐ Participate in row delete

The view object's updated `WHERE` clause includes the addition `(+)` operator on the right side of the equals sign for the related table whose data is allowed to be missing in the left outer join:

```
PersonEO.MEMBERSHIP_ID = MembershipBaseEO.MEMBERSHIP_ID(+)
```

Before you begin:

It may be helpful to have an understanding of how the type of view object effects joins. For more information, see Working with Multiple Tables in Join Query Results.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired entity objects, as described in How to Create Multiple Entity Objects and Associations from Existing Tables.

To change an inner join type to an outer join:

1. In the Applications window, double-click the view object that you want to modify.
2. In the overview editor, click the **Entity Objects** navigation tab.

   The entity object you select represents the table on the right side of the join.
3. In the Entity Objects page, in the **Selected** list, select the entity object that you want to change the join type for.

   The entity object you select represents the table on the right side of the join.
4. In the **Association** dropdown list, if only one association is defined, leave it selected; otherwise, select among the list of entity object associations that relate the secondary entity object to the desired entity object.

   The entity usage that represents the joined table will be displayed in the **Source Usage** dropdown list. The entity object in the **Source Usage** dropdown list that you choose through the association selection represents the table on the left side of the join.

5. In the **Join Type** dropdown list, decide how you want the view object to return rows from the joined entity objects:

   - **left outer join** will include rows from the left table in the join, even if there is no matching row from the right table.
   - **right outer join** will include rows from the right table in the join, even if there is no matching row from the left table.

   The **Source Usage** dropdown list is the left side of the join and the current entity usage in the **Selected** list is the right side.

How to Select Additional Attributes from Reference Entity Usages

After adding secondary entity usages, you can use the overview editor for the view object to select the specific, additional *attributes* from these new usages that you want to include in the view object.

> **Tip:**
>
> The overview editor lets you sort attributes displayed in the Attributes page by their entity usages. By default, the attributes table displays attributes in the order they appear in the underlying entity object. To sort the attributes by entity usage, click the header for the **Entity Usage** column of the attributes table. If the **Entity Usage** column does not appear in the attributes table, click the dropdown menu on the top-right corner of the table (below the button bar) and choose **Select Columns** to add the column to the **Selected** list.

Before you begin:

It may be helpful to have an understanding of how the type of view object effects joins. For more information, see Working with Multiple Tables in Join Query Results.

You may also find it helpful to understand Oracle Database features related to join queries. For more information, see the SQL Queries and Subqueries in the *Oracle Database SQL Language Reference*.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

Create the desired entity objects, as described in How to Create Multiple Entity Objects and Associations from Existing Tables.

To select attributes from a secondary entity usage:

1. In the Applications window, double-click the entity-based view object that you want to modify.

2. In the overview editor, click the **Attributes** navigation tab and then click the **Create new attribute** button and choose **Add Attribute from Entity** to view the list of available entity-derived attributes.
3. In the Attributes dialog, select the desired attribute and add it to the **Selected** list.

   Note that even if you didn't intend to include them, JDeveloper automatically verifies that the primary key attribute from each entity usage is part of the **Selected** list. If it's not already present in the list, JDeveloper adds it for you. When you are finished, the overview editor Query page shows that JDeveloper has included the new columns in the `SELECT` statement.
4. Click **OK**.

How to Remove Unnecessary Key Attributes from Reference Entity Usages

The view object attribute corresponding to the primary key attribute of the primary entity usage acts as the primary key for identifying the view row. When you add secondary entity usages, JDeveloper marks the view object attributes corresponding to their primary key attributes as part of the view row key as well. When your view object consists of a *single* updatable primary entity usage and a number of reference entity usages, the primary key attribute from the primary entity usage is enough to uniquely identify the view row. Further key attributes contributed by secondary entity usages are not necessary and you should disable their **Key Attribute** settings.

For example, based on the view object with primary entity usage `ShippingOptionEO`, you could disable the **Key Attribute** property for the `ShippingOptionTranslationEO` entity usage so that this property is no longer selected for this additional key attribute: `ShippingTranslationsId`.

However, when your view object consists of *multiple* updatable primary entity usages, then the primary key to identify the view row must consist at the minimum of *all* the key attributes of *all* updatable entity usages included in the view object.

Before you begin:

It may be helpful to have an understanding of how the type of view object effects joins. For more information, see Working with Multiple Tables in Join Query Results.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

Create the desired entity objects, as described in How to Create Multiple Entity Objects and Associations from Existing Tables.

To remove unnecessary key attributes:

1. In the Applications window, double-click the entity-based view object that you want to modify.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, in the attributes table, select the key attribute (identified by the key icon in the **Name** column), and then click the **Details** tab and deselect the **Key Attribute** property.

How to Hide the Primary Key Attributes from Reference Entity Usages

Since you generally won't want to display the primary key attributes that were automatically added to the view object, you can set the attribute's **Display Hint** property to **Hide**.

Before you begin:

It may be helpful to have an understanding of how the type of view object effects joins. For more information, see Working with Multiple Tables in Join Query Results.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

Create the desired entity objects, as described in How to Create Multiple Entity Objects and Associations from Existing Tables.

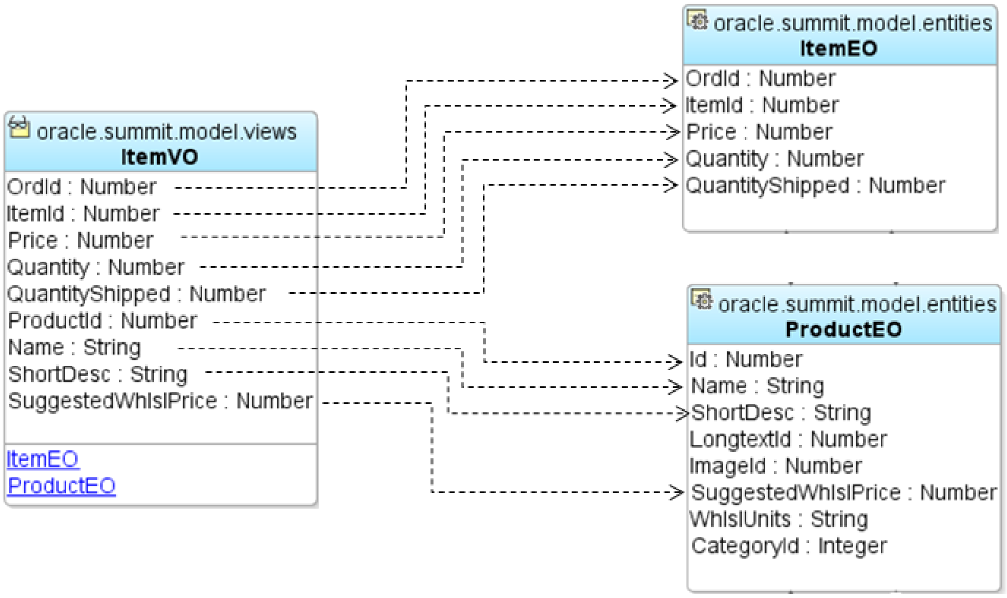
To hide the primary key attribute:

1. In the Applications window, double-click the entity-based view object that you want to modify.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the primary key attribute (identified by the key icon in the **Name** column), and then click the **UI Hints** tab and select **Hide** for the **Display** type.

What Happens When You Reference Multiple Entities in a View Object

Figure 5-7 depicts the entity-based view object `ItemVO` and the two entity usages referenced in its query statement. The dotted lines represent the metadata captured in the entity-based view object's XML document that map `SELECT` list columns in the query to attributes of the entity objects used in the view object. The query of the entity-based view object joins data from a primary entity usage (`ItemEO`) with that from the secondary reference entity usage (`ProductEO`).

Figure 5-21 View Object Maps Attributes of Multiple Entity Objects



When you create a join view object to include one or more secondary entity usages by reference, JDeveloper updates the view object's XML document to include information about the additional entity usages. For example, the `ItemVO.xml` file for the view object includes an additional reference entity usage. You will see this information recorded in the multiple <`EntityUsage`> elements. For example, Figure 5-5 shows an entity usage entry that defines the primary entity usage.

```
<EntityUsage
   Name="ItemEO"
   Entity="oracle.summit.model.entities.ItemEO"/>
```

The secondary reference entity usages will have a slightly different entry, including information about the association that relates it to the primary entity usage, like the entity usage shown in the following example.

```
<EntityUsage
   Name="ProductEO"
   Entity="oracle.summit.model.entities.ProductEO"
   Association="oracle.summit.model.entities.assoc.SItemProductIdFkAssoc"
   AssociationEnd="oracle.summit.model.entities.assoc.
                    SItemProductIdFkAssoc.ProductEO"
   SourceUsage="oracle.summit.model.views.ItemVO.ItemEO"
   ReadOnly="true"
   Reference="true"
   Participant="false"
   JoinType="INNER JOIN/>
```

Each attribute entry in the XML file indicates which entity usage it references. For example, the entry for the `OrdId` attribute in the following example shows that it's related to the `ItemEO` entity usage, while the `Name` attribute is related to the `ProductEO` entity usage.

```
   <ViewAttribute
      Name="OrdId"
      IsNotNull="true"
      EntityAttrName="OrdId"
      EntityUsage="ItemEO"
      AliasName="ORD_ID" >
   </ViewAttribute>
...
   <ViewAttribute
      Name="Name"
      IsUpdatable="true"
      IsNotNull="true"
      EntityAttrName="Name"
      EntityUsage="ProductEO"
      AliasName="NAME" >
   </ViewAttribute>
```

The Create View Object wizard uses this association information at design time to automatically build the view object's join WHERE clause. It uses the information at runtime to enable keeping the reference information up to date when the end user changes foreign key attribute values.

What You May Need to Know About Outer Joins

If you specify an outer join and no matching outer entity row is found, the database return null for that portion of the query. For example, if you join Dept entity and Emp entity through DeptEmpView with an outer join and Dept 40 has no employees. Then, when the row for Dept 40 is reached, database returns [40, null] and ADF Business Components will create an entity row for Dept 40 and an blank Emp entity row. If the Emp entity in the view object is set as **Updatable**, you can set attribute values into this blank entity row. Later if you commit the transaction, a new entity row will be inserted.

What You May Need to Know About Entity Based Joins and Entity Cardinality

Suppose you have Customer and Order entity objects and you create view object joins based on the entity association CustOrderIdFKAssoc, where Customer has cardinality many and Order has cardinality 1.

If you were to create a 1-many join OrderCustVO view object that joins Order entity (the primary entity with cardinality of 1) to Customer entity (secondary entity with cardinality of many), the application may return the same Customer entity row for many Order rows.

If you were to create a many-1 join CustOrderVO view object that joins Customer (primary, many) to Order (secondary, one), the application may return the same Customer entity row with many Order entity rows.

In the OrderCustVO (1-many) case, where Customer is a reference entity, when the end user deletes a row, the application only deletes the Order entity row and Customer is unaffected. Similarly, in the CustOrderView (m-1 case), where Order is a reference entity, when the end user deletes a row, the application only deletes the Customer entity row and Order is unaffected.

But, in the CustOrderVO (many-1) case, when the end user deletes one row, the application may remove multiple rows from the join view instance. For example, suppose you have three orders (A, B, C) for customer 10. If the end user deletes the first of these joined view rows [10, A], the application will actually remove three view rows: [10, A], [10, B], and [10, C]. At the entity level, only `Customer` 10 entity row is removed because `Order` is a reference entity.

What You May Need to Know About Entity Based Joins and Participates in Row Delete

Suppose you create a 1-many join (like `OrderCustVO` view object) and a many-1 join (like `CustOrderVO` view object) where the secondary entity object has **Participate in Row Delete** enabled (and `Customer` 10 has `Orders` A, B, C).

If you were to create a 1-many join `OrderCustVO` and the `Customer` entity object has **Participate in Row Delete** enabled, when the end user deletes [A, 10], the application will delete `Order` A entity row first, followed by the `Customer` 10 entity row. When this `Customer` 10 is deleted, the application actually remove all view rows that refer to that entity row. This mean [A, 20] and [A, 30] will also be removed (3 view rows in total).

If you were to create a many-1 join `CustOrderVO` and the `Order` entity object has **Participate in Row Delete** enabled, when the end user deletes [10, A], the application will delete `Customer` 10 entity row first. The application will then remove all view rows that refer to that entity row. This means [20, A] and [30, A] will be removed from the view. Then, the application will delete the `Order` A entity row.

What You May Need to Know About Composition Associations and Joins

Suppose the association between entity objects `Order` and `OrderItem` is a composition association and you create a view object joins based on these entities, where `Order` A contains `Items` 1, 2, 3.

In the `ItemOrdVO` view object case, where `Order` (secondary) is a reference entity, when the end user deletes [1, A], the application will only delete the 1 `OrderItem` entity row and there will be no issue. However, when the `Order` entity object has **Participate in Row Delete** enabled, when the end user deletes [1, A], the application will also attempt to delete the `Item` 1 entity row, followed by deleting `Order` A. However, due to the composition relationship, this will fail and the application will throw `RemoveWithDetailsException` because `Order` A still has `OrderItem` 2 and `OrderItem` 3 that belong to `Order` A.

In the `OrdItemVO` view object case, where Item (secondary) entity is a reference entity, when the end user deletes [A, 1], the application will also attempt to delete the `Order` A entity row. However, due to the composition relationship, this will fail and the application will throw `RemoveWithDetailsException` because `Order` A still has `Item` 1, `Item` 2, and `Item` 3 that belong to `Order` A.

If the `Item` (secondary) entity object has **Participate in Row Delete** enabled, removing [A, 1] will produce the same exception since `Order` A has child rows.

The situation is different if the entity association has **Implement Cascade Delete** under **Composition Association** enabled.

In the `ItemOrderVO` view object case, where `Order` is a reference entity, when the end user deletes [1, A], the application only deletes the `Item` A entity row (with no exception thrown). If the `Order` entity object has **Participate in Row Delete** enabled, when the end user deletes [1, A], the application will delete `Item` A first, followed by deletion of `Order` A. Because cascade delete is enabled, deletion of `Order` A will delete all the remaining children of `Order` A, including `Item` 2 and `Item` 3. This will result in removal of view rows [2, A] and [3, A] from the view instance.

Similarly, in the `OrderItemVO` view object case, where `Item` is a reference entity, when the end user deletes [A, 1], the application deletes `Order` A. Because **Implement Cascade Delete** is enabled, the application will also delete all the children of `Order` A, including `Item` 1, 2, and 3. This will result in the removal of view rows [A, 2], [A, 2], and [A, 3] from the view instance.

If the `Item` entity object has **Participate in Row Delete** enabled, the same behavior is produced: all three view rows are removed.

How to Create Joins for Read-Only View Objects

To create a read-only view object joining two tables, use the Create View Object wizard.

Before you begin:

It may be helpful to have an understanding of how the type of view object effects joins. For more information, see Working with Multiple Tables in Join Query Results.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To create a read-only view object joining two tables:

1. In the Applications window, right-click the project in which you want to create the view object and choose **New** and then **View Object**.
2. If you have not yet created a database connection for the data model project, in the Initialize Business Components Project dialog, select the database connection or choose **New** to create a connection. Click **OK**.

   If this is the first component you're creating in the project, the Initialize Business Components Project dialog appears to allow you to select a database connection.
3. In the Create View Object wizard, on the Name page, enter a package name and a view object name. Select **Custom SQL query** to indicate that you want this view object to manage data with read-only access. Click **Next**.
4. On the Query page, use one of the following techniques to create the SQL query statement that joins the desired tables:
   - Type or paste any valid SQL statement into the **Select** box.
   - Click **Query Builder** to open the SQL Statement dialog and build the query statement, as described in How to Use the SQL Statement Dialog with Read-Only View Objects.
5. After entering or building the query statement, click **Next**.
6. On the Bind Variables page, do one of the following:
   - If the query does not reference any bind variables, click **Next** to skip Step 3.
   - To add a bind variable and work with it in the query, see How to Add WHERE Clause Bind Variables to a View Object Definition.
7. Click **Next** on the Attribute Mappings page and the Attribute page.

8. On the Attribute Settings page, click **Finish**.

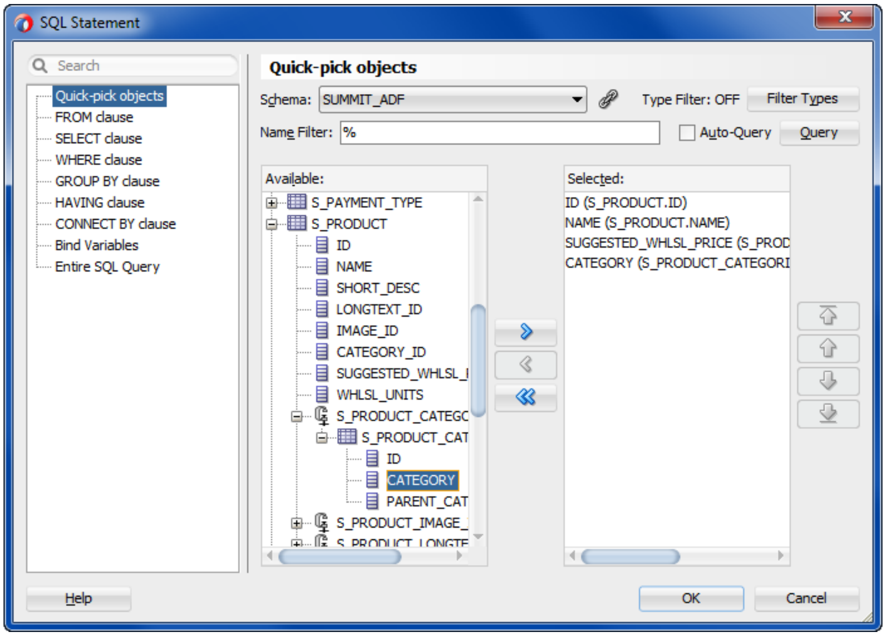
How to Test the Join View

To test the new view object, edit the application module and on the Data Model page add an instance of the new view object to the data model. Then, use the Oracle ADF Model Tester to verify that the join query is working as expected. For details about editing the data model and running the Oracle ADF Model Tester, see Testing View Object Instances Using the Oracle ADF Model Tester.

How to Use the SQL Statement Dialog with Read-Only View Objects

The Quick-pick objects page of the SQL Statement dialog lets you view the tables in your schema, including the foreign keys that relate them to other tables. To include columns in the select list of the query, shuttle the desired columns from the **Available** list to the **Selected** list. For example, Figure 5-22 shows the result of selecting the `ID`, `NAME`, and `SUGGESTED_WHLSL_PRICE` columns from the `S_PRODUCT` table, along with the `CATEGORY` column from the `S_PRODUCT_CATEGORIES` table. The column from the second table appears, beneath the `S_PRODUCT_CATEGORY_ID_FK` foreign key in the **Available** list. When you select columns from tables joined by a foreign key, the SQL Statement dialog automatically determines the required join clause for you.

Figure 5-22 View Object SQL Statement Dialog to Define a Join



Schema: SUMMIT_ADF
Type Filter: OFF
Name Filter: %
□ Auto-Query

Selected:
ID (S_PRODUCT.ID)
NAME (S_PRODUCT.NAME)
SUGGESTED_WHLSL_PRICE (S_PROD
CATEGORY (S_PRODUCT_CATEGORI

Optionally, use the `WHERE` clause page of the SQL Statement dialog to define the expression. To finish creating the query, click **OK** in the SQL Statement dialog. The Query page of the overview editor will show a query like the one shown in the following example.

```
SELECT
    S_PRODUCT.ID ID,
    S_PRODUCT.NAME NAME,
    S_PRODUCT.SUGGESTED_WHLSL_PRICE SUGGESTED_WHLSL_PRICE,
    S_PRODUCT_CATEGORIES.CATEGORY CATEGORY
FROM
    S_PRODUCT JOIN S_PRODUCT_CATEGORIES ON S_PRODUCT.CATEGORY_ID =
                                     S_PRODUCT_CATEGORIES.ID
```

You can use the Attributes page of the Create View Object wizard to rename the view object attribute directly as part of the creation process. Renaming the view object here saves you from having to edit the view object again, when you already know the attribute names that you'd like to use. As an alternative, you can also alter the default Java-friendly name of the view object attributes by assigning a column alias, as described in Attribute Names for Calculated Expressions in Custom SQL Mode.

Working with View Objects and Custom SQL

You can define entity objects in the Normal mode and custom SQL mode depending on whether you require full control over the SELECT or FROM query clause.

When defining entity-based view objects in Normal mode, you can fully specify the WHERE and SORT BY clauses, whereas, by default, the FROM clause and SELECT list are automatically derived. The names of the tables related to the participating entity usages determine the FROM clause, while the SELECT list is based on the:

- Underlying column names of participating entity-mapped attributes
- SQL expressions of SQL-calculated attributes

When you require full control over the SELECT or FROM clause in a query, you can enable custom SQL mode.

> **Tip:**
>
> The view object editors and wizard in the JDeveloper provide full support for generating SQL from choices that you make. For example, two such options allow you to declaratively define outer joins and work in declarative SQL mode (where no SQL is generated until runtime).

How to Create a Custom SQL Mode View Object

When you need full control over the SQL statement, the Create View Object wizard lets you specify this using custom SQL mode. Primarily, the custom SQL view object that you create will be useful when you need to write Unions or Group By queries. Additionally, you can create a custom SQL view object if you need to create SQL-based validation queries used by the view object-based Key Exists validator, provided that you have marked a key attribute.

See about the tradeoffs between working with entity-based view objects and custom SQL view objects that are not based on entity objects, see Using Entity-Based View Objects for Read-Only Data.

To create a custom SQL view object, use the Create View Object wizard, which is available from the New Gallery.

Before you begin:

It may be helpful to have an understanding of view objects. See, see Populating View Object Rows from a Single Database Table.

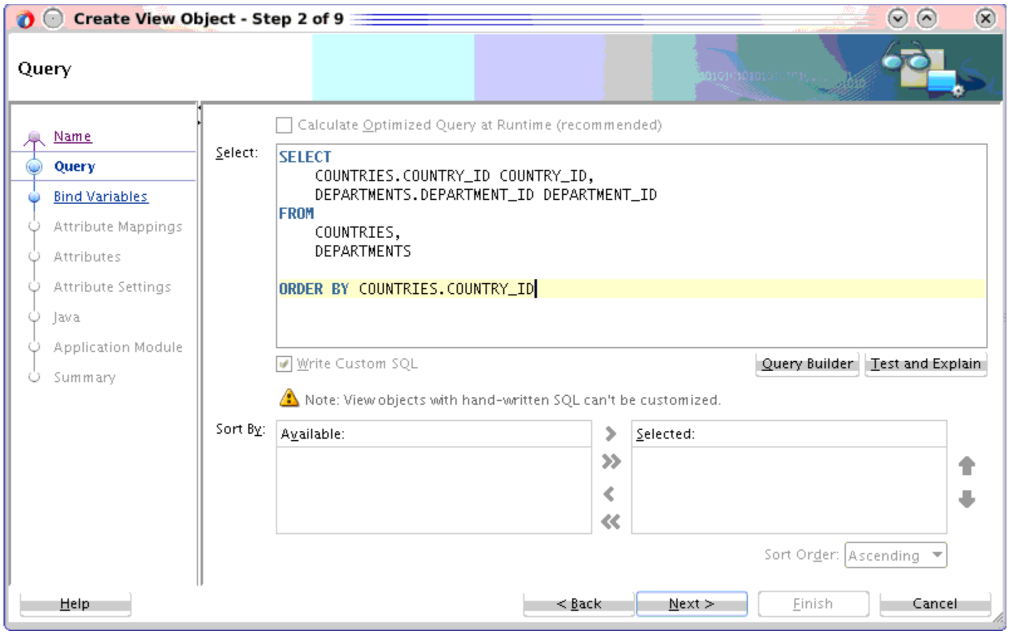
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See, see Additional Functionality for View Objects.

To create a custom SQL view object:

1. In the Applications window, right-click the package in which you want to create the view object and choose **New** and then **View Object**.
2. If you have not yet created a database connection for the data model project, in the Initialize Business Components Project dialog, select the database connection or choose **New** to create a connection. Click **OK**.

   If this is the first component you're creating in the project, the Initialize Business Components Project dialog appears to allow you to select a database connection.
3. In the Create View Object wizard, on the Name page, enter a package name and a view object name. Select **Custom SQL query** to indicate that you want this view object to manage data without the benefit of entity objects. Click **Next**.
4. On the Query page, use one of the following techniques:
   - Type or paste any valid SQL statement into the **Select** text box. The query statement can use a `WHERE` clause and an `Order By` clause. For example, Figure 5-23shows a query statement that uses a `WHERE` clause and an `Order By` clause.
   - Click **Query Builder** to open the SQL Statement dialog and build the query statement.

Figure 5-23 Create View Object Wizard, Query Page



```
SELECT
    COUNTRIES.COUNTRY_ID COUNTRY_ID,
    DEPARTMENTS.DEPARTMENT_ID DEPARTMENT_ID
FROM
    COUNTRIES,
    DEPARTMENTS

ORDER BY COUNTRIES.COUNTRY_ID
```

☑ Write Custom SQL

Note: View objects with hand-written SQL can't be customized.

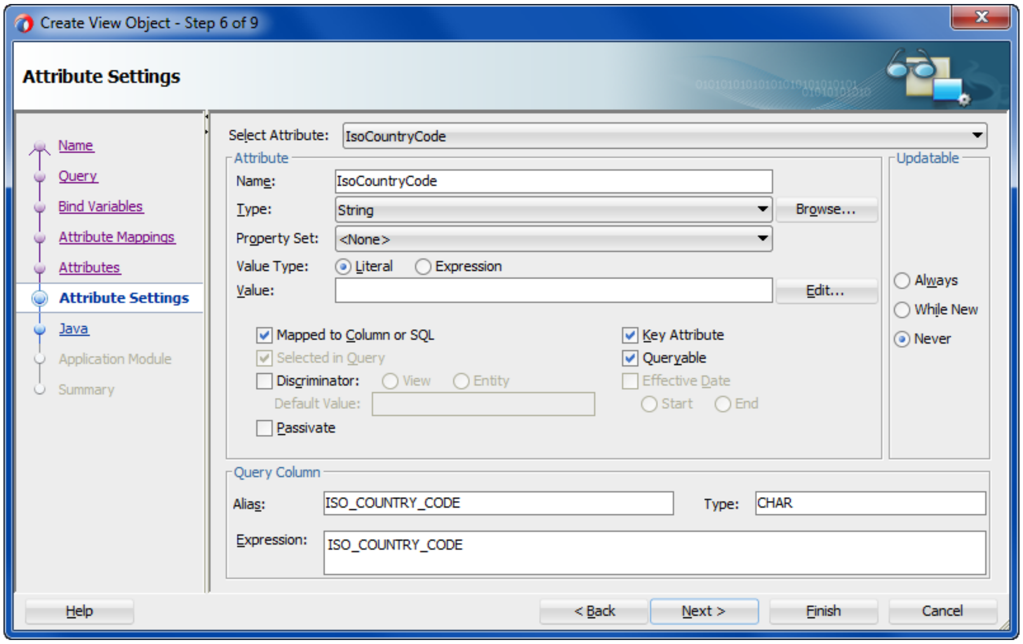
Sort Order: Ascending

> **Note:**
>
> If the Entity Objects page displays instead of the Query page, go back to Step 1 of the wizard and ensure that you've selected **Custom SQL query**.

5. After entering or building the query statement, click **Next**.
6. On the Bind Variables page, do one of the following:
   - If the query does not reference any bind variables, click **Next** to skip this page.
   - To add a bind variable and work with it in the query, see How to Add WHERE Clause Bind Variables to a View Object Definition.
7. On the Attribute Settings page, from the **Select Attribute** dropdown, select the attribute that corresponds to the primary key of the queried table and confirm that the **Key Attribute** checkbox is selected.

   The Create View Object wizard auto-detects key attributes from the database and enables the **Key Attribute** checkbox, as shown in Figure 5-24. Failure to define the key attribute can result in unexpected runtime behavior for **ADF Faces** components with a **data control** based on the view object collection.

Figure 5-24 Create View Object Wizard, Attribute Settings Page



Create View Object - Step 6 of 9

Attribute Settings

Select Attribute: IsoCountryCode

Type: CHAR

Expression: ISO_COUNTRY_CODE

8. Click **Finish**.

> **Note:**
>
> In the ADF Business Components wizards and editors, the default convention is to use camel-capped attribute names, beginning with a capital letter and using uppercase letters in the middle of the name to improve readability when the name comprises multiple words.

What Happens When You Create a Custom SQL View Object

When you create a view object using custom SQL mode, JDeveloper first parses the query to infer the following from the columns in the SELECT list:

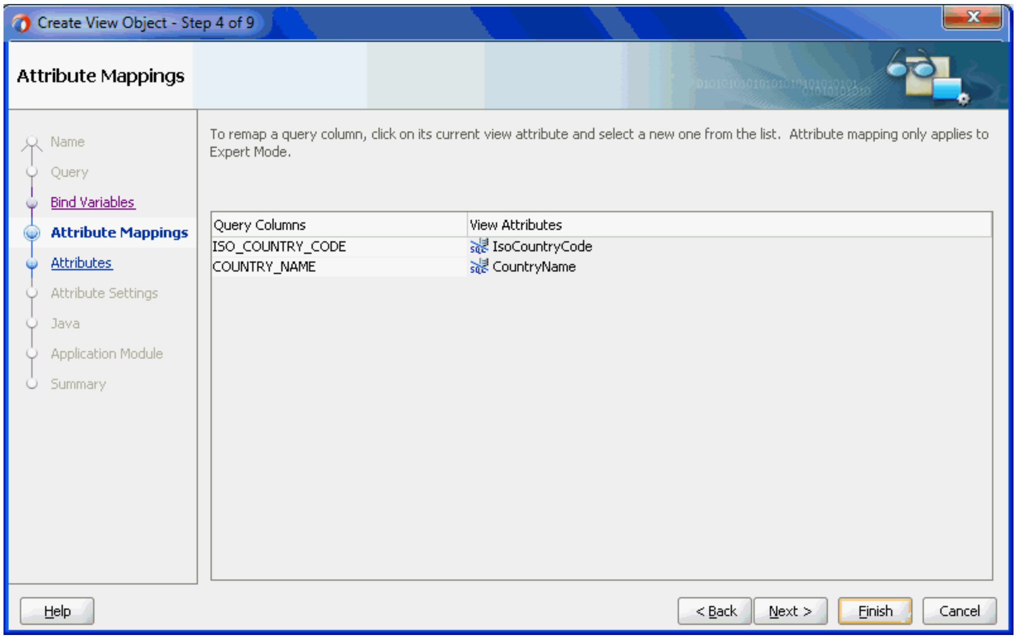
- The Java-friendly view attribute names (for example, `CountryName` instead of `COUNTRY_NAME`)

  By default, the wizard creates Java-friendly view object attribute names that correspond to the `SELECT` list column names, as shown in Figure 5-25.

  For information about using view object attribute names to access the data from any row in the view object's result set by name, see Testing View Object Instances Programmatically.

- The SQL and Java data types of each attribute

Figure 5-25 Create View Object Wizard, Attribute Mappings Page



To remap a query column, click on its current view attribute and select a new one from the list. Attribute mapping only applies to Expert Mode.

Query Columns	View Attributes
ISO_COUNTRY_CODE	IsoCountryCode
COUNTRY_NAME	CountryName

Each part of an underscore-separated column name like *`SOME_COLUMN_NAME`* is turned into a camel-capped word (like *`SomeColumnName`*) in the attribute name. While the view object attribute names correspond to the underlying query columns in the `SELECT` list, the attribute names at the view object level need not match necessarily.

Tip:

You can rename the view object attributes to any names that might be more appropriate without changing the underlying query.

JDeveloper then creates the XML document file that represents the view object's declarative settings and saves it in the directory that corresponds to the name of its package. For example, the XML file created for a view object named `CountriesVO` in the `lookups` package is `./lookups/CountriesVO.xml` under the project's source path.

To view the view object settings, select the desired view object in the Applications window and open the Structure window. The Structure window displays the list of XML definitions, including the SQL query and the list of attributes. To open the XML definition in the editor, right-click the corresponding node and choose **Go to Source**.

How to Customize SQL Statements in Custom SQL Mode

To enable custom SQL mode, select **Write Custom SQL** on the Query page of the Create View Object wizard. You can also modify the SQL statement of an existing entity-based view object in the view object overview editor. In the overview editor, navigate to the Query page and select **Write Custom SQL**.

What Happens When You Enable Custom SQL Mode

When you enable custom SQL mode, the **Select** text box in the Query page of the overview editor or wizard becomes fully editable, displaying the full SQL statement. Using this text box, you can change every aspect of the SQL query.

While you can add the ORDER BY clause directly to the **Select** text box when you are in custom SQL mode, it is still useful to keep the ORDER BY portion of the clause separate, since the runtime engine might need to append additional WHERE clauses to the query. Keeping the ORDER BY clauses separated will ensure they are applied correctly.

What You May Need to Know About Custom SQL Mode

When you define a SQL query using custom SQL mode, you type a SQL language statement directly into the editor. Using this mode places some responsibility on the Business Components developer to understand how the view object handles the metadata resulting from the query definition. Review the following information to familiarize yourself with the behavior of editing queries that you create in custom SQL mode.

Attribute Names for Calculated Expressions in Custom SQL Mode

If your SQL query includes a calculated expression, use a SQL alias to assist the Create View Object wizard in naming the column with a Java-friendly name. The following example shows a SQL query that includes a calculated expression.

```
select CUSTOMER_ID, EMAIL,
       SUBSTR(FIRST_NAME,1,1)||'. '||LAST_NAME
```

```
from CUSTOMERS
order by EMAIL
```

The following example uses a SQL alias USER_SHORT_NAME to assist the Create View Object wizard in naming the column with a Java-friendly name. The wizard will display **UserShortName** as the name of the attribute derived from this calculated expression.

```
select CUSTOMER_ID, EMAIL,
       SUBSTR(FIRST_NAME,1,1)||'. '||LAST_NAME AS USER_SHORT_NAME
from CUSTOMERS
order by EMAIL
```

Attribute Mapping Assistance in Custom SQL Mode

The automatic cooperation of a view object with its underlying entity objects depends on correct attribute-mapping metadata saved in the XML document. This information relates the view object attributes to corresponding attributes from participating entity usages. JDeveloper maintains this attribute mapping information in a fully automatic way for normal entity-based view objects. However, when you decide to use custom SQL mode with a view object, you need to pay attention to the changes you make to the SELECT list. That is the part of the SQL query that directly relates to the attribute mapping. Even in custom SQL mode, JDeveloper continues to offer some assistance in maintaining the attribute mapping metadata when you do the following to the SELECT list:

- Reorder an expression without changing its column alias

  JDeveloper reorders the corresponding view object attribute and maintains the attribute mapping.

- Add a new expression

  JDeveloper adds a new SQL-calculated view object attribute with a corresponding camel-capped name based on the column alias of the new expression.

- Remove an expression

  JDeveloper converts the corresponding SQL-calculated or entity-mapped attribute related to that expression to a transient attribute.

However, if you rename a column alias in the SELECT list, JDeveloper has no way to detect this, so it is treated as if you removed the old column expression and added a new one of a different name.

After making any changes to the SELECT list of the query, visit the Attribute Mappings page of the overview editor to ensure that the attribute-mapping metadata is correct. The table on this page, which is disabled for view objects in normal mode, becomes enabled for custom SQL mode view objects. For each view object attribute, you will see its corresponding SQL column alias in the table. By clicking into a cell in the **View Attributes** column, you can use the dropdown list that appears to select the appropriate entity object attribute to which any entity-mapped view attributes should correspond.

> **Note:**
>
> If the view attribute is SQL-calculated or transient, a corresponding attribute with a "SQL" icon appears in the **View Attributes** column to represent it. Since neither of these type of attributes are related to underlying entity objects, no entity attribute related information is required for them.

Custom Edits in Custom SQL Mode

When you disable custom SQL mode for a view object, it will return to having its `SELECT` and `FROM` clause be derived again. JDeveloper warns you that doing this might cause your custom edits to the SQL statement to be lost. If this is what you want, after acknowledging the alert, your view object's SQL query reverts back to the default.

Changes to SQL Expressions in Custom SQL Mode

Consider a `Products` view object with a SQL-calculated attribute named `Shortens` whose SQL expression you defined as `SUBSTR(NAME,1,10)`. If you switch this view object to custom SQL mode, the **Select** text box will show a SQL query similar to the one shown in the following example.

```
SELECT Products.PROD_ID,
       Products.NAME,
       Products.IMAGE,
       Products.DESCRIPTION,
       SUBSTR(NAME,1,10) AS SHORT_NAME
FROM PRODUCTS Products
```

If you go back to the attribute definition for the `Shortens` attribute and change the **SQL Expression** field from `SUBSTR(NAME,1,10)` to `SUBSTR(NAME,1,15)`, then the change will be saved in the view object's XML document. Note, however, that the SQL query in the **Select** text box will remain as the original expression. This occurs because JDeveloper never tries to *modify* the text of a custom SQL statement. In custom SQL mode, the developer is in full control. JDeveloper attempts to adjust metadata as a result of some kinds of changes you make yourself to the custom SQL statement, but it does not perform the reverse. Therefore, if you change view object metadata, the custom SQL statement is not updated to reflect it.

Therefore, you need to update the expression in the custom SQL statement itself. To be completely thorough, you should make the change *both* in the attribute metadata *and* in the custom SQL statement. This would ensure — if you (or another developer on your team) ever decides to toggle custom SQL mode *off* at a later point in time — that the automatically derived `SELECT` list would contain the correct SQL-derived expression.

> **Note:**
>
> If you find you had to make numerous changes to the view object metadata of a custom SQL mode view object, you can avoid having to manually translate any effects to the SQL statement by copying the text of your customized query to a temporary backup file. Then, you can disable custom SQL mode for the view object and acknowledge the warning that you will lose your changes. At this point JDeveloper will rederive the correct generated SQL statement based on all the new metadata changes you've made. Finally, you can enable custom SQL mode once again and reapply your SQL customizations.

SQL Calculations that Change Entity Attributes in Custom SQL Mode

If you need to present altered versions of entity-mapped attribute data, you must introduce a new SQL-calculated attribute with the appropriate expression to handle the task. In custom SQL mode, when editing the SELECT list expression that corresponds to *entity-mapped* attributes, you must not introduce SQL calculations into SQL statements that change the value of the attribute when retrieving the data.

To illustrate the problem that will occur if you introduce SQL calculations into SQL statements, consider the query for a simple entity-based view object named Products shown in the following example.

```
SELECT Products.PROD_ID,
       Products.NAME,
       Products.IMAGE,
       Products.DESCRIPTION
FROM PRODUCTS Products
```

Imagine that you wanted to limit the name column to display only the first ten characters of the name of a product query. The correct way to do that would be to introduce a new SQL-calculated field, such as ShortName with an expression like SUBSTR(Products.NAME,1,10). One way you should *avoid* doing this is to switch the view object to custom SQL mode and change the SELECT list expression for the entity-mapped NAME column to the include the SQL-calculate expression, as shown in the following example.

```
SELECT Products.PROD_ID,
       SUBSTR(Products.NAME,1,10) AS NAME,
       Products.IMAGE,
       Products.DESCRIPTION
FROM PRODUCTS Products
```

This alternative strategy would initially appear to work. At runtime, you see the truncated value of the name as you are expecting. However, if you modify the row, when the underlying entity object attempts to lock the row it does the following:

- Issues a SELECT FOR UPDATE statement, retrieving all columns as it tries to lock the row.
- If the entity object successfully locks the row, it compares the original values of all the persistent attributes in the entity cache as they were last retrieved from the database with the values of those attributes just retrieved from the database during the lock operation.

- If any of the values differs, then the following error is thrown:

  ```
  (oracle.jbo.RowInconsistentException)
  JBO-25014: Another user has changed the row with primary key [...]
  ```

If you see an error like this at runtime even though you are the *only* user testing the system, it is most likely due to your inadvertently introducing a SQL function in your custom SQL view object that changed the selected value of an entity-mapped attribute. In the above example, the `SUBSTR(Products.NAME,1,10)` function introduced causes the original selected value of the `Name` attribute to be truncated. When the row-lock SQL statement selects the value of the `NAME` column, it will select the entire value. This will cause the comparison shown in the above example to fail, producing the "phantom" error that another user has changed the row.

The same thing would happen with `NUMBER`-valued or `DATE`-valued attributes if you inadvertently apply SQL functions in custom SQL mode to truncate or alter their retrieved values for entity-mapped attributes.

Formatting of the SQL Statement in Custom SQL Mode

When you change a view object to custom SQL mode, its XML document changes from storing parts of the query in separate XML attributes, to saving the entire query in a single `<SQLQuery>` element. The query is wrapped in an XML `CDATA` section to preserve the line formatting you may have done to make a complex query be easier to understand.

Query Clauses in Custom SQL Mode

If your custom SQL view object:

- Contains a `ORDERBY` clause specified in the **Order By** field of the Query page of the overview editor at design time, or
- Has a dynamic `WHERE` clause or `ORDERBY` clause applied at runtime using `setWhereClause()` or `setOrderByClause()`

Then its query gets nested into an inline view before applying these clauses. For example, suppose your custom SQL query was defined like the one shown in the following example.

```
select CUSTOMER_ID, EMAIL, FIRST_NAME, LAST_NAME
from CUSTOMERS
union all
select CUSTOMER_ID, EMAIL, FIRST_NAME, LAST_NAME
from INACTIVE_CUSTOMERS
```

Then, at runtime, when you set an additional `WHERE` clause like `email = :TheUserEmail`, the view object nests its original query into an inline view like the one shown in the following example.

```
SELECT * FROM(
select CUSTOMER_ID, EMAIL, FIRST_NAME, LAST_NAME
from CUSTOMERS
union all
select CUSTOMER_ID, EMAIL, FIRST_NAME, LAST_NAME
from INACTIVE_CUSTOMERS) QRSLT
```

And, the view object adds the dynamic `WHERE` clause predicate at the end, so that the final query the database sees looks like the one shown in the following example.

```
SELECT * FROM(
select CUSTOMER_ID, EMAIL, FIRST_NAME, LAST_NAME
from CUSTOMERS
union all
select CUSTOMER_ID, EMAIL, FIRST_NAME, LAST_NAME
from INACTIVE_CUSTOMERS) QRSLT
WHERE email = :TheUserEmail
```

This query "wrapping" is necessary in general for custom SQL queries, because the original query could be arbitrarily complex, including SQL `UNION`, `INTERSECT`, `MINUS`, or other operators that combine multiple queries into a single result. In those cases, simply "gluing" the additional runtime `WHERE` clause onto the end of the query text could produce unexpected results. For example, the clause might apply only to the *last* of several `UNION`'ed statements. By nesting the original query verbatim into an inline view, the view object guarantees that your additional `WHERE` clause is correctly used to filter the results of the original query, regardless of how complex it is.

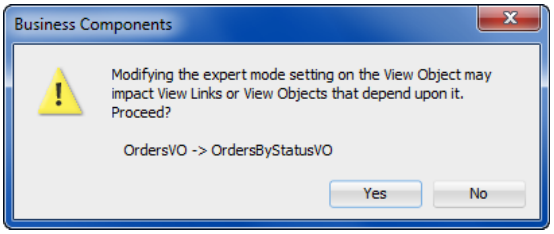
Inline View Wrapping at Runtime

Inline view wrapping of custom SQL view objects, limits a dynamically added `WHERE` clause to refer only to columns in the `SELECT` list of the original query. To avoid this limitation, when necessary you can disable the use of the inline view wrapping by calling `setNestedSelectForFullSql(false)`.

Custom SQL Affect on Dependent Objects

When you modify a view object query to be in custom SQL mode after you have already created the view links that involve that view object or after you created other view objects that extend the view object, JDeveloper will warn you with the alert shown in Figure 5-26. The alert reminds you that you should revisit these dependent components to ensure their SQL statements still reflect the correct query.

Figure 5-26 Proactive Reminder to Revisit Dependent Components



Business Components

Modifying the expert mode setting on the View Object may impact View Links or View Objects that depend upon it. Proceed?

OrdersVO -> OrdersByStatusVO

For example, if you were to modify the `OrdersVO` view object to use custom SQL mode, because the `OrdersByStatusVO` view object extends it, you need to revisit the extended component to ensure that its query still logically reflects an extension of the modified parent component.

Custom SQL Affect on View Object Query Auto Refresh

When you create a view object query statement in custom SQL mode and you wish to enable automatic query updates using Oracle Database change notification, you will need to test the query statement for compatibility with query result change notification. You can test the query in the Test Query dialog by clicking the **Test and Explain** button in the Query page of the view object overview editor. The Change Notification tab in the Test Query dialog will confirm whether the query can be registered for change notification. If the query statement is not compatible, you will need to revise the query as required by Oracle Database query result change notification registration requirements. For more information, see How to Automatically Refresh the View Object of the View Accessor.

SQL Types of Attributes in Custom SQL Mode

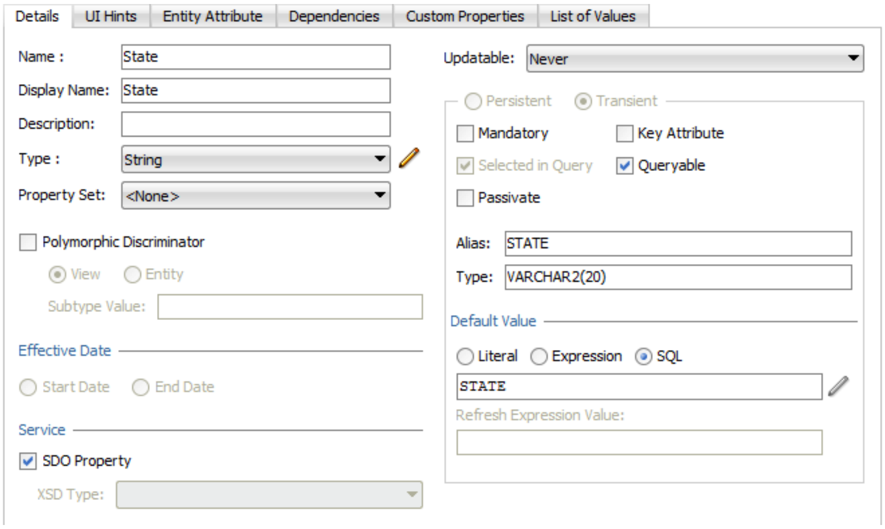
JDeveloper tries to infer the SQL type of the mapped column for view object attributes that you create in custom SQL mode automatically. The **Type** property of the attribute records the SQL type of the column, including the length information for `VARCHAR2` columns and the precision and scale information for `NUMBER` columns. However, for some SQL expressions the inferred value might default to `VARCHAR2(255)`.

You can update the **Type** value for this type of attribute to reflect the correct length if you know it. For example, `VARCHAR2(20)` which shows as the **Type** for the `State` attribute in Figure 5-27 means that it has a maximum length of 20 characters. For a `NUMBER` column, you would indicate a **Type** of `NUMBER(7,2)` for an attribute that you want to have a precision of 7 digits and a scale of 2 digits after the decimal.

Performance Tip:

Your SQL expression can control how long the describe from the database says the column is. Use the `SUBSTR()` function around the existing expression. For example, if you specify `SUBSTR(`*`yourexpression`*`, 1, 15)`, then the describe from the database will inform JDeveloper that the column has a maximum length of 15 characters.

Figure 5-27 Custom Attribute Settings in the Details Section of SQL-Derived Attributes



Name : State
Display Name: State
Description:
Type : String

In the case of entity-based view objects, you must edit the **Type** property in the Details section of the Attributes page of the overview editor that you display for the entity object, as described in How to Indicate Data Type, Length, Precision, and Scale.

Working with Named View Criteria

You can define ADF view criteria to filter data from view object rows. You can create specific usages of the view object by defining different named view criteria.

A view criteria lets you specify filter information for the rows of a view object collection. The view criteria object is a row set of one or more view criteria groups, whose attributes mirror those in the view object. The view criteria definition comprises query conditions that augment the `WHERE` clause of the target view object. However, unlike the `WHERE` clause defined by the view object query statement, which applies to all instances of the view object, the view criteria query condition is added to specific view object instances. This allows you to create specific usages of the target view object definition using query conditions that apply to the individual attributes of the target view object.

View criteria definitions support Query-by-Example operators and therefore allows the user to enter conditions such as "`OrderId > 304`", for example.

The Edit View Criteria dialog lets you create view criteria and save them as part of the view object's definition, where they appear as named view criteria. You use the View Criteria page of the overview editor to define view criteria for specific view objects. View criteria that you define at design time can participate in these scenarios where filtering results is desired at runtime:

- Supporting Query-by-Example search forms that allow the end user to supply values for attributes of the target view object.

  For example, the end user might input the value of a customer name and the date to filter the results in a web page that displays the rows of the `CustomerOrders` view object. The web page designer will see the named view criteria in the JDeveloper Data Controls panel as well as ADF Business Components data control, and, from them, easily create a search form. For more information about the utilizing the named view criteria in the Data Controls panel, see Creating Query Search Forms.

- Supporting row finder operations that the application may use to perform row look ups using any non-key attribute.

  For example, it is usually preferable to allow the end user to make row updates without the need to know the row key value (often an ID). In this case, a row finder that you apply to a view criteria supports locating a row using easily identifiable attribute values, such as by user name and user email address. See Working with Row Finders.

- Filtering the **list of values (LOV)** components that allow the end user may select from one attribute list (displayed in the UI as an LOV component).

  The web page designer will see the attributes of the view object in the JDeveloper Data Controls panel and, from them, easily create LOV controls. For information about utilizing LOV-enabled attributes in the Data Controls panel, see Creating a Selection List.

- Validating attribute values using a **view accessor** with a view criteria applied to filter the view accessor results.

For information about create view accessor validators, see How to Validate Against the Attribute Values Specified by a View Accessor.

- Creating the application module's data model from a single view object definition with a unique view criteria applied for each view instance.

  The single view object query modified by view criteria is useful with look up data that must be shared across the application. In this case, a base view object definition queries the lookup table in the database and the view criteria set the lookup table's `TYPE` column to define application-specific views. To define view instances in the data model using the view criteria you create for a base view object definition, see How to Define the WHERE Clause of the Lookup View Object Using View Criteria.

Additionally, view criteria have full API support, and it is therefore possible to create and apply view criteria to view objects programmatically.

How to Create Named View Criteria Declaratively

View criteria have a number of uses in addition to applying them to declarative queries at runtime. In all usages, the named view criteria definition consists of a set of attribute requirements that you specify to filter individual view object results. The features of the view criteria definition that you can use will depend on its intended usage.

To define view criteria for the view object you wish to filter, you open the view object in the overview editor and click the **Create** button in the **View Criteria** page. A dedicated editor (the Create View Criteria dialog) helps you to build a `WHERE` clause using attribute names instead of the target view object's corresponding SQL column names. You may define multiple named view criteria for each view object.

Before you work with the Create View Criteria dialog to create named view criteria, familiarize yourself with the usages described in Working with Named View Criteria. The chapter references provide additional details that will help you to anticipate using the appropriate features of the Create View Criteria dialog. For example, when you create a view criteria to specify the searchable attributes of a search form, the view criteria condition defines a simple list of attributes (a subset of the view object's attributes) to be presented to the user, but then the view criteria definition requires that you specify UI hints (model-level properties) to control the behavior of those attributes in the search form. The Create View Criteria dialog displays all the UI hints in a separate tabbed page that you select for the view criteria you are defining. Whereas, when your view criteria is intended to specify view instances in the data model, you can define arbitrarily complex query filter conditions, but you can ignore the UI hints features displayed by the Create View Criteria dialog.

Each view criteria definition consists of the following elements:

- An arbitrary number of view criteria groups or an arbitrary number of references to another named view criteria already defined for the current view object.
- An arbitrary number of view criteria items (grouped by view criteria groups) consisting of an attribute name, an attribute-appropriate operator, and an operand. Operands can be a literal value when the filter value is defined or a bind variable that can optionally utilize a scripting expression that includes dot notation access to attribute property values.

  Expressions are based on the Groovy scripting language, as described in Using Groovy Scripting Language with Business Components.

When you define a view criteria, you control the source of the filtered results. You can limit the results of the filtered view object to:

- Just the database query results.
- Just the in-memory results of the view object query. For example, new rows added by the user.
- Both the database and the in-memory results of the view object query.

Filtering on both database tables and the view object's in-memory results allows you to filter rows that were created in the transaction but not yet committed to the database.

View criteria expressions you construct in the Edit View Criteria dialog use logical conjunctions to specify how to join the selected criteria item or criteria group with the previous item or group in the expression:

- `AND` conjunctions specify that the query results meet both joined conditions. This is the default for each view criteria item you add.
- `OR` conjunctions specify that the query results meet either or both joined conditions. This is the default for view criteria groups.

Additionally, you may create nested view criteria when you want to filter rows in the current view object based on criteria applied to view-linked detail views. A nested view criteria group consists of an arbitrary number of nested view criteria items. You can use nested view criteria when you want to have more controls over the logical conjunctions among the various view criteria items. The nested criteria place restrictions on the rows that satisfy the criteria under the nested criteria's parent view criteria group. For example, you might want to query both a list of employees with (`Salary > 3000`) and belonging to (`DeptNo = 10` or `DeptNo = 20`). You can define a view criteria with the first group with one item for (`Salary > 3000`) and a nested view criteria with the second group with two items `DeptNo = 10` and `DeptNo =20`.

Before you begin:

It may be helpful to have an understanding of the ways you can use view criteria. The usage you intend will affect the best practices for creating named view criteria. For more information about the supported usages, see Working with Named View Criteria.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

- Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.
- If the view criteria will use a bind variable in the operand, create the bind variable, as described in How to Add View Criteria Bind Variables to a View Object Definition.

To define a named view criteria:

1. In the Applications window, double-click the view object for which you want to create the named view criteria.
2. In the overview editor, click the **View Criteria** navigation tab and then click the **Create New View Criteria** button.

3. In the Create View Criteria dialog, enter the name of the view criteria to identify its usage in your application.

4. In the **Query Execution Mode** dropdown list, decide how you want the view criteria to filter the view object query results.

   You can limit the view criteria to filter the database table specified by the view object query, the in memory row set produced by the query, or both the database table and the in-memory results.

   Choosing **Both** may be appropriate for situations where you want to include rows created as a result of enforced view link consistency. In this case, in-memory filtering is performed after the initial fetch. For details about view link consistency, see Maintaining New Row Consistency Between View Objects Based on the Same Entity.

5. In the Criteria Definition tab, click one of these **Add** buttons to define the view criteria.

   - **Add Item** to add a single criteria item. The editor will add the item to the hierarchy beneath the current group or view criteria selection. By default each time you add an item, the editor will choose the next attribute to define the criteria item. You can change the attribute to any attribute that the view object query defines.

   - **Add Group** to add a new group that will compose criteria items that you intend to add to it. When you add a new group, the editor inserts the `OR` conjunction into the hierarchy. You can change the conjunction as desired.

   - **Add Criteria** to add a view criteria that you intend to define. This selection is an alternative to adding a named criteria that already exists in the view object definition. When you add a new view criteria, the editor inserts the `AND` conjunction into the hierarchy. You can change the conjunction as desired. Each time you add another view criteria, the editor nests the new view criteria beneath the current view criteria selection in the hierarchy. The root node of the hierarchy defines the named view criteria that you are currently editing.

     Search forms that the UI designer will create from view criteria are not able to use directly nested view criteria. For more information about defining nested expressions for use with search forms, see What You May Need to Know About Nested View Criteria Expressions.

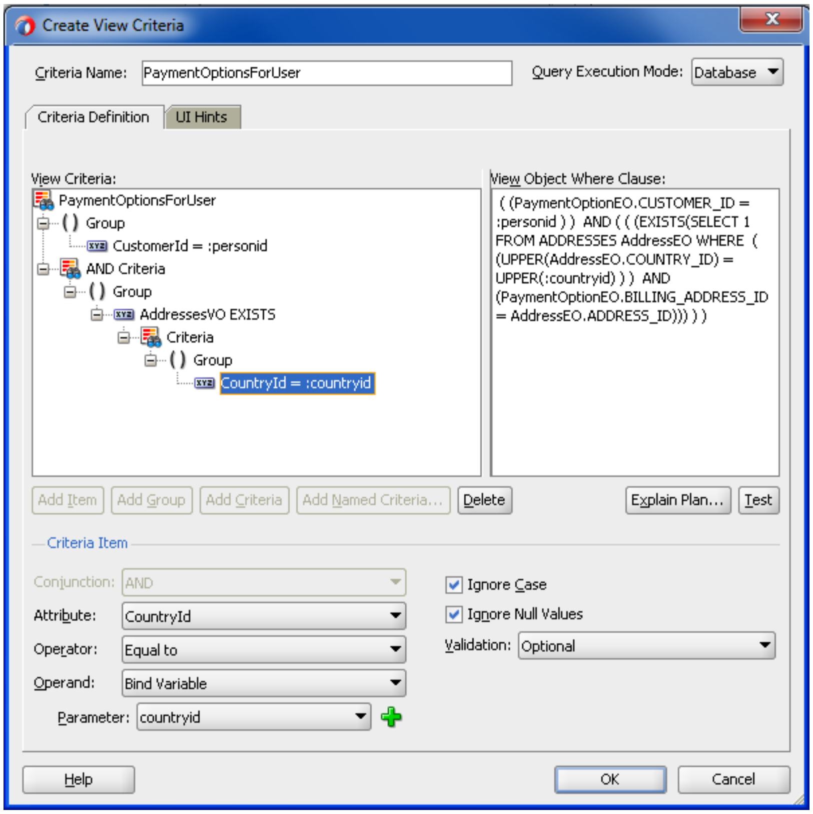
   - **Add Named Criteria** to add a view criteria that the view object defines. The named criteria must appear in the overview editor for the view object you are defining the view criteria.

6. Select a view criteria item node in the view criteria hierarchy and define the added node in the **Criteria Item** section.

   - Choose the desired **Attribute** for the criteria item. By default the editor adds the first one in the list.

     Optionally, you can add a nested view criteria inline when a view link exists for the current view object you are editing. The destination view object name will appear in the **Attribute** dropdown list. Selecting a view object lets you filter the view criteria based on view criteria items for the nested view criteria based on a view link relationship. For example, `EmpVO` is linked to the `PaymentOptionsVO` and a view criteria definition for `PaymentOptionsVO` will display the destination view object `AddressVO`. You could define the nested view criteria to filter payment options based on the `CountryId` attribute of the current customer, as specified by the `CustomerId` criteria item, as shown in Figure 5-28.

Figure 5-28   Edit View Criteria Dialog with Nested View Criteria Specified



Criteria Name: PaymentOptionsForUser

Query Execution Mode: Database

View Criteria:

```
PaymentOptionsForUser
  ( ) Group
      CustomerId = :personid
  AND Criteria
    ( ) Group
      AddressesVO EXISTS
        Criteria
          ( ) Group
              CountryId = :countryid
```

View Object Where Clause:

```
( (PaymentOptionEO.CUSTOMER_ID =
:personid ) )  AND ( ( (EXISTS(SELECT 1
FROM ADDRESSES AddressEO WHERE  (
(UPPER(AddressEO.COUNTRY_ID) =
UPPER(:countryid) ) )  AND
(PaymentOptionEO.BILLING_ADDRESS_ID
= AddressEO.ADDRESS_ID))) ) )
```

Criteria Item

Conjunction: AND

Attribute: CountryId

Operator: Equal to

Operand: Bind Variable

Parameter: countryid

☑ Ignore Case

☑ Ignore Null Values

Validation: Optional

- Choose the desired **Operator**.

  The list displays only the operators that are appropriate for the selected attribute or view object. In the case of a view object selection, the **exists** operator applies to a view criteria that you will define (or reference) as an operand. In the case of String and Date type attributes, the **Between** and **Not between** operators require you to supply two operand values to define the range. In the case of Date type attributes, you can select operators that test for a date or date range (with date values entered in the format YYYY-MM-DD). For example, for December 16th, 2010, enter 2010-12-16.

  JDeveloper does not support the `IN` operator. However, you can create a view criteria with the `IN` operator using the API, as described in How to Create View Criteria Programmatically.

7. Choose the desired **Operand** for the view criteria item selection.

   - Select **Literal** when you want to supply a value for the attribute or when you want to define a default value for a user-specified search field for a Query-by-Example search form. When the view criteria defines a query search form for the user interface, you may leave the **Value** field empty. In this case, the user will supply the value. You may also provide a value that will act as a search field default value that the user will be able to override. The value you supply in the **Value** field can include wildcard characters `*` or `%`.

   - Select **Bind Variable** when you want the value to be determined at runtime using a bind variable. If the variable was already defined for the view criteria, select it from the **Parameter** dropdown list. Otherwise, click **New** to display the New Variable dialog that lets you name a new bind variable on the view criteria.

When you select an existing bind variable from the dropdown list for use by the view criteria, you will be able to select bind variables that have been defined for the view object query or for the view criteria. The difference between these two sets of bind variables is that query bind variables (ones that you define in the Query page of the overview editor) are typically used within the view object query statement and therefore support different validation use cases than view criteria-defined bind variables. For view criteria, typically you always select a bind variable that is defined in the View Criteria page of the overview editor.

For further discussion about view criteria use cases for bind variables and literals, see What You May Need to Know About Bind Variables in View Criteria.

8. For each item, group, or nested view criteria that you define, optionally change the default conjunction to specify how the selection should be joined.
   - **AND** conjunction specifies that the query results meet both joined conditions. This is the default for each view criteria item or view nested view criteria that you add.
   - **OR** conjunction specifies that the query results meet either or both joined conditions. This is the default for view criteria groups.
9. Verify that the view criteria definition is valid by doing one of the following:
   - Click **Explain Plan** to visually inspect the view criteria's generated `WHERE` clause.
   - Click **Test** to allow JDeveloper to verify that the `WHERE` clause is valid.
10. To disable case-sensitive filtering of the attribute based on the case of the runtime-supplied value, leave **Ignore Case** selected.

    The criteria item can be a literal value that you define or a runtime parameter that the end user supplies. This option is supported for attributes of type String only. The default disables case sensitive searches.
11. In the **Validation** dropdown list, decide whether the view criteria item is a required or an optional part of the attribute value comparison in the generated `WHERE` clause.
    - **Selectively Required** means that the `WHERE` clause will ignore the view criteria item at runtime if no value is supplied and there exists at least one criteria item in the same view criteria group that has a criteria value. Otherwise, an exception is thrown.
    - **Optional** means the view criteria (or search field) is added to the `WHERE` clause only if the value is non-`NULL`. The default **Optional** for each new view criteria item means no exception will be generated for null values.
    - **Required** means that the `WHERE` clause will fail to execute and an exception will be thrown when no value is supplied for the criteria item.
12. If the view criteria uses a bind variable as the operand, decide whether the `IS NULL` condition is the generated in the `WHERE` clause. This field is enabled only if you have selected **Optional** for the validation of the bind variable.
    - Leave **Ignore Null Values** selected (default) when you want to permit the view criteria to return a result even when the bind variable value is not supplied

at runtime. For example, suppose you define a view criteria to allow users to display a cascading list of countries and states (or provinces) through a bind variable that takes the `countryID` as the child list's controlling attribute. In this case, the default behavior for the view criteria execution returns the list of *all* states if the user makes no selection in the parent LOV (an empty `countryId` field). The generated `WHERE` clause would look similar to `(((CountryEO.COUNTRY_ID =:bvCountryId) OR (:bvCountryId IS NULL)))`, where the test for a null value guarantees that the child list displays a result even when the bind variable is not set. When validation is set to **Required** or **Selectively Required**, the view criteria expects to receive a value and thus this option to ignore null values is disabled.

- Deselect **Ignore Null Values** when you expect the view criteria to return a null result when the bind variable value is not supplied at runtime. In the example of the cascading lists, the view criteria execution returns *no* states if the user makes no selection with an empty `countryID` field. In this case, the generated `WHERE` clause would look similar to `((CountryEO.COUNTRY_ID=:bvCountryId))`, where the test for null is not performed, which means the query is expected to function correctly with a null value bind variable. Note that the combination of optional validation with null values is only possible for bind variables that are required. Required bind variables are those defined in the Query page of the overview editor and used in the query `WHERE` clause.

  Note that the validation settings **Required** or **Selectively Required** also remove the null value condition but can be used in combination with a deselected **Ignore Null Values** setting to support a different use case. For more details about the interaction of these settings, see What You May Need to Know About Bind Variables in View Criteria.

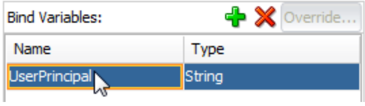
13. Click **OK**.
14. If any of the view criteria conditions you defined reference a bind variable, then in the View Criteria page, select the bind variable and then in the **Details** section, click the **Value** tab and optionally specify a default value for the bind variable:
    - When you want the value to be determined at runtime using an expression, enter a Groovy scripting language expression, select the **Expression** value type and enter the expression in the **Value** field.
    - When you want to define a default value, select the **Literal** value type and enter the literal value in the **Value** field.
15. Leave **Updatable** selected when you want the bind variable value to be defined through the user interface.

    The **Updatable** checkbox controls whether the end user will be allowed to change the bind variable value through the user interface. If a bind variable is not updatable (it may not be changed either programmatically or by the end user), deselect **Updatable**.
16. In the View Criteria page, click the **UI Hints** tab and specify hints like **Label**, **Format Type**, **Format** mask, and others.

    The view layer will use bind variable UI hints when you build user interfaces like search pages that allow the user to enter values for the named bind variables. Note that formats are only supported for bind variables defined by the `Date` type or any numeric data type.
17. If you created bind variables that you do not intend to reference in the view criteria definition, select the bind variable and click the **Delete** button.

Confirm that your bind variable has been named in the view criteria by moving your cursor over the bind variable name field, as shown in Figure 5-29. JDeveloper identifies unreferenced bind variables by displaying the name field with an orange border.

Figure 5-29 Orange Border Reminds to Reference the Bind Variable



What Happens When You Create a Named View Criteria

The Create View Criteria dialog in JDeveloper lets you easily create view criteria and save them as named definitions. These named view criteria definitions add metadata to the XML document file that represents the target view object's declarative settings. Once defined, named view criteria appear by name in the View Criteria page of the overview editor for the view object.

To view the view criteria, expand the desired view object in the Applications window, select the XML file under the expanded view object, open the Structure window, and expand the View Criteria node. Each view criteria definition for a view object contains one or more `<ViewCriteriaRow>` elements corresponding to the number of groups that you define in the Create View Criteria dialog. The following example shows the `ProductsVO.xml` file with the `<ViewCriteria>` definition `FindByProductNameCriteria` and a single `<ViewCriteriaRow>` that defines a developer-defined search form for products using the bind variable `:bvProductName`. Any UI hints that you selected to customize the behavior of a developer-defined search from will appear in the `<ViewCriteria>` definition as attributes of the `<CustomProperties>` element. For details about specific UI hints for view criteria, see How to Set User Interface Hints on View Criteria to Support Search Forms.

```
<ViewObject
    xmlns="http://xmlns.oracle.com/bc4j"
    Name="ProductsVO"
    ... >
  <SQLQuery>
    ...
  </SQLQuery>
  ...
  <ViewCriteria
    Name="FindByProductNameCriteria"
    ViewObjectName="oracle.summit.model.views.ProductsVO"
    Conjunction="AND">
    <Properties>
      <CustomProperties>
        <Property
          Name="mode"
          Value="Basic"/>
        <Property
          Name="autoExecute"
          Value="false"/>
        <Property
          Name="showInList"
          Value="true"/>
        <Property
          Name="displayName"
          Value="Find Products By Name"/>
        <Property
          Name="displayOperators"
          Value="InAdvancedMode"/>
        <Property
          Name="allowConjunctionOverride"
          Value="true"/>
      </CustomProperties>
    </Properties>
    <ViewCriteriaRow
      Name="vcrow87">
      <ViewCriteriaItem
        Name="ProductName"
        ViewAttribute="ProductName"
        Operator="CONTAINS"
        Conjunction="AND"
        Value=":bvProductName"
        UpperColumns="1"
        IsBindVarValue="true"
        Required="Optional"/>
    </ViewCriteriaRow>
  </ViewCriteria>
  ...
</ViewObject>
```

Additionally, when you create view objects and specify them as instances in an application module, JDeveloper automatically creates a **data control** to encapsulate the collections (view instances) that the application module contains. JDeveloper then populates the Data Controls panel with these collections and any view criteria that you have defined, as shown in How View Objects Appear in the Data Controls Panel.

What You May Need to Know About Bind Variables in View Criteria

The view criteria filter that you define using a bind variable expects to obtain its value at runtime. This can be helpful in a variety of user interface scenarios. To support a particular use case, familiarize yourself with the combination of the **Validation** and **Ignore Null Values** settings shown in Table 5-1.

Table 5-1 Use Cases for Bind Variable Options in View Criteria

Validation	Ignore Null Values	Use Cases	Notes
`Optional`	`True` (Default)	Configure cascading **List of Values (LOV)** where the parent LOV value is optional. Generate an optional search field in a search form.	This combination generates the SQL query `(ProductName = :bind) OR (:bind IS NULL)`. When used for cascading LOVs, no selection in the parent LOV returns all rows in the child LOV. To ensure that all rows are not returned prior to executing a search, a view criteria item with a literal operand (not a bind variable) type is preferred. When a bind variable on a view criteria with optional validation usage is not resolved, the result will be all rows returned.

Table 5-1 (Cont.) Use Cases for Bind Variable Options in View Criteria

Validation	Ignore Null Values	Use Cases	Notes
`Optional`	`False` (must select a required bind variable that has been defined in a query `WHERE` clause to achieve this combination)	Configure cascading LOVs where the parent LOV value is required.	This combination generates the SQL query (`ProductName = :bind`). When used for cascading LOVs, no selection in the parent LOV returns no rows in the child LOV. Avoid this combination for search forms, because when the user leaves the search field blank the search will attempt to find rows where this field is explicitly NULL. A better way to achieve this is for the user to explicitly select the "IS NULL" operator in advanced search mode.
`Required`	`False` (default and cannot be modified for this combination)	Generate a required search field in a search form.	This combination generates the SQL query `ProductName = :bind`. Avoid this setting for cascading LOVs, because no selection in the parent LOV will cause a validation error. To ensure that a non-NULL search result exists prior to executing a search, a view criteria item with a literal operand (not a bind variable) type is preferred. When a bind variable on a view criteria with required validation usage is not resolved, the result will be no rows returned.

What You May Need to Know About Nested View Criteria Expressions

Search forms that the UI designer will create from view criteria are not able to work with all types of nested expressions. Specifically, search forms do not support expressions with directly nested view criteria. This type of nested expression defines one view criteria as a direct child of another view criteria. Query search forms do support nested expressions where you nest the view criteria as a child of a criteria item which is itself a child of a view criteria. For more information about using view criteria to create search forms, see Implicit and Named View Criteria.

How to Set User Interface Hints on View Criteria to Support Search Forms

Named view criteria that you create for view object collections can be used by the web page designer to create Query-by-Example search forms. Web page designers select your named view criteria from the JDeveloper Data Controls panel to create search forms for the Fusion web application. In the web page, the search form utilizes an ADF Faces query search component that will be bound initially to the named view criteria selected in the Data Controls panel. At runtime, the end user may select among all other named view criteria that appear in the Data Controls panel. Named view criteria that the end user can select in a search form are known as **developer-defined system searches**. The query component automatically displays these system searches in its **Saved Search** dropdown list. For more information about creating search forms and using the ADF query search component, see Creating Query Search Forms.

> **Note:**
>
> By default, any named view criteria you create in the Edit View Criteria dialog will appear in the Data Controls panel. As long as the **Show In List** option appears selected in the UI Hints page of the Edit View Criteria dialog, JDeveloper assumes that the named view criteria should be available as a developer-defined system search. When you want to create a named view criteria that you do not want the end user to see in search forms, deselect the **Show In List** option in the dialog. For example, you might create a named view criteria only for an LOV-enabled attribute and so you would need to deselect **Show In List**.

Because developer-defined system searches are created in the data model project, the UI Hints page of the Edit View Criteria dialog lets you specify the default properties for the query component's runtime usage of individual named view criteria. At runtime, the query component's behavior will conform to the selections you make for the following system search properties:

Search Region Mode: Select the mode that you want the query component to display the system search as. The **Basic** mode has all features of **Advanced** mode, except that it does not allow the end user to dynamically modify the displayed search criteria fields. The default is **Basic** mode for a view criteria you define in the Edit View Criteria dialog.

Query Automatically: Select when you want the query associated with the named view criteria to be executed and the results displayed in the web page. Any developer-defined system search with this option enabled will automatically be executed when the end user selects it from the query component's **Saved Search** list. Deselect when the web page designer prefers not to update the previously displayed results until the end user submits the search criteria values on the form. Additionally, when a search form is invoked from a task flow, the search form will appear empty when this option is deselected and populated when enabled. By default, this option is disabled for a view criteria you define in the Edit View Criteria dialog.

Show Operators: Determine how you want the query component to display the operator selection field for the view criteria items to the end user. Note that the operators displayed by the query component when the users changes the mode of the query component from advanced to basic may change depending upon how you have configured **Show Operators**. The query component will only preserve the user’s selection between modes when you set **Show Operators** to **Always** to allow the full list of operators in both modes. However, if you set **Show Operators** to **In Advanced Mode** to only show the full list of operators in advanced mode, then after the user makes their selections and switches to basic mode, the operators will default to the ones defined by the view criteria and for this reason the user’s selections may appear to change. Select **Never** when you want the view criteria to be executed using ONLY the operators it defines (where the full list of operators will not be exposed in either basic or advance modes). Note that although search forms display any bind variables used in the query `WHERE` clause as search criteria, the **Show Operators** setting does not support displaying the operators associated with these bind variable expressions.

Show Match All and Match Any: Select to allow the query component to display the **Match All** and **Match Any** radio selection buttons to the end user. When these buttons are present, the end user can use them to modify the search to return matches for all view criteria items or any one view criteria item. This is equivalent to enforcing `AND` (match all) or `OR` (match any) conjunctions between view criteria items. Deselect when you want the view criteria to be executed using the view criteria item conjunctions it defines. In this case, the query component will not display the radio selection buttons.

Rendered Mode: Select individual view criteria items from the view criteria tree component and choose whether you want the selected item to appear in the search form when the end user toggles the query component between basic mode and advanced mode. The default for every view criteria item is **All**. The default mode permits the query component to render an item in either basic or advanced mode. By changing the **Rendered Mode** setting for individual view criteria items, you can customize the search form's appearance at runtime. For example, you may want basic mode to display a simplified search form to the end user, reserving advanced mode for displaying a search form with the full set of view criteria items. In this case, you would select **Advanced** for the view criteria item that you do not want displayed in the query component's basic mode. In contrast, when you want the selected view criteria item to be rendered only in basic mode, select **Basic**. Set any item that you do not want the search form to render in either basic or advanced mode to **Never**.

> **Note:**
>
> When your view criteria includes an item that should not be exposed to the user, use the **Rendered Mode** setting **Never** to prevent it from appearing in the search form. For example, a view criteria may be created to search for products in the logged-in customer's cart; however, you may want to prevent the user from changing the customer ID to display another customer's cart contents. In this scenario, the view criteria item corresponding to the customer ID would be set to the current customer ID using a named bind variable. Although the bind variable definition might specify the variable as not required and not updatable, with the UI hint property **Display** set to **Hide**, only the **Rendered Mode** setting determines whether or not the search form displays the value.

Support Multiple Value Selection: Select when you want to allow the end user to make multiple selections for an individual criteria item that the query component displays. This option is only enabled when the view object attribute specified by the view criteria item has a List of Values (LOV) defined. Additionally, multiple selections will only be supported by the query component when the end user selects the operator **equal to** or **not equal to**. For example, if the criteria item names an attribute `CountryId` and this attribute derives its values from a list of country IDs accessed by the attribute's associated LOV, then selecting this option would allow the end user to submit the query with multiple country selections. At runtime, the query component will generate the appropriate query clause based on the end user's operator selection.

Display Width: Enter the character width to be used by the control that displays this criteria item in the query component. The value you enter will override the display width **control hint** defined for the criteria item's corresponding view object attribute. For example, in an edit form the attribute control hint may allow text of 1024 length, but in the search form you might want to limit the field for the criteria item to 20 character length.

Show In List: Select to ensure that the view criteria is defined as a developer-seeded query. Deselect when the named view criteria you are defining is not to be used by the query search component to display a search form. Your selection determines whether the named view criteria will appear in the query search component's **Saved Search** dropdown list of available system searches. By default, this option is enabled for a view criteria you define in the Edit View Criteria dialog.

Display Name: Enter the name of the system search that you want to appear in the query component's **Saved Search** dropdown list or click the **...** button (to the right of the edit field) to select a message string from the resource bundle associated with the view object. The display name will be the name by which the end user identifies the system search. When you select a message string from the resource bundle, JDeveloper saves the string's corresponding message key in the view object definition file. At runtime, the UI locates the string to display based on the end user's locale setting and the message key in the localized resource bundle. When you do not specify a display name, the view criteria name displayed in the Edit View Criteria dialog will be used by default.

To create a system search for use by the ADF query search component, you select **Show In List** in the UI Hints page of the Edit View Criteria dialog. You deselect **Show In List** when you do not want the end user to see the view criteria in their search form.

Before you begin:

It may be helpful to have an understanding of view criteria. See Working with Named View Criteria.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See Additional Functionality for View Objects.

You will need to complete these tasks:

- Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.
- Create the view criteria, as described in How to Create Named View Criteria Declaratively.

For information abou defining UI hints for view object attributes, see How to Add Attribute-Specific UI Hints.

To customize a named view criteria for the user interface:

1. In the Applications window, double-click the view object that defines the named view criteria you want to use as a system search.
2. In the overview editor, click the **View Criteria** navigation tab and select the named view criteria that you want to allow in system searches and then click the **Edit Selected View Criteria** button.
3. In Edit View Criteria dialog, click the **UI Hints** tab and ensure that **Show In List** is selected.

   This selection determines whether or not the query component will display the system search in its **Saved Search** dropdown list.
4. Enter a user-friendly display name for the system search to be added to the query component's Saved Search dropdown list.

   When left empty, the view criteria name displayed in the Edit View Criteria dialog will be used by the query component.

5. Optionally, enable **Query Automatically** when you want the query component to automatically display the search results whenever the end user selects the system search from the **Saved Search** dropdown list.

   By default, no search results will be displayed.

6. Optionally, apply **Criteria Item UI Hints** to customize whether the query component renders individual criteria items when the end user toggles the search from between basic and advanced mode.

   By default, all view criteria items defined by the system search will be displayed in either mode.

   If a rendered criteria item is of type `Date`, you must also define UI hints for the corresponding view object attribute. Set the view object attribute's Format Type hint to **Simple Date** and set the Format Mask to an appropriate value. This will allow the search form to accept date values.

7. Click **OK**.

How to Test View Criteria Using the Oracle ADF Model Tester

To test the view criteria you added to a view object, use the Oracle ADF Model Tester, which is accessible from the Applications window.

The Oracle ADF Model Tester, for any view object instance that you browse, lets you bring up the View Criteria dialog, as shown in Figure 5-30. The dialog allows you to create a view criteria comprising one or more view criteria groups.

To apply criteria attributes from a single view criteria group, click the **Specify View Criteria** toolbar button in the browser and enter Query-by-Example criteria in the desired fields, then click **Find**.

To test view criteria using the Oracle ADF Model Tester:

1. In the Applications window, expand the project containing the desired application module and view objects.

2. Right-click the application module and choose **Run**.

3. In the Oracle ADF Model Tester, double-click the view instance you want to filter, and then right-click the view instance and choose **Find**.

   Alternatively, after you double-click a view instance, you can click the **Specify View Criteria** toolbar button to test the view criteria.

4. In the View Criteria dialog, perform one of the following tasks:

   - To test a view criteria that you added to the view object in your project, select from the list and click **Find**. Any additional criteria that you enter in the ad hoc Criteria panel will be added to the filter.

   - To test ad hoc criteria attributes from a single view criteria group, enter the desired values for the view criteria and click **Find**. For example, Figure 5-30 shows the filter to return all customers whose names begins with "S" and who live in CA.

   - To test additional ad hoc view criteria groups, click the **OR** tab and use the additional tabs that appear to switch between pages, each representing a distinct view criteria group. When you click **Find**, the Oracle ADF Model Tester will create and apply the view criteria to filter the result.

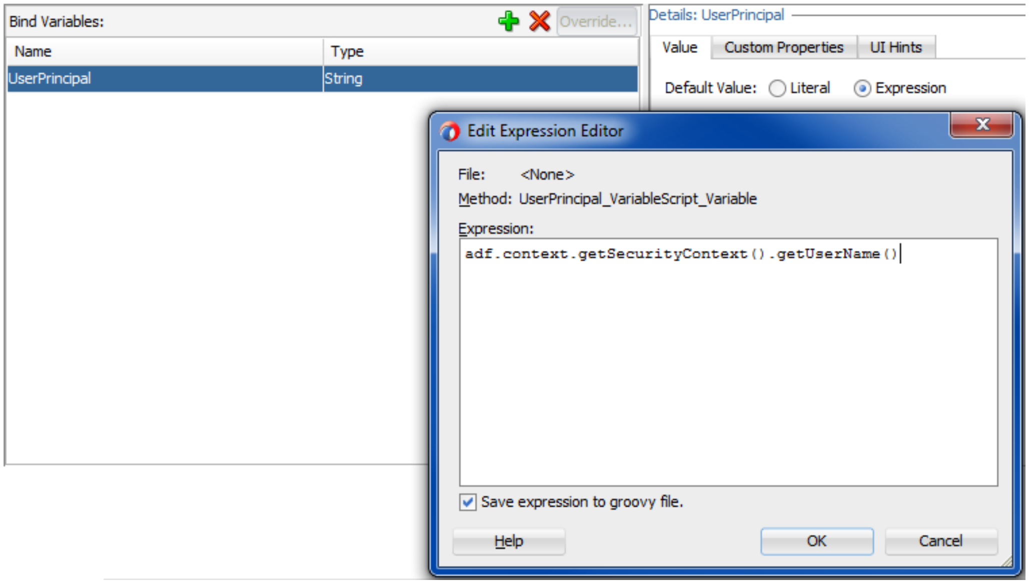
How to Use View Criteria to Filter a View Object for the Current User

You can use the Groovy expression `adf.context.getSecurityContext().getUserName()` to set the default value for the named bind variable that you use to provide the current user in a view instance filter. Specifically, you can use the bind variable in a named view criteria that you define to filter a view object instance in the data model for the project. For example, the named bind variable `UserPrincipal` is defined in the View Criteria page of the overview editor, as shown in Figure 5-31. Note that you can write Groovy expressions on business components to access the security context using expressions similar to `adf.context.getSecurityContext()`*`methodName()`*. For example, from the security context you can access information about the current user like their user name or whether they belong to a particular role. For more information about the ADF security context, see Getting Information from the ADF Security Context.

Figure 5-31 Groovy Expression Used to Set UserPrincipal Bind Variable



```
adf.context.getSecurityContext().getUserName()
```

The `CustomerVO` view object also defines the `AuthenticatedUserByPrincipalCriteria` view criteria. This view criteria defines a filter for the `PrincipalName` attribute of the `PersonsVO` with the bind variable `userPrincipal` providing the value. In this example, the bind variable `userPrincipal` is defined with **Updatable** enabled. This ensures that the view criteria is able to set the value obtained at runtime from the ADF security context. Since the bind variable is not used in the SQL `WHERE` clause for the `PersonsVO` view object, the **Required** field is unselected. This ensures that the value is optional and that no runtime exception will be thrown if the bind variable is not resolved.

Then in the data model, where the `CustomerVO` specifies the view definition for the usage `AuthenticatedUser`, the view criteria `AuthenticatedUserByPrincipalCriteria` with the named bind variable is defined as the view usage's runtime filter. For details about creating view instances for your project's data model, see Customizing a View Object Instance that You Add to an Application Module.

How to Create View Criteria Programmatically

The following example shows the `main()` method finds the `CustomerList` view object instance to be filtered, creates a view criteria for the attributes of this view object, and applies the view criteria to the view object.

To create a view criteria programmatically, follow these basic steps (as illustrated in the following example from the `oracle.summit.model.viewobjects.ProgrammaticVOCriteria.java` example in the `SummitADF_Examples` workspace):

1. Find the view object instance to be filtered.
2. Create a view criteria row set for the view object.
3. Use the view criteria to create one or more empty view criteria groups
4. Set attribute values to filter on the appropriate view criteria groups.

You use the `ensureCriteriaItem()`, `setOperator()`, and `setSearchValue()` methods on the view criteria groups to set attribute name, comparison operator, and value to filter on individually.

5. Add the view criteria groups to the view criteria row set.Apply the view criteria to the view object.
6. Execute the query.

The last step to execute the query is important, since a newly applied view criteria is applied to the view object's SQL query only at its next execution.

```
public class ProgrammaticVOCriteria {
    public static void main(String[] args) {

      // get the application module
      String amDef = "oracle.summit.model.viewobjects.AppModule";
      String config = "AppModuleLocal";
      ApplicationModule am =
            Configuration.createRootApplicationModule(amDef, config);

      // 1. Find the View Object you want to filter
      ViewObject customerList = am.findViewObject("SCustomerView1");

      // Work with your appmodule and view object here

      // iterate through all the rows first, just to see to full VO results
      customerList.executeQuery();
      while (customerList.hasNext()) {
          Row customer = customerList.next();
          System.out.println("Customer: " + customer.getAttribute("Name") + "
                State: " + customer.getAttribute("State"));

      System.out.println("********* Set View Criteria and requery *********");

      // 2. Create a view criteria row set for this view object
      ViewCriteria vc = customerList.createViewCriteria();

      // 3. Use view criteria row set to create at least one view criteria group
      ViewCriteriaRow vcr1 = vc.createViewCriteriaRow();

      // 4. Set attribute values to filter on
      ViewCriteriaItem vci = vcr1.ensureCriteriaItem("State");
      vci.setOperator("=");
      vci.setSearchValue("TX");

      // 5. Add the view criteria group to the view criteria row set
      vc.add(vcr1);

      // 6. Apply the view criteria to the view object
      customerList.applyViewCriteria(vc, true);

      // 7. Execute the query
      customerList.executeQuery();

      // Iterate throught the rows to see the new results
      while (customerList.hasNext()) {
          Row customer = customerList.next();
          System.out.println("Customer: " + customer.getAttribute("Name") + "
                  State: " + customer.getAttribute("State"));
      }
```

```
        System.out.println("********* Set View Criteria and requery *********");

        // set the attribute to a different value
           vci.setSearchValue("CA")

        // Execute the query
          customerList.executeQuery();

        // iterate throught the rows to see the new results
        while (customerList.hasNext()) {
            Row customer = customerList.next();
            System.out.println("Customer: " + customer.getAttribute("Name") + "
                        State: " + customer.getAttribute("State"));
        }

        Configuration.releaseRootApplicationModule(am, true);
      }
}
```

Running the `ProgrammaticVOCriteria.java` test client produces one set of records each time the query is executed. The first query is with no criteria applied (shows all records), the second query is with one criteria set (shows records for `TX` only), and the third query is with the criteria changed (shows records for `CA` only).

```
Customer: Great Gear   State: TX
Customer: Acme Outfitters   State: TX
Customer: Athena's Closet   State: TX
Customer: Big John's Sports Emporium   State: CA
Customer: Perfect Purchase   State: CA
Customer: Father Gym's   State: CA
...
********* Set View Criteria and requery *********
Customer: Great Gear   State: TX
Customer: Acme Outfitters   State: TX
Customer: Athena's Closet   State: TX
...
********* Set View Criteria and requery *********
Customer: Big John's Sports Emporium   State: CA
Customer: Perfect Purchase   State: CA
Customer: Father Gym's   State: CA
...
```

View criteria can also be created using `buildCriteria()`.

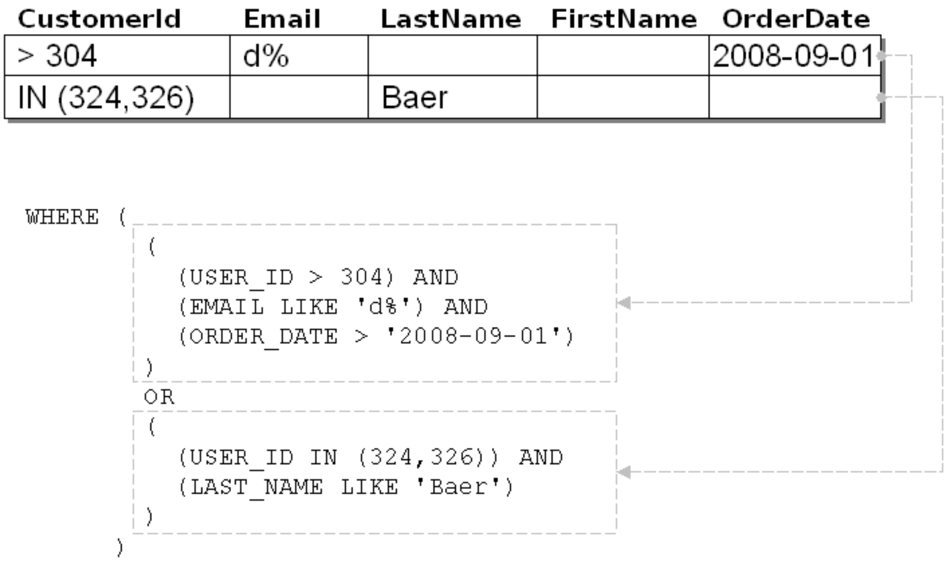
```
 public class ProgrammaticVOCriteria {
    public static void main(String[] args) {
        ProgrammaticVOCriteria pc = new ProgrammaticVOCriteria();
        // get the application module
             String amDef = "model.AppModule";
             String config = "AppModuleLocal";
             ApplicationModule am =
                   Configuration.createRootApplicationModule(amDef, config);
             ViewObjectImpl deptvo = (ViewObjectImpl)
am.findViewObject("DeptView1");
           }
        pc.testExpr("DeptViewCriteria", deptvo, "Deptno in (20, 30, 40)");
        Configuration.releaseRootApplicationModule(am, true);
    }
    public void testExpr(String vcName, ViewObjectImpl vo, String expr){
        System.out.println("Expression = " + expr);
        ViewCriteria vc = vo.buildViewCriteria(vcName, expr);
        System.out.println("VC: " + vc);
        vo.applyViewCriteria(vc);
        vo.executeQuery();
        while(vo.hasNext()){
        Row r = vo.next();
        System.out.println("Dept : " + r.getAttribute("Deptno") + "/" +
r.getAttribute("Dname"));
        }
    }
}
```

What Happens at Runtime: How the View Criteria Is Applied to a View Object

When you apply a view criteria containing one or more view criteria groups to a view object, the next time it is executed it augments its SQL query with an additional WHERE clause predicate corresponding to the Query-by-Example criteria that you've populated in the view criteria groups. As shown in Figure 5-32, when you apply a view criteria containing multiple view criteria groups, the view object augments its design time WHERE clause by adding an additional runtime WHERE clause based on the non-null example criteria attributes in each view criteria group.

A corollary of the view criteria feature is that each time you apply a new view criteria (or remove an existing one), the text of the view object's SQL query is effectively changed. Changing the SQL query causes the database to reparse the statement the next time it is executed. You can eliminate the reparsing and improve the performance of a view criteria, as described in What You May Need to Know About Query-by-Example Criteria.

Figure 5-32 View Object Automatically Translates View Criteria Groups into Additional Runtime WHERE Filter



CustomerId	Email	LastName	FirstName	OrderDate
> 304	d%			2008-09-01
IN (324,326)		Baer		

```
WHERE (
        (
          (USER_ID > 304) AND
          (EMAIL LIKE 'd%') AND
          (ORDER_DATE > '2008-09-01')
        )
        OR
        (
          (USER_ID IN (324,326)) AND
          (LAST_NAME LIKE 'Baer')
        )
      )
```

What You May Need to Know About the View Criteria API

When you need to perform tasks that the Edit View Criteria dialog does not support, review the View Criteria API. For example, programmatically, you can alter compound search conditions using multiple view criteria groups, search for a row whose attribute value is NULL, search case insensitively, and clear view criteria in effect.

Referencing Attribute Names in View Criteria

The setWhereClause() method allows you to add a dynamic WHERE clause to a view object, as described in ViewObject Interface Methods for Working with the View Object's Default RowSet. You can also use setWhereClause() to pass a string that contains literal database column names like this:

```
vo.setWhereClause("LAST_NAME LIKE UPPER(:NameToFind)");
```

In contrast, when you use the view criteria mechanism, described in How to Create View Criteria Programmatically, you must reference the view object attribute name instead, like this:

```
    ViewCriteriaItem vc_item1 = vc_row1.ensureCriteriaItem("UserId");
    vc_item1.setOperator(">");
    vc_item1.setValue("304");
```

Note that method calls like vcr.setAttribute("UserId", "> 304") as documented in a past release must not be used to set the attribute values for the view criteria.

The view criteria groups are then translated by the view object into corresponding WHERE clause predicates that reference the corresponding column names. The programmatically set WHERE clause is AND-ed with the WHERE clauses of any view criteria that have been defined for the view object at design time.

Referencing Bind Variables in View Criteria

When you want to set the value of a view criteria item to a bind variable, use setIsBindVarValue(true), like this:

```
    ViewCriteriaItem vc_item1 = vc_row1.ensureCriteriaItem("UserId");
    vc_item1.setIsBindVarValue(true);
    vc_item1.setValue(":VariableName");
```

Searching for a Row Whose Attribute Is NULL

To search for a row containing NULL in a column, populate a corresponding view criteria group attribute with the value "IS NULL" or use ViewCriteriaItem.setOperator("ISBLANK").

Searching for Rows Using a Date Comparison

When you want to perform a comparison of date values in a view criteria item, use the following predefined operators:

- BEFORE
- AFTER

- ONORBEFORE
- ONORAFTER

For example, to search for rows that contain a DATE type attribute whose value is after a given date, you would use ViewCriteriaItem.setOperator("AFTER").

Do not use operators like <, >, <=, and >= because these operators perform string comparisons that yield inaccurate results for date values.

Searching for Rows Whose Attribute Value Matches a Value in a List

To search for all rows with a value in a column that matches any value in a list of values that you specify, populate a corresponding view criteria group attribute with the comma-separated list of values and use the IN operator. For example, to filter the list of persons by IDs that match 204 and 206, set:

```
ViewCriteriaItem vci = vcr.ensureCriteriaItem("CustomerId");
vci.setOperator("IN");
vci.setValue(0, 204);
vci.setValue(1, 206);
```

Searching Case-Insensitively

To search case-insensitively, call setUpperColumns(true) on the view criteria group to which you want the case-insensitivity to apply. This affects the WHERE clause predicate generated for String-valued attributes in the view object to use UPPER(COLUMN_NAME) instead of COLUMN_NAME in the predicate. Note that the value of the supplied view criteria group attributes for these String-valued attributes must be uppercase or the predicate won't match. In addition to the predicate, it also possible to use UPPER() on the value. For example, you can set UPPER(ename) = UPPER("scott").

Clearing View Criteria in Effect

To clear any view criteria in effect, you can call getViewCriteria() on a view object and then delete all the view criteria groups from it using the remove() method, passing the zero-based index of the criteria row you want to remove. If you don't plan to add back other view criteria groups, you can also clear the entire view criteria in effect by simply calling removeApplyViewCriteriaName("*namedViewCriteria*") on the view object with the name of the view criteria passed in.

Altering Compound Search Conditions Using Multiple View Criteria

When you add multiple view criteria, you can call the setConjunction() method on a view criteria to alter the conjunction used between the predicate corresponding to that view criteria and the one for the previous view criteria. The legal constants to pass as an argument are:

- ViewCriteriaComponent.VC_CONJ_AND
- ViewCriteriaComponent.VC_CONJ_NOT
- ViewCriteriaComponent.VC_CONJ_UNION
- ViewCriteriaComponent.VC_CONJ_OR (*default*)

The NOT value can be combined with AND or OR to create filter criteria like:

```
( PredicateForViewCriteria1 ) AND (NOT ( PredicateForViewCriteria2 ) )
```

or

```
( PredicateForViewCriteria1 ) OR (NOT ( PredicateForViewCriteria2 ) )
```

The syntax to achieve compound search conditions requires using Java's bitwise `OR` operator like this:

```
vc2.setConjunction(ViewCriteriaComponent.VC_CONJ_AND |
 ViewCriteriaComponent.VC_CONJ_NOT);
```

> **Performance Tip:**
>
> Use the `UNION` value instead of an `OR` clause when the `UNION` query can make use of indices. For example, if the view criteria searches for `sal > 2000 or job = 'CLERK'` this query may turn into a full table scan. Whereas if you specify the query as the union of two inner view criteria, and the database table has an index on `sal` and an index on `job`, then the query can take advantage of these indices and the query performance will be significantly better for a large data set.

The limitation for the `UNION` clause is that it must be defined over one view object. This means that the `SELECT` and the `FROM` list will be the same for inner queries of the `UNION` clause. To specify a `UNION` query, call `setConjunction()` on the outer view criteria like this:

```
vc.setConjunction(ViewCriteriaComponent.VC_CONJ_UNION);
```

The outer view criteria should contain inner queries whose results will be the union. For example, suppose you want to specify the union of these two view criteria:

- A view criteria named `MyEmpJob`, which searches for `Job = 'SALESMAN'`.
- A view criteria named `MyEmpSalary`, which searches for `Sal = 1500`.

To create the `UNION` query for these two view criteria, you would make the calls shown in the following example.

```
vcu = voEmp.createViewCriteria();
vcm = voEmp.getViewCriteriaManager();

vcu.setConjunction(ViewCriteria.VC_CONJ_UNION);
vcu.add(vcm.getViewCriteria("MyEmpJob"));
vcu.add(vcm.getViewCriteria("MyEmpSal"));

voEmp.applyViewCriteria(vcu);
```

When this view criteria is applied, it will return rows where `Job` is `SALESMAN` or `Sal` is greater than `1500`.

When you use a `UNION` view criteria, be sure that only one of the applied view criteria has the `UNION` conjunction. Other view criteria that you apply will be applied to each inner query of the `UNION` query.

What You May Need to Know About Query-by-Example Criteria

For performance reasons, you want to avoid setting a bind variable as the value of a view criteria item in these two cases:

- In the specialized case where the value of a view criteria item is defined as selectively required and the value changes from non-`NULL` to `NULL`.

  In this case, the SQL statement for the view criteria will be regenerated each time the value changes from non-`NULL` to `NULL`.
- In the case where the value of the view criteria item is optional and that item references an attribute for an indexed column.

  In the case of optional view criteria items, an additional SQL clause `OR (:Variable IS NULL)` is generated, and the clause does not support using column indices.

In either of these cases, you will get better performance by using a view object whose `WHERE` clause contains the named bind variables, as described in How to Add WHERE Clause Bind Variables to a View Object Definition.

Working with Bind Variables

You can define bind variables to supply runtime attribute values to the ADF view object or view criteria.

Bind variables provide you with the means to supply attribute values at runtime to the view object or view criteria. All bind variables are defined at the level of the view object and used in one of the following ways:

- You can select the bind variable from a selection list to define the attribute value for a view criteria in the Edit View Criteria dialog you open on the view object. In this case, the bind variables allow you to change the values for attributes you will use to filter the view object row set. For more information about filtering view object row sets, see Working with Named View Criteria.

  If the view criteria is to be used in a UI developer-defined search form, you have the option of making the bind variable updatable by the end user. With this updatable option, end users will be expected to enter the value in a search form corresponding to the view object query.
- You can type the bind variable directly into the `WHERE` clause of your view object's query to include values that might change from execution to execution. In this case, bind variables serve as placeholders in the SQL string whose value you can easily change at runtime without altering the text of the SQL string itself. Since the query doesn't change, the database can efficiently reuse the same parsed representation of the query across multiple executions, which leads to higher runtime performance of your application.

In contrast, to query `WHERE` clause bind variables that are needed anytime the view object is executed, bind variables that you define for view criteria are needed only when the view criteria is applied.

> **Note:**
>
> Oracle recommends that your application use view criteria to filter view objects rather than hardcoding the filter in the query `WHERE` clause. When you use view criteria you can change the values of the search criteria without changing the text of the view object's SQL statement each time those values change.

You can define a default value for the bind variable or write scripting expressions for the bind variable that includes dot notation access to attribute property values. Expressions are based on the Groovy scripting language, as described in Using Groovy Scripting Language With Business Components.

How to Add View Criteria Bind Variables to a View Object Definition

Bind variable usages that you specify in a view criteria also require that you add the bind variable to the view object definition. If you add a bind variable usage to the view criteria definition and the view object does not have a bind variable definition, a runtime exception will result when the view criteria is applied. To create the bind variable definition, you use the View Criteria page in the overview editor for the view object. When you define the variable in the editor, the bind variable will receive a value at runtime, which when left undefined will be null. The default value of null may be suitable in some scenarios but not in others. When a non-null value is required, you can specify a default value for the bind variable definition, or you may let the end user supply the value at runtime (for example, through search criteria in the case of query search forms).

To add a view criteria bind variable to a view object, use the View Criteria page of the overview editor for the view object.

Before you begin:

It may be helpful to have an understanding of the support for bind variables at the level of view objects. For more information, see Working with Bind Variables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To define a named bind variable for the view criteria:

1. In the Applications window, double-click the view object.
2. In the overview editor, click the **View Criteria** navigation tab.
3. In the Query page, in the **Bind Variables** section, click the **Create New Bind Variable** button.
4. In the New Variable dialog, enter the name of bind variable and select the data type. Click **OK**.

Because the bind variables share the same namespace as view object attributes, specify names that don't conflict with existing view object attribute names. As with view objects attributes, by convention bind variable names are created with an initial capital letter, but you can rename it as desired.

5. Optionally, in the View Criteria page, in the **Details** section, click the **Value** tab and specify a default value for the bind variable:

   - When you want the value to be determined at runtime using an expression, enter a Groovy scripting language expression, select the **Expression** value type and enter the expression in the **Value** field. For example, you might want to define a bind variable to filter view instances based on the current user, as described in How to Use View Criteria to Filter a View Object for the Current User.

   - When you want to define a default value, select the **Literal** value type and enter the literal value in the **Value** field.

   - If you do not supply a default value for your named bind variable, it defaults to `NULL` at runtime and the view criteria will return no rows.

6. Leave **Updatable** selected when you want the bind variable value to be defined through the user interface.

   The **Updatable** checkbox controls whether the end user will be allowed to change the bind variable value through the user interface. If a bind variable is not updatable (it may not be changed either programmatically or by the end user), deselect **Updatable**.

7. In the View Criteria page, click the **UI Hints** tab and specify hints like **Label**, **Format Type**, **Format** mask, and others.

   The view layer will use bind variable UI hints when you build user interfaces like search forms that allow the user to enter values for the named bind variables. Note that formats are only supported for bind variables defined by the `Date` type or any numeric data type.

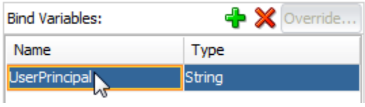
8. Reference the bind variables you defined in the view criteria of the view object.

   You must either reference the bind variable at runtime or use it in the view object query definition. Unreferenced bind variables that you configure in the overview editor will result in a runtime error, as described in Errors Related to the Names of Bind Variables.

9. If you created bind variables that you do not intend to name in your view criteria or reference programmatically, select the bind variable and click the **Delete** button.

   Confirm that your bind variable has been named in the view criteria by moving your cursor over the bind variable name field, as shown in Figure 5-34. JDeveloper identifies unreferenced bind variables by displaying the name field with an orange border.

Figure 5-33 Orange Border Reminds to Reference the Bind Variable



Name	Type
UserPrincipal	String

How to Add WHERE Clause Bind Variables to a View Object Definition

Bind variable usages that you specify in a query WHERE clause also require that you add the bind variable to the view object definition. If you add a bind variable usage to the query statement and the view object does not have a bind variable definition, a runtime exception will result. To create the bind variable definition, you use the Query page in the overview editor for the view object. When you define the variable in the editor, the bind variable will receive a value at runtime, which when left undefined will be null. The default value of null may be suitable in some scenarios but not in others. When a non-null value is required, you can specify a default value for the bind variable definition, or you set the value at runtime, as described in How to Set Existing WHERE Clause Bind Variable Values at Runtime.

To add a WHERE clause bind variable to a view object, use the Query page of the overview editor for the view object. You can define as many bind variables as you need.

> **Caution:**
>
> Unreferenced bind variables that you configure in the overview editor will result in a runtime error, as described in Errors Related to the Names of Bind Variables. Delete all bind variables definitions from the overview editor unless you name it in the view object definition or reference it programmatically.

Before you begin:

It may be helpful to have an understanding of the support for bind variables at the level of view objects. For more information, see Working with Bind Variables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To define a named bind variable for the WHERE clause:

1. In the Applications window, double-click the view object.
2. In the overview editor, click the **Query** navigation tab.
3. In the Query page, in the **Bind Variables** section, click the **Create New Bind Variable** button.
4. In the New Variable dialog, enter the name of bind variable and select the data type. Click **OK**.

   Because the bind variables share the same namespace as view object attributes, specify names that don't conflict with existing view object attribute names. As with view objects attributes, by convention bind variable names are created with an initial capital letter, but you can rename it as desired.

5. Optionally, in the Query page, in the **Details** section, click the **Value** tab and specify a default value for the bind variable:

   - When you want the value to be determined at runtime using an expression, enter a Groovy scripting language expression, select the **Expression** value type and enter the expression in the **Value** field.
   - When you want to define a default value, select the **Literal** value type and enter the literal value in the **Value** field.
   - If you do not supply a default value for your named bind variable, it defaults to `NULL` at runtime and the query will return no rows. If this makes sense for your application, you might want to leverage SQL functions to handle this situation, as described in Default Value of NULL for Bind Variables.

6. Leave **Updatable** selected when you want the bind variable value to be defined through the user interface.

   The **Updatable** checkbox controls whether the end user will be allowed to change the bind variable value through the user interface. If a bind variable is not updatable (it may not be changed programmatically or by the end user), deselect **Updatable**.

7. In the Query page, click the **UI Hints** tab and specify hints like **Label**, **Format Type**, **Format** mask, and others.

   The view layer will use bind variable UI hints when you build user interfaces like search pages that allow the user to enter values for the named bind variables. Note that formats are only supported for bind variables defined by the `Date` type or any numeric data type.

8. Reference the bind variables you defined in the SQL statement of the view object.

   You must either reference the bind variable at runtime or use it in the view object query definition. Unreferenced bind variables that you configure in the overview editor will result in a runtime error, as described in Errors Related to the Names of Bind Variables.

   While SQL syntax allows bind variables to appear both in the `SELECT` list and in the `WHERE` clause, you'll typically use them in the latter context, as part of your `WHERE` clause. For example, the following sample shows the bind variables `LowUserId` and `HighUserId` introduced into a SQL statement created using the Query page in the overview editor for the view object.

```
select CUSTOMER_ID, EMAIL, FIRST_NAME, LAST_NAME
from CUSTOMERS
where (upper(FIRST_NAME) like upper(:TheName)||'%'
   or  upper(LAST_NAME)  like upper(:TheName)||'%')
  and CUSTOMER_ID between :LowUserId and :HighUserId
order by EMAIL
```

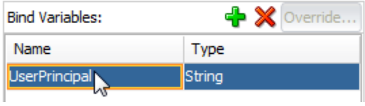
   Notice that you reference the bind variables in the SQL statement by prefixing their name with a colon like `:TheName` or `:LowUserId`. You can reference the bind variables in any order and repeat them as many times as needed within the SQL statement.

9. If you created bind variables that you do not intend to name in your view object SQL query or reference programmatically, select the bind variable and click the **Delete** button.

   Confirm that your bind variable has been named in the view object query by moving your cursor over the bind variable name field, as shown in Figure 5-34.

JDeveloper identifies unreferenced bind variables by displaying the name field with an orange border.

Figure 5-34 Orange Border Reminds to Reference the Bind Variable



Name	Type
UserPrincipal	String

What Happens When You Add Named Bind Variables

Once you've added one or more named bind variables to a view object, you gain the ability to easily see and set the values of these variables at runtime. Information about the name, type, and default value of each bind variable is saved in the view object's XML document file. If you have defined UI hints for the bind variables, this information is saved in the view object's component message bundle file along with other UI hints for the view object.

Note that the overview editor displays an orange warning box around the bind variable name for any bind variable that you define but do not use in the view object query. Be sure to delete bind variables that the query statement or view criteria definition does not reference. A runtime error will result when the view object query is executed and one or more bind variable definitions remain unreferenced, as described in Errors Related to the Names of Bind Variables.

How to Test Named Bind Variables

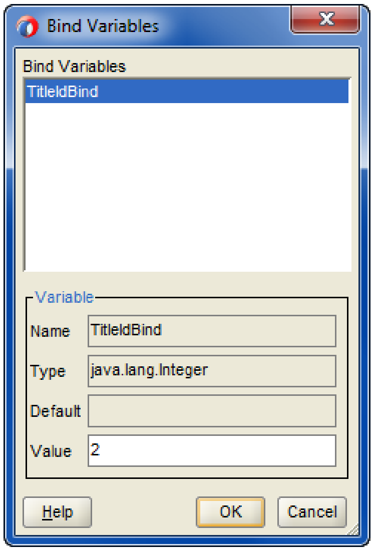
The Oracle ADF Model Tester allows you to interactively inspect and change the values of the named bind variables for any view object, which can really simplify experimenting with your application module's data model when named bind parameters are involved. For more information about editing the data model and running the Oracle ADF Model Tester, see Testing View Object Instances Using the Oracle ADF Model Tester.

The first time you execute a view object in the Oracle ADF Model Tester to display the results in the data view page, a Bind Variables dialog will appear, as shown in Figure 5-35.

The Bind Variables dialog lets you:

- View the name, as well as the default and current values, of the particular bind variable you select from the list
- Change the value of any bind variable by updating its corresponding **Value** field before clicking **OK** to set the bind variable values and execute the query
- Inspect and set the bind variables for the view object in the current data view page, using the **Edit Bind Parameters** button in the toolbar — whose icon looks like "`:id`"
- Verify UI hints are correctly set up by showing the label text hint in the **Bind Variables** list and by formatting the **Value** attribute using the respective format mask

Figure 5-35 Setting Bind Variables in the Oracle ADF Model Tester



TitleIdBind

Name: TitleIdBind
Type: java.lang.Integer
Default:
Value: 2

If you defined the bind variable in the Bind Variables dialog with the **Required** checkbox deselected, you will be able to test view criteria and supply the bind variable with values as needed. Otherwise, if you left the **Required** checkbox selected (the default), then you must supply a value for the bind variable in the Oracle ADF Model Tester. The Oracle ADF Model Tester will throw the same exception seen at runtime for any view object whose SQL statement use bind variables that do not resolve with a supplied value.

How to Add a WHERE Clause with Named Bind Variables at Runtime

Using the view object's `setWhereClause()` method, you can add an additional filtering clause at runtime. This runtime-added `WHERE` clause predicate does *not* replace the design-time generated predicate, but rather further narrows the query result by adding to the existing design time `WHERE` clause. Whenever the dynamically added clause refers to a value that might change during the life of the application, you should use a named bind variable instead of concatenating the literal value into the `WHERE` clause predicate.

For example, assume you want to further filter the `CustomerList` view object at runtime based on the value of the `CUSTOMER_TYPE_CODE` column in the table. Also assume that you plan to search sometimes for rows where `CUSTOMER_TYPE_CODE = 'CUST'` and other times for rows where `CUSTOMER_TYPE_CODE = 'SUPP'`. While it contains slightly fewer lines of code, the following example is not desirable because it changes the `WHERE` clause twice just to query two different *values* of the same `CUSTOMER_TYPE_CODE` column.

```
// Don't use literal strings if you plan to change the value!
vo.setWhereClause("customer_type_code = 'CUST'");
// execute the query and process the results, and then later...
vo.setWhereClause("customer_type_code = 'SUPP'");
```

Instead, you should add a `WHERE` clause predicate that references named bind variables that you define at runtime as shown in the following example.

```
vo.setWhereClause("customer_type_code = :TheCustomerType");
vo.defineNamedWhereClauseParam("TheCustomerType", null, null);
vo.setNamedWhereClauseParam("TheCustomerType","CUST");
// execute the query and process the results, and then later...
vo.setNamedWhereClauseParam("TheCustomerType","SUPP");
```

This allows the text of the SQL statement to stay the same, regardless of the value of CUSTOMER_TYPE_CODE you need to query on. When the query text stays the same across multiple executions, the database will return the results without having to reparse the query.

An updated test client class illustrating these techniques would look like what you see in the following example. In this case, the functionality that loops over the results several times has been refactored into a separate executeAndShowResults() method. The program first adds an additional WHERE clause of customer_id = :TheCustomerId and then later replaces it with a second clause of customer_type_code = :TheCustomerType.

```
package devguide.examples.readonlyvo.client;

import oracle.jbo.ApplicationModule;
import oracle.jbo.Row;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;

public class TestClientBindVars {
  public static void main(String[] args) {
    String        amDef = "devguide.examples.readonlyvo.CustomerService";
    String        config = "CustomerServiceLocal";
    ApplicationModule am =
     Configuration.createRootApplicationModule(amDef,config);
    ViewObject vo = am.findViewObject("CustomerList");
    // Set the two design time named bind variables
    vo.setNamedWhereClauseParam("TheName","shelli%");
    vo.setNamedWhereClauseParam("HighUserId", 215);
    executeAndShowResults(vo);
    // Add an extra where clause with a new named bind variable
    vo.setWhereClause("customer_type_code = :TheCustomerId");
    vo.defineNamedWhereClauseParam("TheCustomerId", null, null);
    vo.setNamedWhereClauseParam("TheCustomerId",116);
    executeAndShowResults(vo);
    vo.removeNamedWhereClauseParam("TheCustomerId");
    // Add an extra where clause with a new named bind variable
    vo.setWhereClause("customer_type_code = :TheCustomerType");
    vo.defineNamedWhereClauseParam("TheCustomerType", null, null);
    vo.setNamedWhereClauseParam("TheCustomerType","SUPP");
    // Show results when :TheCustomerType = 'SUPP'
    executeAndShowResults(vo);
    vo.setNamedWhereClauseParam("TheCustomerType","CUST");
    // Show results when :TheCustomerType = 'CUST'
    executeAndShowResults(vo);
    Configuration.releaseRootApplicationModule(am,true);
  }
  private static void executeAndShowResults(ViewObject vo) {
    System.out.println("---");
    vo.executeQuery();
    while (vo.hasNext()) {
      Row curUser = vo.next();
      System.out.println(curUser.getAttribute("CustomerId")+" "+
                         curUser.getAttribute("ShortName"));
    }
  }
}
```

However, if you run this test program, you may actually get a runtime error like the one shown in the following example.

```
oracle.jbo.SQLStmtException: JBO-27122: SQL error during statement preparation.
Statement:
SELECT * FROM (select PERSON_ID, EMAIL, FIRST_NAME, LAST_NAME
from PERSONS
where (upper(FIRST_NAME) like upper(:TheName)||'%'
   or  upper(LAST_NAME)  like upper(:TheName)||'%')
  and PERSON_ID between :LowUserId and :HighUserId
order by EMAIL) QRSLT  WHERE (person_type_code = :TheCustomerType)
## Detail 0 ##
java.sql.SQLException: ORA-00904: "PERSON_TYPE": invalid identifier
```

The root cause, which appears after the `## Detail 0 ##` in the stack trace, is a SQL parsing error from the database reporting that `PERSON_TYPE_CODE` column does not exist even though the `PERSONS` table definitely has a `PERSON_TYPE_CODE` column. The problem occurs due to the mechanism that view objects use by default to apply additional runtime `WHERE` clauses on top of read-only queries. What Happens at Runtime: Dynamic Read-Only View Object WHERE Clause, explains a resolution for this issue.

How to Set Existing WHERE Clause Bind Variable Values at Runtime

To set named bind variables at runtime, use the `setNamedWhereClauseParam()` method on the `ViewObject` interface. In JDeveloper, you can choose **Refactor > Duplicate** in the main menu to create a new `TestClientBindVars` class based on the existing `TestClient.java` class as shown in How to Create a Command-Line Java Test Client. In the test client class, you can set the values of the bind variables using a few additional lines of code. For example, the `setNamedWhereClauseParam()` might take as arguments the bind variables `HighUserId` and `TheName` as shown in the following example.

```
// changed lines in TestClient class
ViewObject vo = am.findViewObject("CustomerList");
vo.setNamedWhereClauseParam("TheName","alex%");
vo.setNamedWhereClauseParam("HighUserId", 315);
vo.executeQuery();
// etc.
```

Running the test client class shows that your bind variables are filtering the data. For example, the resulting rows for the `setNamedWhereClauseParam()` method shown in example above may produce only two matches based on the name `alex` as shown in the following results.

```
303 ahunold
315 akhoo
```

Whenever a view object's query is executed, you can view the actual bind variable values in the runtime debug diagnostics, as the following results example illustrates.

```
[256] Bind params for ViewObject: CustomerList
[257] Binding param "LowUserId": 0
```

```
[258] Binding param "HighUserId": 315
[259] Binding param "TheName": alex%
```

This information that can be invaluable when debugging your applications. Notice that since the code did not set the value of the `LowUserId` bind variable, it took on the default value of `0` (zero) specified at design time. Also notice that the use of the `UPPER()` function in the `WHERE` clause and around the bind variable ensured that the match using the bind variable value for `TheName` was performed case-insensitively. The sample code set the bind variable value to "`alex%`" with a lowercase "`a`", and the results show that it matched `Alexander`.

What Happens at Runtime: Dynamic Read-Only View Object WHERE Clause

If you dynamically add an additional `WHERE` clause at runtime to a read-only view object, its query gets nested into an inline view before applying the additional `WHERE` clause.

For example, suppose your query was defined as shown in the following example.

```
select PERSON_ID, EMAIL, FIRST_NAME, LAST_NAME
from PERSONS
where (upper(FIRST_NAME) like upper(:TheName)||'%'
   or  upper(LAST_NAME)  like upper(:TheName)||'%')
  and PERSON_ID between :LowUserId and :HighUserId
order by EMAIL
```

At runtime, when you set an additional `WHERE` clause like `person_type_code = :TheCustomerType` as the test program in How to Add a WHERE Clause with Named Bind Variables at Runtime illustrates, the framework nests the original query into an inline view like the following example.

```
SELECT * FROM(
select PERSON_ID, EMAIL, FIRST_NAME, LAST_NAME
from PERSONS
where (upper(FIRST_NAME) like upper(:TheName)||'%'
   or  upper(LAST_NAME)  like upper(:TheName)||'%')
  and PERSON_ID between :LowUserId and :HighUserId
order by EMAIL) QRSLT
```

Then the framework adds the dynamic `WHERE` clause predicate at the end, so that the final query the database sees is like the following example.

```
SELECT * FROM(
select PERSON_ID, EMAIL, FIRST_NAME, LAST_NAME
from PERSONS
where (upper(FIRST_NAME) like upper(:TheName)||'%'
   or  upper(LAST_NAME)  like upper(:TheName)||'%')
  and PERSON_ID between :LowUserId and :HighUserId
order by EMAIL) QRSLT
WHERE person_type_code = :TheCustomerType
```

This query "wrapping" is necessary in the general case since the original query could be arbitrarily complex, including SQL `UNION`, `INTERSECT`, `MINUS`, or other operators that combine multiple queries into a single result. In those cases, simply "gluing" the additional runtime `WHERE` clause onto the end of the query text could produce unexpected results because, for example, it might apply only to the *last* of several

UNION'ed statements. By nesting the original query verbatim into an inline view, the view object guarantees that your additional WHERE clause is correctly used to filter the results of the original query, regardless of how complex it is. The consequence (that results in an ORA-00904 error) is that the dynamically added WHERE clause can refer only to columns that have been selected in the original query.

The simplest solution is to add the dynamic query column names to the end of the query's SELECT list in the Query page of the overview editor for the view object. Just adding the new column name at the end of the existing SELECT list — of course, preceded by a comma — is enough to prevent the ORA-00904 error: JDeveloper will automatically keep your view object's attribute list synchronized with the query statement. Alternatively, Inline View Wrapping at Runtime explains how to disable this query nesting when you don't require it.

The test client program described in How to Add a WHERE Clause with Named Bind Variables at Runtime now produces the following results.

```
---
116 S. Baida
---
116 S. Baida
---
---
116 S. Baida
```

What You May Need to Know About Named Bind Variables

There are several things you may need to know about named bind variables, including the runtime errors that are displayed when bind variables have mismatched names and the default value for bind variables.

Errors Related to the Names of Bind Variables

You need to ensure that the list of named bind variables that you reference in your SQL statement matches the list of named bind variables that you've defined in the **Bind Variables** section of the Query page for the view object overview editor. Failure to have these two agree correctly can result in one of the following two errors at runtime.

If you use a named bind variable in your SQL statement but have not defined it, you'll receive an error like this:

```
(oracle.jbo.SQLStmtException) JBO-27122: SQL error during statement preparation.
## Detail 0 ##
(java.sql.SQLException) Missing IN or OUT parameter at index:: 1
```

On the other hand, if you have defined a named bind variable, but then forgotten to reference it or mistyped its name in the SQL, then you will see an error like this:

```
oracle.jbo.SQLStmtException: JBO-27122: SQL error during statement preparation.
## Detail 0 ##
java.sql.SQLException: Attempt to set a parameter name that does not occur in the
 SQL: LowUserId
```

To resolve either of these errors, double-check that the list of named bind variables in the SQL matches the list of named bind variables in the **Bind Variables** section of the Query page for the overview editor.

Default Value of NULL for Bind Variables

If you do not supply a default value for your named bind variable, it defaults to `NULL` at runtime. This means that if you have a `WHERE` clause like:

```
PERSON_ID = :TheCustomerId
```

and you do not provide a default value for the `TheCustomerId` bind variable, it will default to `NULL` and cause the query to return no rows. Where it makes sense for your application, you can leverage SQL functions like `NVL()`, `CASE`, `DECODE()`, or others to handle the situation as you require. For example, the following `WHERE` clause fragment allows the view object query to match any name if the value of `:TheName` is `null`.

```
upper(FIRST_NAME) like upper(:TheName)||'%'
```

Working with Row Finders

You use row finders using ADF view criteria to retrieve specific rows within a row set. You can use a bind variable in the view criteria statement, where the bind variable's value is value of the filter parameter.

Row finders are objects that the application may use to locate specific rows within a row set using a view criteria. You can define a row finder when you need to perform row lookup operations on the row set and you do not want the application to use row key attributes to specify the row lookup.

Currently, row finders that you define at design time can participate in these scenarios where non-row key attribute lookup is desired at runtime:

- When you expose the row finder in an ADF Business Components web service, the end user may initiate row updates on the specific rows of the service view instance that match one or more row-finder mapped, non-key attribute values. For information about this use case, see What You May Need to Know About View Criteria and Row Finder Usage.
- Programmatically in the application when you want to obtain a set of rows that match one or more row-finder mapped, non-key attribute values. For information about this use case, see Programmatically Invoking the Row Finder.

You can specify the row finder to locate all row matches or a specified number of row matches. If the row finder locates more rows than the fetch limit you specify, you can enable the row finder to throw an exception.

The view object definition with row finder includes the following elements.

1. A specified view criteria that applies one or more view criteria items to filter the owning view object. View criteria items are defined on the owning view object attributes that determine the row match and must be defined by bind variables to allow the row finder to supply the values at runtime.
2. A mapping between view criteria bind variables and the source of the value: either an attribute of the view object or an attribute value expression that need not necessarily map to attributes on the owning view object.

   Use an expression row finder in use cases where you need to filter by one or more attributes that are not mapped to the owning view object and use an attribute row finder in use cases where you need to lookup a row with an attribute key value from the owning view object.

For example, where EmpVO has an attribute email, an EmpVO row finder may locate a specific employee row using a view criteria defined on the EmpVO and the email address of the employee. The view criteria for the EmpVO might look similar to the one shown in the following example. In this example, the view criteria statement uses a bind variable EmailBindVar to set the value of the email attribute on the owning view object EmpVO.

```
 ( (UPPER(EmpEO.EMAIL) = UPPER(:EmailBindVar) ) )
```

The application may invoke the row finder by applying values to the mapped view criteria bind variables in a variety of ways:

- An ADF Business Components web service that makes uses of a single row in an upsert or merge operation. The application must invoke the row finder on the owning view object by using bind variables that map to locator attributes of the owning view object.
- A search field that filters a set of master rows with a value from the child records. The application must invoke the row finder on the master view object that participates in a master-detail relationship by using bind variables that map to a WHERE clause type expression containing one or more attributes of the child view object.
- An ADF Business Components web service that makes use of an update operation may display a form with input fields that are bound to view object attributes that the row finder maps to view criteria bind variables.

  For details about enabling operations of Business Components web services, see How to Enable the Application Module Service Interface.
- The application may invoke the row finder on the view object and programmatically set the value of the mapped view object attributes to the view criteria bind variables. See Programmatically Invoking the Row Finder.

How to Add Row Finders to a View Object Definition

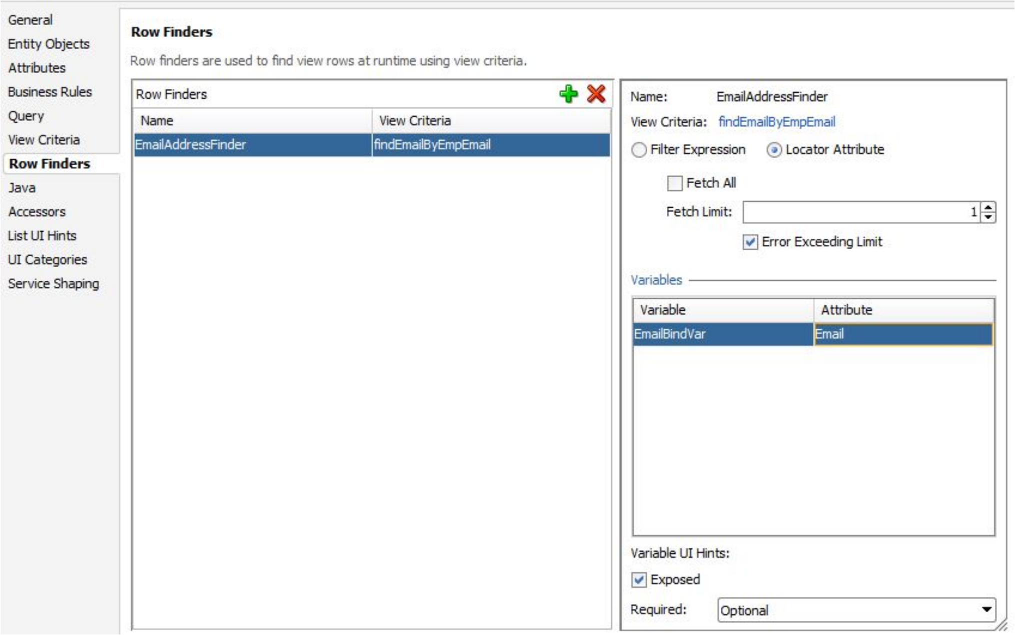
You use the Row Finders page of the view object's overview editor to define the row finder. In the editor, you define a value source for each bind variable of the view criteria that you select. Attributes of the view object or attribute value expressions are both valid sources for bind variables defined by the row finder.

The row finder that you define can map any number of view criteria bind variables to a valid value source. Mapping additional variables in the row finder definition will result in more restrictive row matches. In this regard, row finders are similar to query search operations that do not alter the row set. Using an appropriately defined row finder, the application can locate a single, specific row and the allow the end user to perform row updates on the row.

As a rule of thumb, use an attribute expression row finder in use cases that map to filtering the results with a WHERE clause and use an attribute row finder to lookup a row with a key value.

Figure 5-36 shows the overview editor with a row finder that maps the view criteria bind variable EmailBindVar specified in the findEmpByEmpEmail view criteria to the attribute Email defined by the view object EmpVO as its value source.

Figure 5-36 View Object Overview Editor with Row Finder



Row Finders

Row finders are used to find view rows at runtime using view criteria.

Row Finders

Name	View Criteria
EmailAddressFinder	findEmailByEmpEmail

Name: EmailAddressFinder
View Criteria: findEmailByEmpEmail
○ Filter Expression ● Locator Attribute
□ Fetch All
Fetch Limit: 1
☑ Error Exceeding Limit

Variables

Variable	Attribute
EmailBindVar	Email

Variable UI Hints:
☑ Exposed
Required: Optional

Note:

You can define row finders on view objects in a master-detail hierarchy when you want to filter the master by attributes of the detail view object. In this scenario, use map the bind variable to an expression that contains attributes of the child view object.

Before you begin:

It may be helpful to have an understanding of the row finder. For more information, see Working with Row Finders.

It may be helpful to have an understanding of view criteria. For more information, see Working with Named View Criteria.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

- Create the desired view objects, as described in Populating View Object Rows from a Single Database Table or Working with Multiple Tables in Join Query Results.
- Define a view criteria on the view object, as described in How to Create Named View Criteria Declaratively.
- Optionally, add updatable transient attributes to the view object, as described in How to Add a Transient Attribute. The transient attribute may be set programmatically by the application or exposed in an ADF Business Components

web service payload to solicit the value from an end user. The transient attributes must be defined as updatable to receive the criteria lookup value.

To create a row finder for a view object:

1. In the Applications window, double-click the view object for which you want to create the row finder.
2. In the overview editor, click the **Row Finders** navigation tab and then click the **Add Row Finder** button.
3. In the **Name** field, rename the row finder.

   For example, a row finder that you define to locate an employee by their email address, might be named `EmpByEmailRowFinder`.
4. Select the new row finder in the **Row Finders** list and then, in the **View Criteria** dropdown, select the view criteria that filters the view object row set.

   The desired row finder should appear highlighted, as shown in Figure 5-36. The view criteria list will be empty unless you have created a view criteria for the row finder to use.
5. When you want the end user of an ADF Business Components web service to supply a value, leave **Attribute** selected, select the bind variable from the list, and then, in the **Attribute** dropdown, select the attribute from the view object that supplies the bind variable value at runtime.
6. When you want to filter the results in affect by using a WHERE clause, select **Filter Expression**, select the bind variable from the list, and then, click **New expression method** to enter the attribute value expression and click **OK**.
7. Deselect **Fetch All** when you want to specify the number of rows that the row finder is allowed to match.

   When you enter a number of rows for **Fetch Limit**, you can also select **Error Exceeding Limit** to enable Oracle ADF to throw an exception when more matching rows exist in the database than the number you specify for **Fetch Limit**.
8. Leave **Exposed** selected when you want to associate previously defined UI hints with the current bind variable. If you know that the bind variable will not be utilized by the user interface, you can deselect **Exposed**.
9. You can choose whether you want to make the value of a named bind variable required, optional, or selectively required for the row finder that references the bind variable as a view criteria item.

   Press **F1** to view the JDeveloper Help Center topic for details on the **Required** dropdown options.

What Happens When You Define a Row Finder

When you create a view object row finder, the view object definition contains all the metadata required by the row finder, including the row finder definition itself. As the following example shows, the metadata for a row finder `RowFinder` includes a bind variable `EmailBindVar` in the `<Variable>` element, a transient attribute `TrEmpEmail` in the `<ViewAttribute>` element, a view criteria `findEmpByEmpEmail` and a view criteria row `EmpVOCriteria_Row0` in the `<ViewCriteria>` element, and finally the row finder `EmpByEmailRowFinder` in the `<RowFinders>` element of the view object definition.

The row finder <VarAttributeMapping> subelement maps the view criteria bind variable EmailBindVar to the transient attribute TrEmpEmail of the view object, which allows the end user to supply a value at runtime and allows the application to invoke the row finder with the required criteria attribute. The <ViewCriteriaItem> subelement sets the criteria attribute Email to the value of the bind variable EmailBindVar.

At runtime, when the row finder is invoked on the view object, the transient attribute values passed to one or more criteria attributes identify the matching rows in the row set. In this example, the email address of the employee is used to match the employee record from the EMPLOYEE table. The row finder locates the record for the employee without the need to pass a row key value.

```
<ViewObject
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="EmpVO"
  SelectList="EmpEO.ID,
       EmpEO.LAST_NAME,
       EmpEO.FIRST_NAME"
       EmpEO.USERID"
       EmpEO.DEPT_ID"
       EmpEO.EMAIL"
  FromList="S_EMP EmpEO"
  ...
  <Variable
    Name="EmailBindVar"
    Kind="viewcriteria"
    Type="java.lang.String"/>
  <EntityUsage
    Name="EmpEO"
    Entity="model.entities.EmpEO"/>
  ...
  <ViewAttribute
    Name="TrEmpEmail"
    IsUpdateable="false"
    IsSelected="false"
    IsPersistent="false"
    PrecisionRule="true"
    Type="java.lang.String"
    ColumnType="CHAR"
    AliasName="VIEW_ATTR"
    SQLType="VARCHAR"/>
  ...
  <ViewCriteria
    Name="findEmpByEmpEmail"
    ViewObjectName="model.views.EmpVO"
    Conjunction="AND">
    ...
    <ViewCriteriaRow
      Name="EmpVOCriteria_row_0"
      UpperColumns="1">
      <ViewCriteriaItem
        Name="Email"
        ViewAttribute="Email"
        Operator="="
        Conjunction="AND"
        Value=":EmailBindVar"
        IsBindVarValue="true"
        Required="Optional"/>
    </ViewCriteriaRow>
  </ViewCriteria>
  ...
  <RowFinders>
    <AttrValueRowFinder
      Name="EmpByEmailRowFinder"
      FetchLimit="1"
      ErrorOnExceedingLimit="true">
      <ViewCriteriaUsage
        Name="findEmpByEmpEmail"
        FullName="model.views.EmpVO.findEmpByEmpEmail"/>
      <VarAttributeMap>
        <VariableAttributeMapping
          Variable="EmailBindVar"
          Attribute="TrEmpEmail"/>
      </VarAttributeMap>
    </AttrValueRowFinder>
  </RowFinders>
</ViewObject>
```

What You May Need to Know About View Criteria and Row Finder Usage

Row finders and view criteria can both be used either programmatically or declaratively to filter a view object row set. The row finder differs from the view criteria because it defines a map between transient attributes that you define on the view object and view criteria attribute bind variables. Ultimately, the row finder matches one or more rows on the view object by applying the view criteria to the view object with the bind variable defined by a transient attribute value that is resolved at runtime.

The transient attribute mapped by the row finder allows the row finder to be used in application use cases that would not be suitable for view criteria alone. In particular, row finders are most useful when ADF Business Components web services enable CRUD operations. In this case, the row finder gives the ADF Business Components web services developer the ability to expose CRUD operations without needing obscure row key values.

Fusion web application developers can create a web service data control to expose the view objects of an ADF Business Components web service in the JDeveloper Data Controls panel. The exposed row-finder mapped transient attributes of the view object can then be used to design an input form that allows the end user to make the desired updates. For example, an end user may supply the value of a familiar attribute, such as a person's email address, to match a particular person row and then initiate an update operation on any attribute of that row, such as the one that would allow a name change.

For details about row finder support in ADF web services, see What You May Need to Know About Row Finders and the ADF Web Service Operations. For details about creating data controls based on ADF web services, see Using ADF Data Controls in *Developing Applications with Oracle ADF Data Controls*.

Note that the capability of row finders to match rows using non-key attributes extends to master-detail related view objects, as described in How to Find Rows of a Master View Object Using Row Finders.

Programmatically Invoking the Row Finder

When you define a row finder you invoke the row finder on the view object. If the row finder definition specifies a row limit, the executed row finder will throw a `RowFinderFetchLimitExceededException` exception.

To invoke a row finder that you define on a view object, follow these basic steps (as illustrated in the following example):

1. Find the view object that defines the row finder.
2. Find the row finder from the view object.
3. Create a name value pair for each row finder bind variable mapping.
4. Set each bind variable using a row-finder mapped transient attribute.
5. Invoke the row finder on the desired view object.
6. Throw an exception when the number of matching rows exceeds the row finder fetch limit.

At runtime, when the row finder is invoked on the view object, row-finder mapped transient attribute values populated by `setAttribute()` are set on criteria attributes to identify the matching rows in the row set. In the following example, the email address of the employee is used to match the employee record on the `EmpView` view object. The row finder `EmpByEmailRowFinder` locates the record for the employee using the transient attribute `TrEmpEmail` to specify the criteria attribute without the need to pass a row key value.

```
package model;

import oracle.jbo.*;
import oracle.jbo.client.Configuration;
import oracle.jbo.server.RowFinder;
import oracle.jbo.server.ViewObjectImpl;

public class TestClient
{
   public TestClient()
   {
      super();
   }

   public static void main(String[] args)
   {
      TestClient testClient = new TestClient();
      String amDef = "model.AppModule";
      String config = "AppModuleLocal";
      ApplicationModule am =
                 Configuration.createRootApplicationModule(amDef, config);

      // 1. Find the view object with the row finder
      ViewObjectImpl vo = (ViewObjectImpl)am.findViewObject("EmpView1");
      Row r;
      RowIterator ri;

      // 2. Find the row finder
      RowFinder finder = vo.lookupRowFinder("EmpByEmailRowFinder");
      // 3. Create name value pairs for the row finder
      NameValuePairs nvp = new NameValuePairs();
```

```
        // 4. Set the row-finder mapped transient attribute
        nvp.setAttribute("TrEmpEmail", "cee.mague@company.com");
        // 5. Invoke the row finder
        try
        {
           ri = finder.execute(nvp, vo);
        }
        // 6. Throw an exception when row match exceeds specified limit
        catch(RowFinderFetchLimitExceededException e)
        {
           System.out.println("Warning: more than one row match exists.");
        }

        while (ri.hasNext())
        {
          r = ri.next();
          System.out.println("Find emp row by email finder: " +
             r.getAttribute("FirstName") + "/" + r.getAttribute("LastName"));
        }

        Configuration.releaseRootApplicationModule(am, true);
     }
  }
```

Working with List of Values (LOV) in View Object Attributes

You can define an attribute of a view object in the ADF Model project as a LOV attribute and make it available on the user interface for user input based on selection.

Edit forms displayed in the user interface portion of your application can utilize LOV-enabled attributes that you define in the data model project to predetermine a list of values for individual input fields. For example, the edit form may display a list of countries to populate the corresponding address field in the edit form. To facilitate this common design task, ADF Business Components provides declarative support to specify the LOV usage in the user interface.

Defining an LOV for attributes of a view object in the data model project greatly simplifies the task of working with list controls in the user interface. Because you define the LOV on the individual attributes of the view object, you can customize the LOV usage for an attribute once and expect to see the list component in the form wherever the attribute appears.

> **Note:**
>
> In order for the LOV to appear in the UI, the LOV usage must exist before the user interface designer creates the databound form. Defining an LOV usage for an attribute referenced by an existing form will not change the component that the form displays to an LOV.

You can define an LOV for any view object attribute that you anticipate the user interface will display as a selection list. The characteristics of the attribute's LOV definition depend on the requirements of the user interface. The information you gather from the user interface designer will determine the best solution. For example, you might define LOV attributes in the following cases:

- When you need to display attribute values resulting from a view object query against a business domain object.

  For example, define LOV attributes to display the list of suppliers in a purchase order form.

- When you want to display attribute values resulting from a view object query that you wish to filter using a parameter value from any attribute of the LOV attribute's current row.

  For example, define LOV attributes to display the list of supplier addresses in a purchase order form but limit the addresses list based on the current supplier.

  If you wish, you can enable a second LOV to drive the value of the parameter based on a user selection. For example, you can let the user select the current supplier to drive the supplier addresses list. In this case, the two LOVs are known as a **cascading list**.

Before you can define the LOV attribute, you must create a data source view object in your data model project that queries the eligible rows for the attribute value you want the LOV to display. After this, you work entirely on the base view object to define the LOV. The base view object is the one that contains the primary data for display in the user interface. The LOV usage will define the following additional view object metadata:

- A view accessor to access the data source for the LOV attribute. The view accessor is the ADF Business Components mechanism that lets you obtain the full list of possible values from the row set of the data source view object.
- Optionally, supplemental values that the data source may return to attributes of the base view object other than the data source attribute for which the list is defined.
- User interface hints, including the type of list component to display, attributes to display from the current row when multiple display attributes are desirable, and a few options specific to the choice list component.

> **Note:**
>
> The LOV feature does not support the use of attribute validation to validate the display list. Any validation rules that may have been defined on data source attributes (including supplemental ones) will be suppressed when the list is displayed and will therefore not limit the LOV list. Developers must ensure that the list of values returned from the data source view object contains only desired, valid values.

The general process for defining the LOV-enabled attribute relies on the Create List of Values dialog that you display for the base view object attribute.

To define the LOV-enabled attribute, follow this general process:

1. Open the Create List of Values dialog for the base attribute.
2. Create a new view accessor definition to point to the data source view object or select an existing view accessor that the base view object already defines.

   Always create a new view accessor for each use case that your wish to support. Oracle recommends that you do not reuse a view accessor to define multiple LOV lists that happen to rely on the same data source. Reusing a view accessor can produce unintended results at runtime.

3. Optionally, you can filter the view accessor by creating a view criteria using a bind variable that obtains its value from any attribute of the base view object's current row.

   If you create a view criteria to filter the data source view object, you may also set a prerequisite LOV on the attribute of the base view object that you use to supply the value for the view criteria bind variable. LOV lists that cooperate in this manner, are known as cascading LOV lists. You set cascading LOV lists when you want the user's selection of one attribute to drive the options displayed in a second attribute's list.

4. Select the list attribute from the view accessor's data source view object.

   This maps the attribute you select to the current attribute of the base view object.

5. Optionally, select list return values to map any supplemental values that your list returns to the base view object.

6. Select user interface hints to specify the list's display features.

7. Save the attribute changes.

Once you create the LOV-enabled attribute, the user interface designer can create the list component in the web page by dragging the LOV-enabled attribute's collection from the Data Controls panel. For further information about creating a web page that display the list, see Creating Databound Selection Lists and Shuttles . Specifically, for information about working with LOV-enabled attributes in the web page, see How to Create a Model-Driven List.

How to Define a Single LOV-Enabled View Object Attribute

When an edit form needs to display a list values that is not dependent on another selection in the edit form, you can define a view accessor to point to the list data source. For example, assume that a purchase order form contains a field that requires the user to select the order item's supplier. In this example, you would first create a view accessor that points to the data source view object (`SuppliersView`). You would then set the LOV on the `SupplierDesc` attribute of the base view object (`PurchaseOrdersView`). Finally, you would reference that view accessor from the LOV-enabled attribute (`SupplierDesc`) of the base view object and select the data source attribute (`SupplierDesc`).

You will use the Create List of Values dialog to define an LOV-enabled attribute for the base view object. The dialog lets you select an existing view accessor or create a new one to save with the LOV-attribute definition.

Before you begin:

It may be helpful to have an understanding of LOV-enabled attributes. For more information, see Working with List of Values (LOV) in View Object Attributes.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To define an LOV that displays values from a view object attribute:

1. In the Applications window, double-click the view object that contains the attribute you wish to enable as an LOV.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute that is to display the LOV, and then click the **List of Values** tab and click the **Add list of values** button.

   Use the Create List of Values dialog to create the LOV on the attribute you have currently selected in the attribute list of the overview editor. JDeveloper assigns a unique name to identify the LOV usage. For example, the metadata for the attribute `SupplierDesc` will specify the name `SupplierDescLOV` to indicate that the attribute is LOV enabled.
4. In the Create List of Values dialog, on the Configuration tab, click the **Create new view accessor** button to add a view accessor to the view object you are currently editing.

   Alternatively, you can expand **List Data Source** and select among the existing view accessors. The dropdown list displays all view accessors that you have added to the view object you are editing.
5. In the View Accessors dialog, select the view object definition or shared view instance that defines the data source for the attribute and shuttle it to the view accessors list.

   By default, the view accessor you create will display the same name as the view object. You can edit the accessor name to supply a unique name. For example, assign the name `SuppliersViewAccessor` for the `SuppliersView` view object.

   The view instance is a view object usage that you have defined in the data model of a **shared application module**. For more information about using shared view instances in an LOV, see How to Create an LOV Based on a Lookup Table.
6. Click **OK** to save the view accessor definition for the view object.
7. In the Create List of Values dialog, expand **List Data Source** and select the view accessor you created for the base view object to use as the data source. Then select the same attribute from this view accessor that will provide the list data for the LOV-enabled attribute.

   The editor creates a default mapping between the list data source attribute and the LOV-enabled attribute. For example, the attribute `SuppliersDesc` from the `PurchaseOrdersView` view object would map to the attribute `SuppliersDesc` from the `SuppliersViewAccessor` view accessor.

   The editor does not allow you to remove the default attribute mapping for the attribute for which the list is defined.
8. If you want to specify supplemental values that your list returns to the base view object, click the **Create return attribute map** button in the **List Return Values** section and map the desired base view object attributes with attributes accessed by the view accessor.

   Supplemental attribute return values are useful when you do not require the user to make a list selection for the attributes, yet you want those values, as determined by the current row, to participate in the update. For example, to map the attribute

SupplierAddress from the PurchaseOrdersView view object, you would choose the attribute SupplierAddress from the SuppliersViewAccessor view accessor.

9. Click **OK**.

How to Define Cascading Lists for LOV-Enabled View Object Attributes

When the application user interface requires a list of values in one input field to be dependent on the user's entry in another field, you can create attributes that will display as cascading lists in the user interface. In this case, the list of possible values for the LOV-enabled attributes might be different for each row. As the user changes the current row, the LOV values vary based on the value of one or more controlling attribute values in the LOV-enabled attribute's view row. To apply the controlling attribute to the LOV-enabled attribute, you will create a view accessor to access the data source view object with the additional requirement that the accessor filters the list of possible values based on the current value of the controlling attribute. To filter the LOV-enabled attribute, you can edit the view accessor to add a named view criteria with a bind variable to obtain the user's selection.

For example, assume that a purchase order form contains a field that requires the user to select the supplier's specific site and that the available sites will depend on the order's already specified supplier. To implement this requirement, you would first create a view accessor that points to the data source view object. The data source view object will be specific to the LOV usage, because it must perform a query that filters the available supplier sites based on the user's supplier selection. You might name this data source view object definition SupplierIdsForCurrentSupplierSite to help distinguish it from the SupplierSitesView view object that the data model already contains. The data source view object will use a named view criteria (SupplierCriteria) with a single view criteria item set by a bind variable (TheSupplierId) to obtain the user's selection for the controlling attribute (SupplierId).

You would then set the LOV on the SupplierSiteId attribute of the base view object (PurchaseOrdersView). You can then reference the view accessor that points to the data source view object from the LOV-enabled attribute (PurchaseOrdersView.SupplierSiteId) of the base view object. Finally, you must edit the LOV-enabled attribute's view accessor definition to specify the corresponding attribute (SupplierIdsForCurrentSupplierSite.SupplierSiteId) from the view object as the data source and, importantly, source the value of the bind variable from the view row's result using the attribute SupplierId.

To define cascading lists for LOV-enabled view object attributes:

1. Create a data source view object to control the cascading list.
2. Create a view accessor to filter the cascading list.

Creating a Data Source View Object to Control the Cascading List

The data source view object defines the controlling attribute for the LOV-enabled attribute. To make the controlling attribute accessible to the LOV-enabled attribute of the base view object, you must define a named view criteria to filter the data source attribute based on the value of another attribute. Because the value of the controlling attribute is expected to change at runtime, the view criteria uses a bind variable to set the controlling attribute.

Before you begin:

It may be helpful to have an understanding of cascading LOV-enabled attributes. For more information, see How to Define Cascading Lists for LOV-Enabled View Object Attributes.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To define the view criteria for the data source to be referenced by the LOV-enabled attribute:

1. In the Applications window, double-click the view object that you created to query the list of all possible values for the controlling attribute.

   For example, if the LOV-enabled attribute `SupplierSiteId` depends on the controlling attribute `SupplierId` value, you might have created the data source view object `SupplierIdsForCurrentSupplierSite` to query the list of all supplier sites.
2. In the overview editor, click the **Query** navigation tab.
3. In the Query page, in the **Bind Variables** section, click the **Create New Bind Variable** button to add a bind variable to the data source view object.

   For example, for a data source view object `SupplierIdsForCurrentSupplierSite` used to query the list of all supplier sites, you would create the bind variable `TheSupplierId`, since it will be the controlling attribute for the LOV-enabled attribute.
4. In the **New Variable** dialog, enter the name and select the type of the bind variable and click **OK**.

   By default, the view accessor you create will display the same name as the view object instance. You can edit the accessor name to supply a unique name. For example, assign the name `CurrencyLookupViewAccessor` for the `CurrencyLookupView` view object instance.
5. In the overview editor, click the **View Criteria** navigation tab and click the **Create New View Criteria** button to add the view criteria to the data source view object you are currently editing.
6. In the Create View Criteria dialog, click **Add Group** and define a single **Criteria Item** for the group as follows:
   - Enter a **Criteria Name** to identify the view criteria. For example, you might enter the name `SupplierCriteria` for the `SupplierIdsForCurrentSupplierSite`.
   - Select the controlling attribute from the **Attributes** list. For example, you would select the `SupplierSiteId` attribute from the `SupplierIdsForCurrentSupplierSite`.
   - Select **equal to** from the view criteria **Operator** list.
   - Select **Bind Variable** from the view criteria **Operand** list.

- Select the name of the previously defined bind variable from the **Parameter** list.
- Select among the following bind variable configuration options to determine whether or not the value is required by the parent LOV:

  Optional from the **Validation** menu and deselect **Ignore Null Values** when you want to configure cascading LOVs where the parent LOV value is required. This combination supports the cascading LOV use case where no selection in the parent LOV returns *no* rows in the child LOV. The `WHERE` clause shown in the Edit View Criteria dialog should look similar to `((SupplierIdsForCurrentSupplierSite.SUPPLIER_ID = :TheSupplierId))`.

  Optional from the **Validation** menu and leave **Ignore Null Values** selected (default) when you want to configure cascading LOVs where the parent LOV value is optional. This combination supports the cascading LOV use case where no selection in the parent LOV returns *all* rows in the child LOV. The `WHERE` clause shown in the Edit View Criteria dialog should look similar to `(((SupplierIdsForCurrentSupplierSite.SUPPLIER_ID = :TheSupplierId) OR ( :TheSupplierId IS NULL )))`.

  For more details about these settings, see What You May Need to Know About Bind Variables in View Criteria. Do not select **Required** for the Validation option for cascading LOVs, because no selection in the parent LOV will cause a validation error.

7. Click **OK**.

Creating a View Accessor to Filter the Cascading List

To populate the cascading LOV-enabled attribute, you must first set up a named view criteria on a data source view object. To make the LOV-enabled attribute of the base view object dependent on the controlling attribute of the data source view object, you then add a view accessor to the LOV-enabled attribute of the base view object and reference the previously defined data source view object's named view criteria.

Before you begin:

It may be helpful to have an understanding of cascading LOV-enabled attributes. For more information, see How to Define Cascading Lists for LOV-Enabled View Object Attributes.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the data source view object and named view criteria, as described in Creating a Data Source View Object to Control the Cascading List.

To create a view accessor that filters display values for an LOV-enabled attribute based on the value of another attribute in the same view row:

1. In the Applications window, double-click the base view object that contains the attribute you want to use the filtered view accessor as the list data source.

   For example, the base view object `PurchaseOrdersView` might contain the attribute `SupplierSiteId` that will depend on the value of the controlling attribute `SupplierId`.

2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute that is to filter the cascading LOV, and then click the **List of Values** tab and click the **Add List of Values** button.
4. In the Create List of Values dialog, click the **Create New View Accessor** button to add a view accessor to the view object you are currently editing.

   Alternatively, you can expand **List Data Source** and select among the existing view accessors. The dropdown list displays all view accessors that you have added to the view object you are editing.
5. In the View Accessors dialog, select the view object instance name that you created for the data source view object and shuttle it to the view accessors list.
6. With the new view accessor selected in the dialog, click **Edit**.
7. In the Edit View Accessor dialog, apply the previously defined view criteria to the view accessor and provide a value for the bind variable as follows:
   - Click the data source view object's view criteria in the **Available** list and add it to the Selected list. For example, you would select `SupplierCriteria` from the `SupplierIdsForCurrentSupplierSite` view object definition.
   - Set the value for the bind variable to the name of the controlling attribute. The attribute name must be identical to the base view object's controlling attribute. For example, if the base view object `PurchaseOrdersView` contains the LOV-enabled attribute `SupplierSiteId` that depends on the value of the controlling attribute `SupplierId`, you would enter `SupplierId` for the bind variable value.
   - Select the name of the previously defined bind variable from the **Parameter** list.
   - Select **Required** from the **Usage** dropdown list.
8. Click **OK** to save the view accessor definition for the base view object.
9. In the Attributes page of the overview editor, select the attribute that is to display the LOV, and then click the **List of Values** tab and click the **Add list of values** button.
10. In the Create List of Values dialog, expand **List Data Source** and select the view accessor you created for the data source view object instance to use as the data source. Then select the controlling attribute from this view accessor that will serve to filter the attribute you are currently editing.

    The editor creates a default mapping between the view object attribute and the LOV-enabled attribute. You use separate attributes in order to allow the bind variable (set by the user's controlling attribute selection) to filter the LOV-enabled attribute. For example, the LOV-enabled attribute `SupplierId` from the `PurchaseOrdersView` view object would map to the controlling attribute `SupplierSiteId` for the `SupplierIdsForCurrentSupplierSiteViewAccessor`. The runtime automatically supports these two cascading LOVs where the row set and the base row attribute differ.
11. Click **OK**.

How to Specify Multiple LOVs for a Single LOV-Enabled View Object Attribute

Another way to vary the list of values that your application user interface can display is to define multiple list of values for a single LOV-enabled view object attribute. In contrast to a cascading list, which varies the list contents based on a dependent LOV list selection, an LOV-enabled switcher attribute with multiple LOVs lets you vary the entire LOV itself. The LOV choice to display is controlled at runtime by the value of an attribute that you have defined specifically to resolve to the name of the LOV to apply.

For example, you might want to define one LOV to apply in a create or edit form and another LOV to apply for a search component. In the first case, the LOV-enabled attribute that the form can use is likely to be an entity-based view accessor that is shared across all the view objects that reference the entity. The entity-based view accessor is useful for user interface forms because a single accessor definition can apply to each instance of the same LOV in the forms. However, in the case of the search component, LOV definitions based on view accessors derived from an underlying entity will not work. The LOV definitions for search components must be based on view accessors defined in the view object. Note that when the user initiates a search, the values in the criteria row will be converted into WHERE clause parameters. Unlike a regular view row displayed in create or edit type forms, the criteria row is not backed by an entity. In this scenario, one LOV uses the entity-based accessor as a data source and a second LOV uses the view object-based accessor as a data source.

To address this requirement to define multiple LOV lists that access the same attribute, you add a switcher attribute to the base view object. For example, you might add a ShipperLOVSwitcher attribute for the Orders view object that resolves through an expression to the name of the LOV to display. Such an expression can specify two LOVs that may apply to the ShipperID attribute:

```
(adf.isCriteriaRow) ? "LOV_ShipperID_ForSearch" : "LOV_ShipperID"
```

This expression would appear in the **Value** field of the switcher attribute. At runtime, in the case of the search component, the expression resolves to the value that identifies the view object-based accessor LOV. In the case of the create or edit form, the expression resolves to the value that identifies the entity-based accessor LOV.

You will use the Create List of Values dialog to add multiple LOV lists to an attribute of the base view object. You will also use the List of Values section in the Attributes page of the overview editor for the base view object to define the default LOV to display and the switcher attribute to apply.

Before you begin:

It may be helpful to have an understanding of LOV-enabled attributes. For more information, see Working with List of Values (LOV) in View Object Attributes.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

- Create the first LOV list for the attribute, as described in How to Define a Single LOV-Enabled View Object Attribute.

Note that the switcher attribute scenario requires that you create unique view accessors. You must not reuse a view accessor to define multiple LOV lists. Reusing a view accessor across various use cases can produce unintended results at runtime.

To specify additional LOV lists for a view object attribute with an existing LOV:

1. In the Applications window, double-click the view object that contains the attribute for which you want to specify multiple LOV lists.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the desired attribute, and then click the **List of Values** tab and click the **Add list of values** button.
4. In the Create List of Values dialog, define the first LOV, as described in How to Define a Single LOV-Enabled View Object Attribute.

   When you define the LOV, change the name of the LOV to match the value returned by the attribute that you will use to determine which LOV your application applies to the LOV-enabled attribute.
5. After you define the first LOV, return to the **List of Values** tab of the Attributes page of the overview editor and, with the original attribute selected, click the **Add List of Values** button.

   If you have selected the correct attribute from the Attributes page of the overview editor, the **List of Values** section should display your previously defined LOV.
6. In the Create List of Values dialog, repeat the procedure described in How to Define a Single LOV-Enabled View Object Attribute to define each subsequent LOV.

   The name of each LOV must correspond to a unique value returned by the attribute that determines which LOV to apply to the LOV-enabled attribute.

   You must define the second LOV using a unique view accessor, but you may use any attribute. There are no restrictions on the type of LOV lists that you can add to an attribute with multiple LOV lists specified.

   After you finish defining the second LOV, the **List of Values** section in the view object overview editor changes to display additional features that you will use to control the selection of the LOV.
7. In the Attributes page of the overview editor, click the **List of Values** tab and use the **List of Values Switcher** dropdown list to select the attribute that will return the name of the List of Value to use.

   The dropdown list displays the attributes of the base view object. If you want your application to dynamically apply the LOV from the LOVs you have defined, your view object must define an attribute whose values resolve to the names of the LOVs you defined. If you have not added this attribute to the view object, be sure that the dropdown list displays **<None Specified>**. In this case, at runtime your application will display the LOV-enabled attribute with the default LOV and it will not be possible to apply a different LOV.
8. To change the default LOV to apply at runtime, choose the **Default** radio button corresponding to the desired LOV definition.

   The default LOV selection determines which list of values your application will display when the **List of Values Switcher** dropdown list displays **<None Specified>**. Initially, the first LOV in the overview editor **List of Values** section is the default.

9. To change the component that your application will use to display the various LOV lists, select from desired component from the **List Type UI Hint** dropdown list.

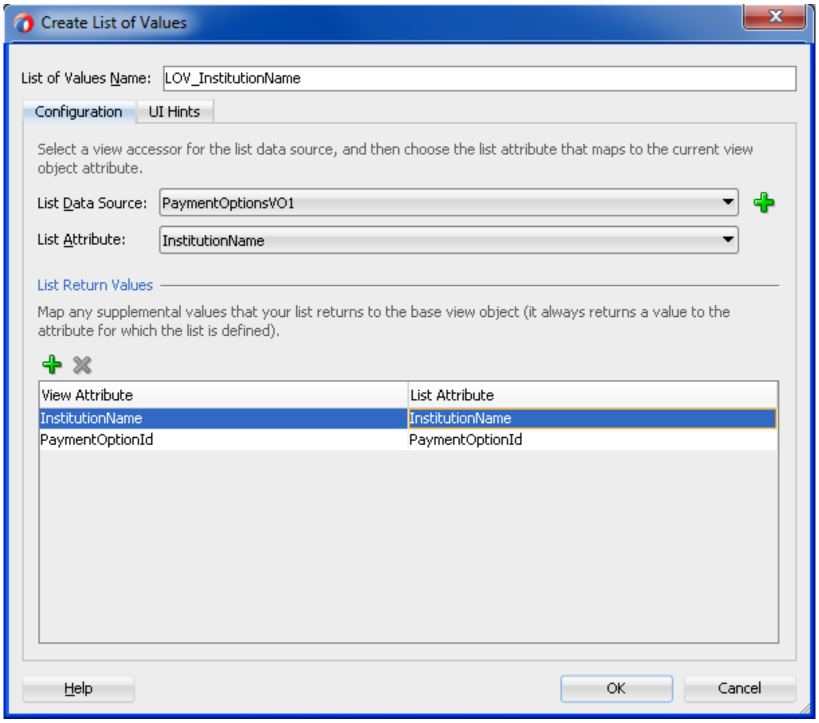
   The component you select will apply to all LOV lists. For a description of the available components, see How to Set User Interface Hints on a View Object LOV-Enabled Attribute.

How to Define an LOV to Display a Reference Attribute

Reference attributes that your view objects define are often desirable attributes to use as the source for LOV lists. Reference attributes belong to secondary entity usages that you have added to the view object to provide meaningful information beyond the entity usage's primary key attribute. For example, when you create an `OrderInfo` view object, the view object may define a secondary entity usage for `PaymentOptionsEO` to include billing information for the order, including the list of credit cards the end user has added to their account.

An LOV that you define for the secondary entity object needs to be able to update the primary attribute value, but to be meaningful to the end user, you typically hide the primary attribute in the list and display one or more reference attributes instead. In this case, your LOV might display the list of credit cards by institution name, but hide the payment option ID value that gets updated by the end user's selection. Figure 5-37 shows the LOV defined on the reference attribute `InstitutionName`. The **List Return Values** section of the Create List of Values dialog lists the reference attribute and then lists the primary key attribute `PaymentOptionId` to provide supplemental values.

Figure 5-37 Create View Criteria Dialog with Reference Attribute Specified



Create List of Values

List of Values Name: LOV_InstitutionName

Configuration | UI Hints

Select a view accessor for the list data source, and then choose the list attribute that maps to the current view object attribute.

List Data Source: PaymentOptionsVO1

List Attribute: InstitutionName

List Return Values

Map any supplemental values that your list returns to the base view object (it always returns a value to the attribute for which the list is defined).

View Attribute	List Attribute
InstitutionName	InstitutionName
PaymentOptionId	PaymentOptionId

Before you begin:

It may be helpful to have an understanding of reference attributes in secondary entity usages. For more information, see Working with List of Values (LOV) in View Object Attributes.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the entity-based view object and add a secondary entity usage that defines the desired LOV attributes, as described in How to Define a Single LOV-Enabled View Object Attribute. By default, the secondary entity usage will include the primary key attribute that you want the LOV to update.

To define reference attributes for an LOV:

1. In the Applications window, double-click the view object that contains the secondary entity usage attribute you wish to enable as an LOV.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the desired reference attribute that is to display the LOV, click the **List of Values** tab, and then click the **Add List of Values** button.

   Use the Create List of Values dialog to create the LOV on the attribute you have currently selected in the attribute list of the overview editor. JDeveloper assigns a unique name to identify the LOV usage. For example, the metadata for the attribute `SupplierDesc` will specify the name `SupplierDescLOV` to indicate that the attribute is LOV-enabled.
4. In the Create List of Values dialog, click the **Create new view accessor** button to add a view accessor to the view object you are currently editing.

   Alternatively, you can expand **List Data Source** and select among the existing view accessors. The dropdown list displays all the view accessors that you have added to the view object you are editing.
5. In the View Accessors dialog, select the view object definition or shared view instance that defines the data source for the attribute and shuttle it to the view accessors list.

   By default, the view accessor you create will display the same name as the view object. You can edit the accessor name to supply a unique name. For example, assign the name `SuppliersViewAccessor` for the `SuppliersView` view object.
6. Click **OK** to save the view accessor definition for the view object.
7. In the Create List of Values dialog, expand **List Data Source** and select the view accessor you created for the base view object to use as the data source. Then select the same attribute from this view accessor that will provide the list data for the LOV-enabled attribute.

   The editor creates a default mapping between the list data source attribute and the LOV-enabled attribute. For example, the attribute `SuppliersDesc` from the `PurchaseOrdersView` view object would map to the attribute `SuppliersDesc` from the `SuppliersViewAccessor` view accessor.

   The editor does not allow you to remove the default attribute mapping for the attribute for which the list is defined.
8. If you want to specify supplemental values that your list returns to the base view object, click the **Create return attribute map** button in the **List Return Values**

section and map the desired base view object attributes with attributes accessed by the view accessor.

Supplemental attribute return values are useful when you do not require the user to make a list selection for the attributes, yet you want those values, as determined by the current row, to participate in the update. For example, to map the attribute `SupplierAddress` from the `PurchaseOrdersView` view object, you would choose the attribute `SupplierAddress` from the `SuppliersViewAccessor` view accessor.

9. Click **OK**.

How to Set User Interface Hints on a View Object LOV-Enabled Attribute

When you know how the view object attribute that you define as an LOV should appear in the user interface, you can specify additional properties of the LOV to determine its display characteristics. These properties, or **UI hints**, augment the attribute hint properties that ADF Business Components lets you set on any view object attribute. Among the LOV UI hints for the LOV-enabled attribute is the type of component the user interface will use to display the list. For a description of the available components, see Table 5-2. (Not all ADF Faces components support the default list types, as noted in the Table 5-2.)

Table 5-2   List Component Types for List Type UI Hint

LOV List Component Type	Usage
Choice List  Literal Value Literal Value Query Result View Object Attribute View Accessor Attribute Transient Expression Entity Attribute	This component does not allow the user to type in text, only select from the dropdown list.
Combo Box  Gold membership discount. Gold membership discount. Gold membership discount. Basic corporate discount. Basic corporate discount. Basic corporate discount. Basic corporate discount. Basic partner discount. <null>	This component allows the user to type text or select from the dropdown list. This component sometimes supports auto-complete as the user types. This component is *not* supported for ADF Faces.

Table 5-2 (Cont.) List Component Types for List Type UI Hint

LOV List Component Type	Usage
Combo Box with List of Values  Equals Equals NotEquals LessThan GreaterThan LessOrEqualTo More...	This component is the same the as the combo box, except that the last entry (More...) opens a List of Values lookup dialog that supports query with filtering when enabled for the LOV attribute in its UI hints. The default UI hint enables queries on all attributes. Note that when the LOV attribute appears in a table component, the list type changes to an **Input Text with List of Values** component.
Input Text with List of Values 	This component displays an input text field with an LOV button next to it. The List of Values lookup dialog opens when the user clicks the button or enters an invalid value into the text field. The List of Values lookup dialog for this component supports query with filtering when enabled in the UI hints for the LOV attribute. The default UI hint enables queries on all attributes. This component may also support auto-complete when a unique match exists.
List Box  Comm Deptno Empno Ename Hiredate Job Mgr Sal ViewAttr	This component takes up a fixed amount of real estate on the screen and is scrollable (as opposed to the choice list, which takes up a single line until the user clicks on it).
Radio Group 	This component displays a radio button group with the selection choices determined by the LOV attribute values. This component is most useful for very short, fixed lists.

Before you begin:

It may be helpful to have an understanding of LOV-enabled attributes. See Working with List of Values (LOV) in View Object Attributes.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See Additional Functionality for View Objects.

You will need to complete this task:

Create the LOV list for the attribute, as described in How to Define a Single LOV-Enabled View Object Attribute.

To set view object attribute UI hints for an LOV-enabled attribute:

1. In the Applications window, double-click the view object that contains the attribute that you want to customize.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the desired attribute and then click the **List of Values** tab.
4. In the List of Values page, select the LOV list that you want to customize and click the **Edit list of values** button.
5. In the Edit List of Values dialog, click the **UI Hints** tab.
6. In the UI Hints page, select a default list type as the type of component to display the list.

   For a description of the available components, see Table 5-2.

   The list component displayed by the web page and the view object's default list type must match at runtime or a method-not-found runtime exception results. To avoid this error, confirm the desired list component with the user interface designer. You can also edit the default list type to match, so that, should the user interface designer subsequently change the component used in the web page, the two stay in sync.
7. Optionally, select additional display attributes to add values to the display.

   The list of additional attributes is derived from the LOV-enabled attribute's view row. The additional attribute values can help the end user select an item from the list.
8. If you selected the **Combo Box with List of Values** type component, by default, the dropdown list for the component will display the first 10 records from the data source. This limit also serves to keep the view object fetch size small. To change the number of records the dropdown list of a Combo Box with List of Values component can display, enter the number of records for **Query Limit**.

   When you want the user to be able to view the full set of records, do not use **Query Limit** for this purpose. Because **Query Limit** also controls the number of rows the view object will fetch (it sets the view object definition `ListRangeSize` property), the value should be keep small for optimal performance. The end user who needs access to the full set of records should click on the component's lookup icon to open an LOV lookup dialog and view the records there.

   Query Limit is disabled for all other component types and those components place no restriction on the number of rows that the LOV will access.

   For details about the `ListRangeSize` property, see What Happens at Runtime: How an LOV Queries the List Data Source.

9. If you selected a component type that allows the user to open a List of Values lookup dialog to select a list value (this includes either the **Combo Box with List of Values** type component or **Input Text with List of Values** type component), by default, the lookup dialog will display a search form that will allow the user to search on all queryable attributes of the data source view object (the one defined by the LOV-enabled attribute's view accessor). Decide how you want to customize these components.

   a. When you select the **Combo Box with List of Values** type component and you have added a large number of attributes to the **Selected** list, use **Show in Combo Box** to improve the readability of the dropdown list portion of the component. To limit the attribute columns to display in the dropdown list that the Combo Box with List of Values component displays, choose **First** from **Show in Combo Box** and enter a number corresponding to the number of attributes from the top of the **Selected** list that you want the dropdown list to display (this combination means you are specifying the "first" *x* number of attributes to display from the Create List of Values dialog's **Selected** list). Limiting the number of attribute columns to display in the dropdown list ensures that the user does not have to horizontally scroll to view the full list, but it does not limit the number of attribute columns to display in the List of Values lookup dialog. This option is disabled for all list component types except Combo Box with List of Values.

   b. You can limit the attributes to display in the List of Values lookup dialog by selecting a view criteria from the **Include Search Region** dropdown list. To appear in the dropdown list, the view criteria must already have been defined on the data source view object (the one that the LOV-enabled attribute's view accessor defines). Click the **Edit View Criteria** button to set search form properties for the selected view criteria. For more information about customizing view criteria for search forms, see How to Set User Interface Hints on View Criteria to Support Search Forms.

   c. You can prepopulate the results table of the List of Values lookup dialog by selecting **Query List Automatically**. The List of Values lookup dialog will display the results of the query when the user opens the dialog. If you leave this option deselected, no results will be displayed until the user submits the search form.

10. Alternatively, if you prefer not to display a search region in the List of Values lookup dialog, select **<No Search>** from the **Include Search Region** dropdown list. In this case, the List of Values lookup dialog will display only attributes you add to the **Display Attributes** list.

11. If you selected a choice type component to display the list, you can specify a **Most Recently Used Count** as an alternative to displaying all possible values.

    For example, your form might display a choice list of `SupplierId` values to drive a purchase order form. In this case, you can allow the user to select from a list of their most recently viewed suppliers, where the number of supplier choices is determined by the count you enter. The default count `0` (zero) for the choice list displays all values for the attribute.

12. If you selected a **Combo Box with List of Values** type component to display the list, you can select a view criteria from the **Filter Combo Box Using** dropdown list to limit the list of valid values the LOV will display.

    When you enable **Filter Combo Box Using**, the dropdown list displays the existing view criteria from the view object definition related to the LOV's view accessor. If the dropdown list displays no view criteria, then the data source view object defines no view criteria. When you do not enable this feature, the Combo Box with List of Values component derives its values from the full row set returned by the view accessor. The filtered Combo Box with List of Values is a useful feature when you want to support the use of an LOV with popup search dialog or LOV with a dropdown list that has a limited set of valid choices. For details about using the Combo Box with List of Values component in user interfaces, see List of Values (LOV) Input Fields.

13. Decide how you want the list component to handle a null value choice to display in the list component. This option is not enabled for every list component type that you can select.

    If you enable **Include "No Selection" Item**, you can also determine how the null value selection should appear in the list by making a selection from the dropdown list. For example, when you select **Labeled Item**, you can enter the desired label in the edit field to the right of the dropdown list or you can click the **...** button (to the right of the edit field) to select a message string from the resource bundle associated with the view object. When you select a message string from the resource bundle, JDeveloper saves the string's corresponding message key in the view object definition file. At runtime, the UI locates the string to display based on the current user's locale setting and the message key in the localized resource bundle.

14. Click **OK**.

How to Handle Date Conversion for List Type UI Components

When the LOV-enabled attribute of the view object is bound to date information (such as the attribute `OrderShippedDate`), by default Oracle ADF assumes a format for the field like `yyyy-MM-dd hh:mm:ss`, which combines date and time. This combined date-time format is specified by the ADF Business Components Date domain class (`jbo.domain.Date`) and creates a conversion issue for the ADF Faces component when the user selects a date supplied by the LOV-enable attribute. When the ADF Faces component is unable to convert the domain type to the Date type, the user interface invalidates the input field and displays the message `Error: The date is not in the correct format`.

To avoid this potential conversion error, configure a UI hint setting for the date value attribute of the view object that you want to enable for an LOV. The UI hint you specify will define a date-only mask, such as `yyyy-MM-dd`. Subsequently, any ADF Faces component that references the attribute will perform the conversion based on a pattern specified by its EL value-binding expression (such as `#{bindings.Hiredate.format}`) and will reference the UI hint format instead of the ADF Business Components domain date-time. The conversion error happens when the EL expression evaluates to null because no format mask has been specified.

Before you begin:

It may be helpful to have an understanding of LOV-enabled attributes. For more information, see Working with List of Values (LOV) in View Object Attributes.

You may also find it helpful to understand support for UI hints at the level of view objects. For more information about UI hints, see Defining UI Hints for View Objects.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

Create the LOV list for the attribute, as described in How to Define a Single LOV-Enabled View Object Attribute.

To set a UI hint to match the date format for the LOV-enable attribute:

1. In the Applications window, double-click the view object that contains the LOV-enabled attribute.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the date-value attribute that you want to customize with UI hints, and then click the **UI Hints** tab.
4. In the UI Hints page, select **Simple Date** for the **Format Type** and choose the format with the date-only mask.

   Mapping of the ADF Business Components domain type to its available formatters is provided in the `formatinfo.xml` file in the BC4J subdirectory of the JDeveloper system directory (for example, `C:\Documents and Settings\<username>\Application Data\JDeveloper\system<version#>\o.BC4J.\formatinfo.xml`).

How to Automatically Refresh the View Object of the View Accessor

If you need to ensure that your view accessor always queries the latest data from the database table, you can set the **Auto Refresh** property on the data source view object. This property allows the view object instance to refresh itself after a change in the database. You can enable this feature for any read-only view instance that your application modules define. Once you enable this property on a view object, it ensures that the changes a user commits to a database table will become available to any other user working with the same database table. A typical use case is to enable auto refresh for the data source view object when you define a view accessor for an LOV-enabled view object attribute.

Because the auto-refresh feature relies on Oracle Database change notification feature, observe these restrictions when enabling auto-refresh for your view object:

- Ensure the view objects query only read-only tables, and as few tables as possible. This will ensure the best performance and prevent the database invalidation queue from becoming too large.
- Configure the application module that contains updatable, auto-refresh view instances to be shared and to lock rows during updates.
- Ensure the database user has database notification privileges. For example, to accomplish this with a SQL*Plus command use `grant change notification to <user name>`.
- Test the query for compatibility with query result change notification before you enable auto refresh on the view object. Not all query definitions satisfy the requirements for query result change notification.

When you enable auto refresh for the view object and observe these restrictions, the refresh is accomplished through the Oracle database change notification feature. At runtime, prior to executing the view object query, the framework will use the JDBC API to register the view object query to receive database change notifications for underlying data changes. When the view object receives a notification (because its underlying data has changed), the row sets of the view object are marked as dirty and the framework will refresh the row set on the next server trip from the client to the middle tier. At that point, the dirty collections will be discarded and the request for the updated data will trigger a new query execution by the view object. Because the application module waits until the next checkout, the row set currency of the current transaction is maintained and the end user is not hampered by the update.

For example, assume that a user can create or edit a calendar entry but cannot edit calendar entries added by other users. When the user creates and commits a new entry, then in the same server trip the calendar entries that other users modified or entered will be updated. But when another user creates a calendar entry, the view object receives a notification and waits for the next server trip before it refreshes itself; the delay to perform the update prevents contention among various users to read the same data.

In another example, say an LOV displays a list of postal codes that is managed in read-only fashion by a database administrator. After the administrator adds a new postal code as a row to the database, the application module detects a time when there are no outstanding requests and determines that a pending notification exists for the view instance that accesses the list of postal codes; at that point, the view object refreshes the data and all future requests will see the new postal code.

> **Note:**
>
> Use optimistic row locking for web applications. Optimistic locking, the default configuration setting, assumes that multiple transactions can complete without affecting each other. Optimistic locking therefore allows auto-refresh to proceed without locking the rows being refreshed. Pessimistic row locking prevents the row set refresh and causes the framework to throw an exception anytime the row set has a transaction pending (for example, a user may be in the process of adding a new row). To ensure that the application module configuration uses optimistic row locking, open the Business Components page of the `adf-config.xml` overview editor and confirm that **Locking Mode** (corresponding to the `jbo.locking.mode` property) is set to `optimistic`, as described in How to Confirm That Fusion Web Applications Use Optimistic Locking.

Before you begin:

It may be helpful to have an understanding of LOV-enabled attributes. See Working with List of Values (LOV) in View Object Attributes.

It may be helpful to understand the query definition requirements for registering a query for query result change notification. See Using Continuous Query Notification in the *Oracle Database Advanced Application Developer's Guide*.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will also need to complete this task:

- Create the view accessor, as described in How to Create a View Accessor for an Entity Object or View Object.

For information about queries see Using Continuous Query Notification in the *Oracle Database Advanced Application Developer's Guide*.

To register a view object to receive data change notifications:

1. In the Applications window, double-click the view object that you want to receive database change notifications.
2. In the overview editor, click the **Query** navigation tab.
3. In the Query page, click **Test and Explain**.
4. In the Test Query dialog, click the **Change Notification** tab to validate the query is compatible with Oracle Database change notification.

   If the Test Query dialog shows the query does not pass change notification compatibility, you can not enable auto refresh on the view object. Not all query definitions satisfy the requirements for query result change notification.
5. If the query is compatible with change notification, in the overview editor, click the **General** navigation tab.
6. In the Properties window, expand the **Tuning** section, and select **True** from the **Auto Refresh** dropdown list.

   If the **Tuning** section is not displayed in the Properties window, click the **General** navigation tab in the overview editor to set the proper focus.

How to Test LOV-Enabled Attributes Using the Oracle ADF Model Tester

To test the LOV you created for a view object attribute, use the Oracle ADF Model Tester, which is accessible from the Applications window.

The Oracle ADF Model Tester, for any view object instance that you browse, will display any LOV-enabled attributes using one of two component types you can select in the UI Hints page of the List of Values dialog. Currently, only a Choice List component type and Input Text with List of Values component type are supported. Otherwise, the Oracle ADF Model Tester uses the default choice list type to display the LOV-enabled attribute.

Before you begin:

It may be helpful to have an understanding of LOV-enabled attributes. For more information, see Working with List of Values (LOV) in View Object Attributes.

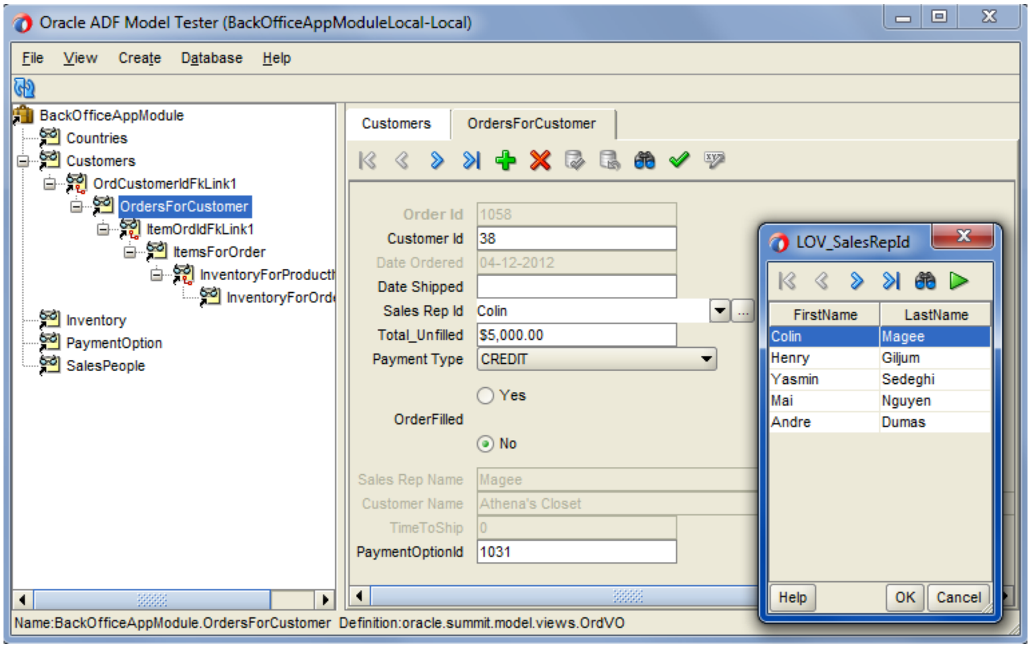
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

To test an LOV using the Oracle ADF Model Tester:

1. In the Applications window, expand the project containing the desired application module and view objects.
2. Right-click the application module and choose **Run**.
3. In the Oracle ADF Model Tester, select the desired view object from the section on the left. The Oracle ADF Model Tester displays the LOV-enabled attribute values in a dropdown list unless you specified the component type as an Input Text with List of Value, UI hint.

Figure 5-38 shows an LOV-enabled attribute, `SalesRepId` for the `CustomerVO`, that specifies an input text field and List of Values dialog as the UI hint list type. The Input Text with List of Values component is useful when you want to display the choices in a separate LOV dialog. Other list types are not supported by the Oracle ADF Model Tester.

Figure 5-38 Displaying LOV-Enabled Attributes in the Oracle ADF Model Tester



Order Id	1058
Customer Id	38

Name:BackOfficeAppModule.OrdersForCustomer Definition:oracle.summit.model.views.OrdVO

What Happens When You Define an LOV for a View Object Attribute

When you define an LOV for a view object attribute, the view object metadata defines the following additional information, as shown in the following example for the `CustomerVO.SalesRepId` attribute.

- The `<ViewAttribute>` element names the attribute, points to the list binding element that defines the LOV behavior, and specifies the component type to display in the web page. For example, the LOV-enabled attribute `SalesRepId` points to the list binding named `LOV_SalesRepId` and defines the `CONTROLTYPE` input text field with list (`input_text_lov`) to display the LOV data.

  When the user interface designer creates the web page using the Data Controls panel, the `<CONTROLTYPE Value="`*`namedType`*`"/>` definition determines the component that JDeveloper will add to the web page. When the component type definition in the data model project does not match the component type displayed in the web page, a runtime exception will result. For more information, see What Happens at Runtime: How an LOV Queries the List Data Source.

- The `<ListBinding>` element defines the behavior of the LOV. It also identifies a view accessor to access the data source for the LOV-enabled attribute. The view accessor is the ADF Business Components mechanism that lets you obtain the full list of possible values from the row set of the data source view object. For example, `ListVOName="EmpVO1"` points to the `EmpVO1` view accessor, which accesses the view object `EmpVO`.

- The <ListBinding> element maps the list data source attribute to the LOV-enabled attribute. For example, the ListAttrNames item Id is mapped to the LOV-enabled attribute SalesRepId.
- The <ListBinding> element also identifies one or more attributes to display from the current row and provides a few options that are specific to the choice list type component. For example, the ListDisplayAttrNames item FirstName and LastName are extra attributes displayed by the LOV-enabled attribute SalesRepId. In this example, the value none for NullValueFlag means the user cannot select a blank item from the list.

```
<ViewAttribute
    Name="SalesRepId"
    LOVName="LOV_SalesRepId"
    PrecisionRule="true"
    EntityAttrName="SalesRepId"
    EntityUsage="CustomerEO"
    AliasName="SALES_REP_ID">
    <Properties>
      <SchemaBasedProperties>
        <LABEL
          ResId="oracle.summit.model.views.CustomerVO.SalesRepId_LABEL"/>
        <CONTROLTYPE
          Value="input_text_lov"/>
      </SchemaBasedProperties>
    </Properties>
</ViewAttribute>
. . .
<ListBinding
    Name="LOV_SalesRepId"
    ListVOName="EmpVO1"
    ListRangeSize="10"
    NullValueFlag="none"
    MRUCount="0">
    <AttrArray Name="AttrNames">
      <Item Value="SalesRepId"/>
    </AttrArray>
    <AttrArray Name="ListAttrNames">
      <Item Value="Id"/>
    </AttrArray>
    <AttrArray Name="ListDisplayAttrNames">
      <Item Value="Id"/>
      <Item Value="FirstName"/>
      <Item Value="LastName"/>
    </AttrArray>
    <DisplayCriteria
      Hint="hide"/>
</ListBinding>
. . .
<ViewAccessor
    Name="EmpVO1"
    ViewObjectName="oracle.summit.model.views.EmpVO"
    OrderBy="EmpEO.LAST_NAME">
    <ViewCriteriaUsage
      Name="FilterByTitleIdVC"
      FullName="oracle.summit.model.views.EmpVO.FilterByTitleIdVC"/>
    <ParameterMap>
      <PIMap Variable="TitleIdBind">
        <TransientExpression><![CDATA[2]]></TransientExpression>
      </PIMap>
    </ParameterMap>
  </ViewAccessor>
```

What Happens at Runtime: How an LOV Queries the List Data Source

The ADF Business Components runtime adds view accessors in the attribute setters of the view row and entity object to facilitate the LOV-enabled attribute behavior. In order to display the LOV-enabled attribute values in the user interface, the LOV facility fetches the data source, and finds the relevant row attributes and mapped target attributes. The databound list component's default `AutoSubmit` property setting of `false` ensures the browser makes a server roundtrip only when the end user selects a value. As a result of the roundtrip, all list bindings in the **ADF Model layer** that are derived from the same LOV-enabled attribute get updated and the end-user selection is reflected in the corresponding list components of the user interface.

The number of data objects that the LOV facility fetches is determined in part by the `ListRangeSize` setting in the LOV-enabled attribute's list binding definition, which is specified in the Edit List of Values dialog that you display on the attribute from the view object overview editor. By default, the number of fetched records for LOV queries is not truncated for all types of list components (including LOV and non-LOV type list components). The default value `-1` specified by `ListRangeSize` means that the user will be able to view all the data objects from the data source. However, if the number of records fetched is very large and you want to truncate the values available to the list component used to display the records, then on `ListRangeSize` you can specify a discrete value for the number of records to fetch. The `ListRangeSize` value has no effect on the records that the end user can search on in the lookup dialog displayed for the two LOV type components. For more information about how each list component displays values, see How to Set User Interface Hints on a View Object LOV-Enabled Attribute.

Note that although you can alter the `ListRangeSize` value in the metadata definition for the `<ListBinding>` element, setting the value to a discrete number of records (for example, `ListRangeSize="5"`) most likely will not provide the user with the desired selection choices. Instead, if the value is `-1` (default for list components), then no restrictions are made to the number of records the list component will display, and the user will have access to the full set of values.

Performance Tip:

To limit the set of values an LOV displays, use a view accessor to filter the LOV binding, as described in How to Define a Single LOV-Enabled View Object Attribute. Additionally, in the case of component types that display a choice list, you can change the **Most Recently Used Count** setting to limit the list to display the user's previous selections, as described in How to Set User Interface Hints on a View Object LOV-Enabled Attribute.

Note, a runtime exception will occur when a web page displays a UI component for an LOV-enabled attribute that does not match the view object's `CONTROLTYPE` definition. When the user interface designer creates the page in JDeveloper using the Data Controls panel, JDeveloper automatically inserts the list component identified by the **Default List Type** selection you made for the view object's LOV-enabled attribute in the List UI Hint dialog. However, if the user interface designer changes the list type subsequent to creating the web page, you will need to edit the selection in the List UI Hint dialog to match.

What You May Need to Know About Lists

There are several things you may need to know about LOVs that you define for attributes of view objects, including how to propagate LOV-enabled attributes from parent view objects to child view objects (by extending an existing view object) and when to use validators instead of an LOV to manage a list of values.

Inheritance of AttributeDef Properties from Parent View Object Attributes

When a view object extends another view object, you can create the LOV-enabled attribute on the base object. Then when you define the child view object in the overview editor, the LOV definition will be visible on the corresponding view object attribute. This inheritance mechanism allows you to define an LOV-enabled attribute once and later apply it across multiple view objects instances for the same attribute.

You can also use the overview editor to extend the inherited LOV definition. For example, you may add extra attributes already defined by the base view object's query to display in selection list. Alternatively, you can define a view object that uses a custom `WHERE` clause to query the supplemental attributes not already queried by the based view object. For information about customizing entity-based view objects, see Working with Bind Variables.

Using Validators to Validate Attribute Values

If you have created an LOV-enabled attribute for a view object, there is no need to validate the attribute using a List Validator. You only use an attribute validator when you do not want the list to display in the user interface, but still need to restrict the list of valid values. List validation may be a simple static data or it may be a list of possible values obtained through a view accessor you define. Alternatively, you might prefer to use Key Exists validation when the attribute displayed in the UI is one that references a key value (such as a primary, foreign, or alternate key). For information about declarative validation in ADF Business Components, see Defining Validation and Business Rules Declaratively.

Defining UI Hints for View Objects

You define UI Hints on an ADF view object attributes to display context-sensitive UI information to the end user.

One of the built-in features of ADF Business Components is the ability to define UI hints on view objects and attributes of view objects. UI hints are settings that the view layer can use to automatically display the queried information to the user in a consistent, locale-sensitive way. For example, in web pages, a UI developer may access UI hint values by entering EL expressions utility methods defined on the `bindings` name space and specified for **ADF binding** instance names.

JDeveloper stores the hints in resource bundle files that you can easily localize for multilingual applications.

How to Add Attribute-Specific UI Hints

To create UI hints for attributes of a view object, use the overview editor for the view object, which is accessible from the Applications window. You can also display and edit UI hints using the Properties window that you display for an attribute.

Before you begin:

It may be helpful to have an understanding of attribute UI hints. For more information, see Defining UI Hints for View Objects.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To customize view object attribute with UI hints:

1. In the Applications window, double-click the view object that you want to customize with UI hints.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute that you want to customize with UI hints, and then click the **UI Hints** tab and define the desired hints.

   For example, for an attribute `UserId`, you might enter a value for its **Label Text** hint like "`Id`" or set the **Format Type** to Number, and enter a **Format** mask of `00000`.

> **Note:**
>
> Java defines a standard set of format masks for numbers and dates that are different from those used by the Oracle database's SQL and PL/SQL languages. For reference, see the Javadoc for the `java.text.DecimalFormat` and `java.text.SimpleDateFormat` classes.

How to Add View Object UI Hints

To create UI hints for a view object, use the overview editor for the view object, which is accessible from the Applications window. You can also display and edit several additional UI hints using the Properties window that you display for the view object.

Before you begin:

It may be helpful to have an understanding of UI hints. For more information, see Defining UI Hints for View Objects.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To customize view objects with UI hints:

1. In the Applications window, double-click the view object that you want to customize with UI hints.
2. In the overview editor, click the **General** navigation tab.
3. In the General page, enter a **Display Name** to define an EL accessible hint for the view object name.

   For example, for a view object `OrdersVO`, you might enter a value for its **Display Name** hint like "`Order`".
4. With the General page displayed in the overview editor, open the Properties window for the view object and expand the **UI Hints** section, and then enter additional hints as needed.

   For example, for a view object `OrdersVO`, you might enter a value for the **Display Name (Plural)** hint like "`Orders`" and, for the **Description** hint, you might enter a value like "`customer orders`".

How to Access UI Hints Using EL Expressions

A UI developer can access UI hints using EL expressions and display the hint values as data in a web page. The UI developer may access UI hints through the ADF binding instances that they create after dropping databound components into their web pages.

In the case of the view object hints, the UI developer accesses the view object hints through the collection binding defined for the view object. For example, assume that you have configured the view object UI hints as follows.

- `OrdersVO` view object **Display Name** hint = `Order`
- `OrdersVO` view object **Display Name (Plural)** hint = `Orders`
- `OrdersVO` view object **Description** hint = `customer orders`

The UI developer might display a header that makes use of these hints like this:

`Showing` *`customer orders`* `number 10 of 51` *`Orders`*`.`

The following example shows that the EL expression that produces the above text. In this EL expression the collection binding `OrdersVO1` provides access to the view object hints. The names of the EL expression utility methods match the property names defined in the view object XML definition file for the UI hints. For example, the view object property name `labelPlural`, which defines the **Display Name (Plural)** hint, corresponds to the utility method name used in the expression `bindings.OrdersVO1.hints.labelPlural`.

```
<af:panelHeader id="ph1"
           text="Showing #{bindings.OrdersVO1.hints.description} number
                         #{bindings.OrdersVO1.Orderno.inputValue} of
                         #{bindings.OrdersVO1.estimatedRowCount}
                         #{bindings.OrdersVO1.hints.labelPlural}.">
```

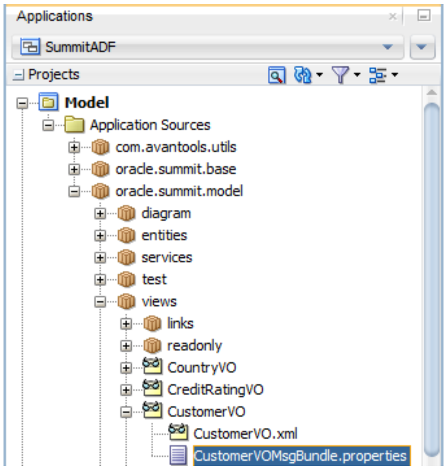
What Happens When You Add UI Hints

When you define attribute UI hints for a view object or view object attributes, by default JDeveloper stores them in a resource bundle file. This allows the hints that you define to be localized for the generated forms and tables of the user interface.

The type of resource bundle file that JDeveloper uses and the granularity of the file are determined by settings on the Resource Bundle page of the Project Properties dialog. By default, JDeveloper sets the option to **Properties Bundle** and generates one `.properties` file for the entire data model project. For example, when you define UI hints for a view object in the `Model` project, JDeveloper creates the bundle file named `ModelBundle.properties` for the package.

Alternatively, if you select the option in the Project Properties dialog to generate one resource bundle per file, you can inspect the message bundle file for any view object by selecting the object in the Applications window and looking under the corresponding **Sources** node in the Structure window. The Structure window shows the implementation files for the component you select in the Applications window. You can inspect the resource bundle file for the view object by expanding the parent package of the view object in the Applications window, as shown in Figure 5-39.

Figure 5-39 Resource Bundle File in Applications Window



For more information on the resource bundle options you can select, see How to Set Message Bundle Options.

The following example shows a sample message bundle file where the UI hint information appears. The first entry in each `String` array is a message key; the second entry is the locale-specific `String` value corresponding to that key.

```
oracle.summit.model.views.CustomerVO.Id_FMT_FORMATTER=
                                       oracle.jbo.format.DefaultNumberFormatter
oracle.summit.model.views.CustomerVO.Id_FMT_FORMAT=00000
oracle.summit.model.views.CustomerVO.Id_LABEL=Id
oracle.summit.model.views.CustomerVO.Email_LABEL=Email Address
oracle.summit.model.views.CustomerVO.LastName_LABEL=Surname
oracle.summit.model.views.CustomerVO.FirstName_LABEL=Given Name
```

How to Define UI Category Hints

UI categories provide the means to group attributes that a view object defines. The category names that you create are identifiers to be used by the dynamic rendering user interface to group attributes for display. The user interface will render the attribute with other attributes of the same category. You can use the category hint to aid the user interface to separate a large list of view object attributes into smaller groups related by categories.

Additionally, you can specify the field order hint to reorder how the user interface will render the attribute values within its category. For example, if a view object defines four attributes `attributeA`, `attributeB`, `attributeC`, and `attributeD` and you specify the field order 4, 3, 2, and 1 respectively for each attribute, then wherever the user interface renders the category, the attributes of that category will appear in the order attributeD, attributeC, attributeB, and attributeA.

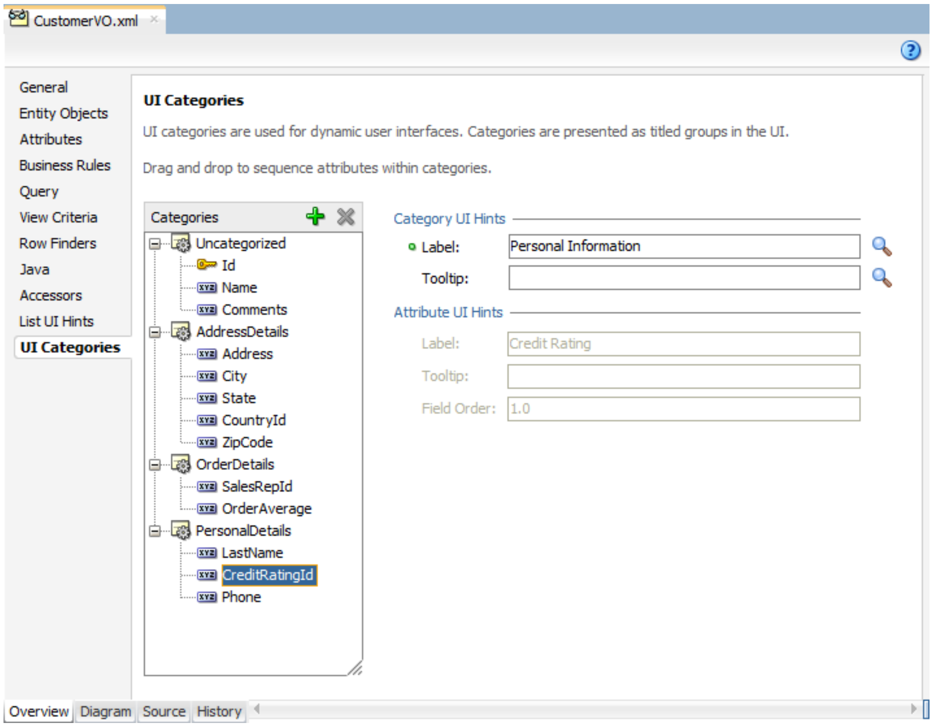
> **Note:**
>
> Use the UI Categories page in the overview editor for the view object to change the order of the attributes listed within a category you've created. JDeveloper automatically assigns and maintains the field order values of the attributes based on their order in the list, and you do not need to edit numeric values to define the field order hint.

The category and field order hints will be utilized by any dynamic rendering user interface that displays the attribute, including dynamic forms and search forms:

- In the case of dynamic forms, the attributes from each category will appear in a separate tab.
- In the case of search forms, the order of the form's individual view criteria is determined by the field order and category assigned to the attribute upon which the view criteria items are based.

To create UI categories for attributes of a view object, use the overview editor for the view object, which is accessible from the Applications window. You can create and edit categories for the entire view object using the UI Categories page, as shown in Figure 5-40.

Figure 5-40 Attribute UI Categories in View Object Overview Editor



UI Categories

UI categories are used for dynamic user interfaces. Categories are presented as titled groups in the UI.

Drag and drop to sequence attributes within categories.

Category UI Hints

Label: Personal Information

Tooltip:

Attribute UI Hints

Label: Credit Rating

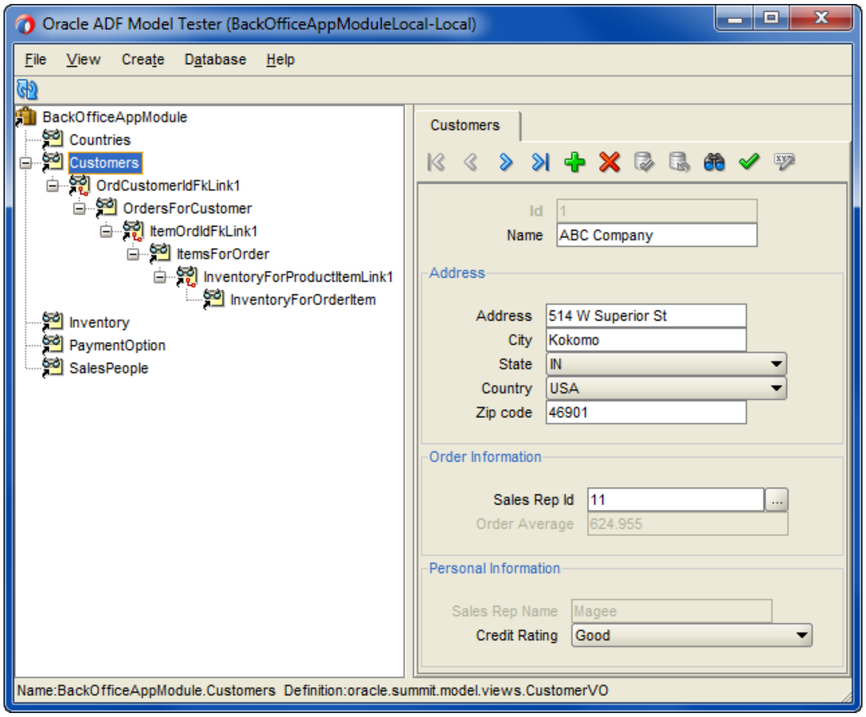
Tooltip:

Field Order: 1.0

When you assign a view object attribute to a category that you create in the UI Categories page, the order of the attributes displayed in the category list determines its numeric field order. The UI Categories page lets you change the field order of the attributes you've assigned to a category by dragging and dropping attributes within the list. When you drag and drop the attributes into the category lists, JDeveloper automatically maintains the correct sequence of the field order hints within the category and displays the field order value of individual attributes in the **Attribute UI Hints** list of the UI Categories page. Other attribute-level UI hints displayed in the UI Categories page are synchronized with settings in the **UI Hints** tab of the Attributes page of the view object editor.

Each category can have a label and tooltip text string resource to be utilized by the user interface when the category is rendered. You can localize these resource strings in the resource bundle file that you select to store the entries. For example, Figure 5-41 shows the attributes `LastName` and `CreditRatingId` with labels **Sales Rep Name** and **Credit Rating** in a category with the label **Personal Information**.

Figure 5-41 UI Categories Displayed in Oracle ADF Model Tester



Id 1
Name ABC Company
Address 514 W Superior St
City Kokomo
State IN
Country USA
Zip code 46901
Sales Rep Id 11
Order Average 624.955
Sales Rep Name Magee
Credit Rating Good

Name:BackOfficeAppModule.Customers Definition:oracle.summit.model.views.CustomerVO

Before you begin:

It may be helpful to have an understanding of UI hints. For more information, see Defining UI Hints for View Objects.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

- Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.
- Optionally, specify attribute UI hints, as described in How to Add Attribute-Specific UI Hints. Attribute UI hints are displayed read-only in the UI Categories page of the view object editor.

To create user interface categories and reorder the attributes for display:

1. In the Applications window, double-click the view object that you want to customize with user interface categories.
2. In the overview editor, click the **UI Categories** navigation tab.
3. In the UI Categories page, click the **Create New Category** button to create the category and then right-click the new category and choose **Rename**.
4. In the Rename dialog, enter the name of the category.
5. In the overview editor, in the **UI Hints** section, enter the user interface **Label Text** and **Tooltip Text** for the category.

The text that you enter will be added to the default resource bundle file for the project, as described in What Happens When You Add UI Hints. To select a different resource bundle file to store the label and tooltip strings, click the browse (**. . .**) button beside the text field.

6. In the **Categories** list, expand the **Uncategorized** list and scroll the list of attributes to locate the attribute you want to add to a category.

   The **Uncategorized** list displays all the attributes that the view object you are editing defines. This list is displayed by the overview editor as a selection list for the creation of UI Category hints. Attributes that you leave in the **Uncategorized** list will appear by default above the attribute categories displayed in the user interface.

7. Select the desired attribute and drag it into the new category you created. If the category contains more than one attribute, the position of the attribute that you drop into the list will determine its field order value.

   Developer automatically assigns a numeric value to the field order hint based on the sequence of the attributes that appear within a UI Category list. The attribute you place at the top of a category list will be rendered by the user interface first, the attribute second in the list will be rendered second, and so on. The field order hint appears in the **Attribute UI Hints** list of the UI Categories page and is not editable. The hint value is also visible in the source for the view object definition and should not be edited in the source.

What Happens When You Assign Attributes to UI Categories

When you define attribute UI categories for a view object, JDeveloper updates the view object's XML document file. JDeveloper adds the `CATEGORY` and the `FIELDORDER` UI hints in the `<SchemaBasedProperties>` element of the `<ViewAttribute>` element. The definition of the categories appears in a new `<Category>` element.

The metadata in the following example shows that the `CustomerId` attribute's `CATEGORY` hint refers to the `AccountInformation` category and the `FirstName` attribute's `CATEGORY` hint refers to the `UserInformation` category. The definition for both categories appears in `<Category>` elements. The `FIELDORDER` hint for each attribute specifies a numeric value, which JDeveloper assigns and maintains based on the order of the attributes in the UI categories lists you create in the overview editor. As shown in the following example, the `FIELDORDER` hint is a decimal value. A decimal value is used by JDeveloper to allow you to insert new attributes into a category without requiring JDeveloper to change all the existing attribute values and still be able to maintain the correct order.

Note that the default field order value for the first attribute in a category is assigned by JDeveloper as `0.0`. The field order value can be changed to any number to sort the category list, and it is not an index. The field order numeric values do not need to be contiguous.

```
<Category
    Name="AccountInformation">
    <Properties>
      <SchemaBasedProperties>
        <LABEL
          ResId="CUSTOMER_DETAILS"/>
        <TOOLTIP
          ResId="AccountInformation_TOOLTIP"/>
      </SchemaBasedProperties>
    </Properties>
</Category>
<Category
    Name="UserInformation">
    <Properties>
      <SchemaBasedProperties>
        <TOOLTIP
          ResId="UserInformation_TOOLTIP"/>
        <LABEL
          ResId="CUSTOMER_DETAILS"/>
      </SchemaBasedProperties>
    </Properties>
</Category>
...
<ViewAttribute
    Name="CustomerId"
    IsNotNull="true"
    PrecisionRule="true"
    EntityAttrName="CustomerId"
    EntityUsage="CustomerEO"
    AliasName="CUSTOMER_ID">
    <Data>
      <Property
        Name="OWNER_SCOPE"
        Value="INSTANCE"/>
      ...
    </Data>
    <Properties>
      <SchemaBasedProperties>
        <CATEGORY
          Value="AccountInformation"/>
        <FIELDORDER
          Value="0.0"/>
      </SchemaBasedProperties>
    </Properties>
  </ViewAttribute>
...
<ViewAttribute
    Name="FirstName"
    PrecisionRule="true"
    EntityAttrName="FirstName"
    EntityUsage="CustomerEO"
    AliasName="FIRST_NAME">
    <Data>
      <Property
        Name="OWNER_SCOPE"
        Value="INSTANCE"/>
      ...
    </Data>
    <Properties>
      <SchemaBasedProperties>
        <CATEGORY
          Value="UserInformation"/>
        <FIELDORDER
          Value="0.0"/>
      </SchemaBasedProperties>
    </Properties>
</ViewAttribute>
```

What You May Need to Know About Resource Bundles

Internationalizing the model layer of an application built using ADF Business Components entails producing translated versions of each component's resource bundle file. For example, the Italian version of the `QueryDataWithViewObjectsBundle.properties` file would be a file named `QueryDataWithViewObjectsBundle_it.properties`, and a more specific *Swiss* Italian version would have the name `QueryDataWithViewObjectsBundle_it_ch.properties`.

Resource bundle files contain entries for the message keys that need to be localized, together with their localized translation. For example, assuming you didn't want to translate the number format mask for the Italian locale, the Italian version of the `QueryDataWithViewoObjects` view object message keys would look like what you see in the following example. At runtime, the resource bundles are used automatically, based on the current user's locale settings.

```
oracle.summit.model.views.CustomerVO.Id_FMT_FORMATTER=

oracle.jbo.format.DefaultNumberFormatter
oracle.summit.model.views.CustomerVO.Id_FMT_FORMAT=00000
oracle.summit.model.views.CustomerVO.Id_LABEL=Codice Utente
oracle.summit.model.views.CustomerVO.Email_LABEL=Indirizzo Email
oracle.summit.model.views.CustomerVO.LastName_LABEL=Cognome
oracle.summit.model.views.CustomerVO.FirstName_LABEL=Nome
```

The resource bundles of the model project contribute one aspect of internationalizing the Fusion web application. Internationalization for specific locales also requires localizing the ADF Faces pages of the user interface. For more information about how to localize ADF Faces pages, see the "Internationalizing and Localizing Pages" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

6

Defining Master-Detail Related View Objects

This chapter describes how to link ADF view objects to other view objects to form master-detail hierarchies of any complexity in an Oracle ADF application.
This chapter includes the following sections:

About Master-Detail View Objects

You can create a link between an ADF view object to a single view object or multiple view objects to create master-detail hierarchies.

A **master-detail relationship** is established when a view link is created to associate two view object instances. A **view link** represents the relationship between two view objects, which is usually, but not necessarily, based on a foreign-key relationship between the underlying data tables. The view link associates a row of one view object instance (the master object) with one or more rows of another view object instance (the detail object).

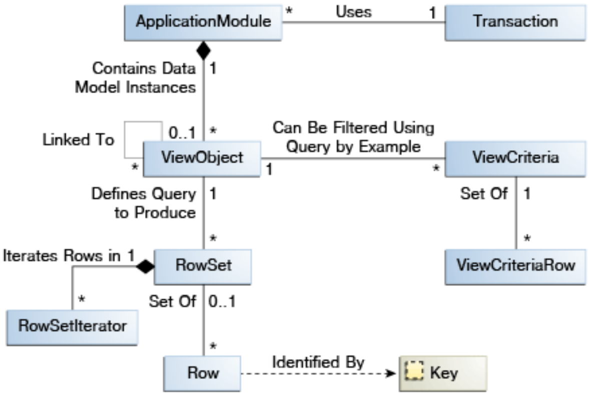
Master-Detail View Object Use Cases and Examples

This chapter helps you understand these **view object** concepts as illustrated in Figure 6-1:

- You can link a view object to one or more others to create master-detail hierarchies of any complexity.
- You can arrange parent-child view object instances in the context of an **application module** such that at runtime the detail view instance is actively coordinated with the current row of the master view instance.
- At design time, you can define a **view link accessor** that specifies an accessor attribute that the master collection uses at runtime to return the detail collection row set.
- You can programmatically access the detail collection row set using the view link accessor attribute that you specify for the master view object in the master-detail relationship.
- You can tune master-detail collection queries, by caching the row set of the detail view instance and support UI components, like the **ADF Faces** tree component, where data for each master node in a tree needs to retain its distinct set of detail rows.

- You can create row finder conditions using **view criteria** to locate specific rows within the master view object.
- You can define a self-referential master and detail hierarchy such that the source and destination view link attributes derive from a single table.
- You can define an inline view criteria to filter the row set of the master view object using attribute values specified by attributes of the detail view object.

Figure 6-1 A View Object Defines a Query and Produces a Row Set of Rows



Additional Functionality for View Objects

You may find it helpful to understand other **Oracle ADF** features before you start working with view objects. Following are links to other functionality that may be of interest.

- For details about using the interactive Oracle ADF Model Tester to validate view object query results, see Testing View Instance Queries.
- For details about creating a data model consisting of view object instances, see Implementing Business Services with Application Modules.
- For a quick reference to the most common code that you will typically write, use, and override in your custom view object classes, see Most Commonly Used ADF Business Components Methods.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Working with Multiple Tables in a Master-Detail Hierarchy

JDeveloper allows you to create source and target view objects in a master-detail hierarchy when there are many queries involving multiple tables related by foreign keys.

Many queries you will work with will involve multiple tables that are related by foreign keys. In this scenario, you can create separate view objects that query the related information and link a "source" view object to one or more "target" view objects to form a master-detail hierarchy.

There are two ways you might handle this situation. You can either:

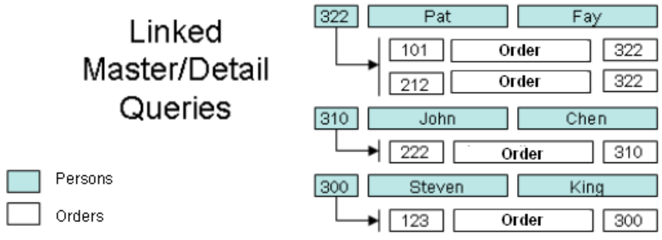
- Create a view link based on an association between **entity objects** when the source and target view objects are based on the underlying entity objects' association.
- Create a view link that defines how the source and target view objects relate.

Whether or not an association exists is determined when entity objects are created. By default, the entity object associations model the hierarchical relationships of the data source. For example, entity objects based on database tables related by foreign keys will capture these relationships in **entity associations**. If you do base the view link on an existing entity association, there is no performance penalty over defining the view link on the view objects alone. In either case, you use the Create View Link wizard to define the master-detail relationship.

> **Note:**
>
> A view link defines a basic master-detail relationship between two view objects. However, by creating more view links you can achieve master-detail hierarchies of any complexity, including:
>
> - Multilevel master-detail-detail
> - Master with multiple (peer) details
> - Detail with multiple masters
>
> The steps to define these more complex hierarchies are the same whether you create the relationships based on view objects alone or view objects with entity associations. In either case, you just need to create each additional hierarchy, one view link at time.

Figure 6-2 illustrates the multilevel result that master-detail linked queries produce.

Figure 6-2 Linked Master-Detail Queries



How to Create a Master-Detail Hierarchy Based on Entity Associations

When you want to show the user a set of master rows, and for each master row a set of coordinated detail rows, then you can create view links to define how you want the master and detail view objects to relate. For example, you could link the `DeptVO` view object to the `EmpVO` view object to create a master-detail hierarchy of departments and the set of employees they define. When these view objects are backed by entity objects related by an existing association, you can select the association to define the master-detail view link.

To create an association-based view link, you use the Create View Link wizard.

Before you begin:

It may be helpful to have an understanding of the ways to create a master-detail hierarchy. For more information, see Working with Multiple Tables in a Master-Detail Hierarchy.

You may also find it helpful to understand how entity associations are created. For more information, see What Happens When You Create Entity Objects and Associations from Existing Tables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired entity-based view objects, as described in How to Create an Entity-Based View Object.

To create an association-based view link

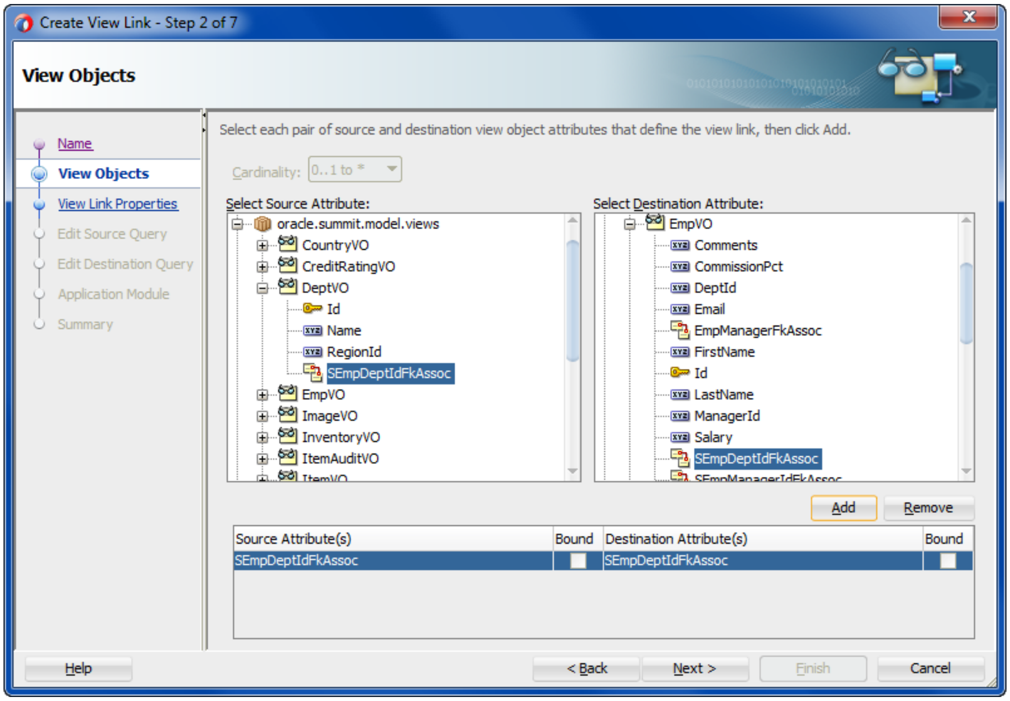
1. In the Applications window, right-click the package node of the project in which you want to create the view object and choose **New** and then **View Link**.
2. In the Create View Link wizard, on the Name page, supply a package and a component name.

   For example, given the purpose of the view link, a name like `DeptToEmpFkLink` is a valid name to identify the link between a department list and its employees when the link is based on a foreign key.
3. On the View Objects page, in the **Select Source Attribute** tree expand the source view object in the desired package. In the **Select Destination Attribute** tree, expand the destination view object.

   For entity-based view objects, notice that in addition to the view object attributes, relevant associations also appear in the list.
4. Select the same association in both **Source** and **Destination** trees. Then click **Add** to add the association to the table below.

   For example, Figure 6-3 shows the same `SEmpDeptIdFkAssoc` association in both **Source** and **Destination** trees selected.

Figure 6-3 Master and Detail Related by an Association Selection



Create View Link - Step 2 of 7

View Objects

Select each pair of source and destination view object attributes that define the view link, then click Add.

Cardinality: 0..1 to *

Source Attribute(s)	Bound	Destination Attribute(s)	Bound
SEmpDeptIdFkAssoc	□	SEmpDeptIdFkAssoc	□

5. Click **Finish**.

How to Create a Master-Detail Hierarchy Based on View Objects Alone

Just as with association-based view links, you can directly link view objects to other view objects to form master-detail hierarchies of any complexity. The only difference in the creation steps, involves the case when both the master and detail view objects are not related by an existing association. In this situation, because there is no association to capture the set of source and destination attribute pairs that relate them, you create the view link by indicating which view object attributes it should be based on.

To create the view link, use the Create View Link wizard.

Before you begin:

It may be helpful to have an understanding of the ways to create a master-detail hierarchy. For more information, see Working with Multiple Tables in a Master-Detail Hierarchy.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

Create the desired read-only view objects, as described in How to Create a Custom SQL Mode View Object.

To create a view link between view objects:

1. In the Applications window, right-click the package node of the project in which you want to create the view object and choose **New** and then **View Link**.
2. In the Create View Link wizard, on the Name page, enter a package name and a view link name. Click **Next**.

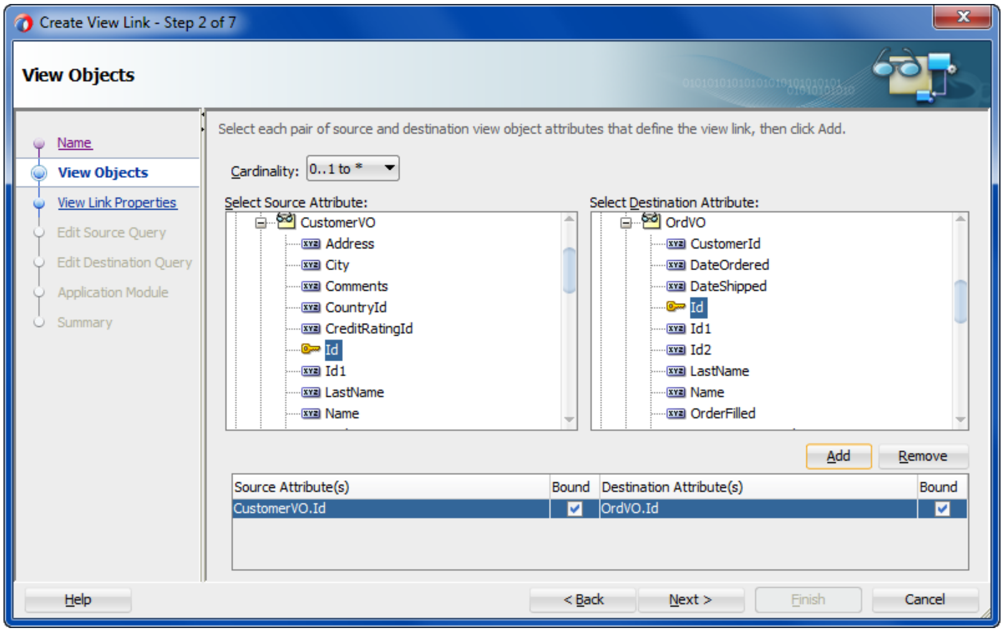
   For example, given the purpose of the view link, a name like `OrdersPlacedBy` is a valid name to identify the link between a customer list and their orders.
3. On the View Objects page, select a "source" attribute from the view object that will act as the master.

   For example, Figure 6-4 shows the `Id` attribute selected from the `CustomerVO` view object to perform this role. Click **Next**.
4. On the View Objects page, select a corresponding destination attribute from the view object that will act as the detail.

   For example, if you want the detail query to show orders that were placed by the currently selected customer, select the `Id` attribute in the `OrdersVO` to perform this role.
5. Click **Add** to add the matching attribute pair to the table of source and destination attribute pairs below. When you are finished defining master and detail link, click **Next**.

   Figure 6-4 shows just one (`CustomerVO.Id`, `OrderVO.Id`) pair. However, if you require multiple attribute pairs to define the link between master and detail, repeat the steps for the View Objects page to add additional source-target attribute pairs.

Figure 6-4 Defining Source/Target Attribute Pairs While Creating a View Link



Create View Link - Step 2 of 7

View Objects

Select each pair of source and destination view object attributes that define the view link, then click Add.

Cardinality: 0..1 to *

Source Attribute(s)	Bound	Destination Attribute(s)	Bound
CustomerVO.Id	☑	OrdVO.Id	☑

6. On the View Link Properties page, you can use the **Accessor Name** field to change the default name of the accessor that lets you programmatically access the destination view object.

   By default, the accessor name will match the name of the destination view object. For example, you might change the default accessor name `OrdersVO1` to

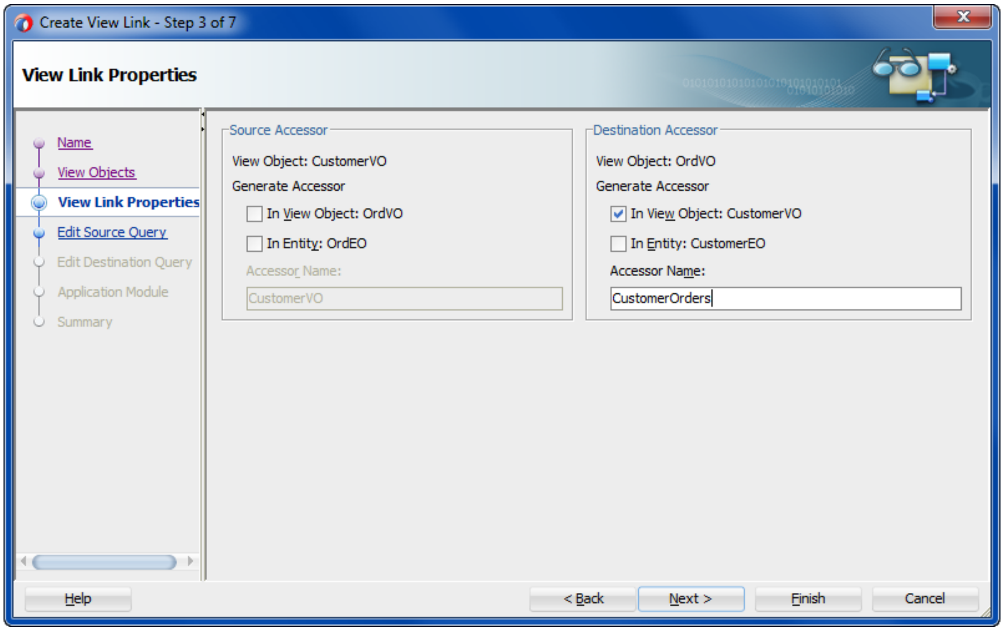
`CustomerOrders` to better describe the master-detail relationship that the accessor defines.

7. Also on the View Link Properties page, you control whether the view link represents a one-way relationship or a bidirectional one.

   By default, a view link is a one-way relationship that allows the current row of the source (master) to access a set of related rows in the destination (detail) view object. Leave the default settings unchanged for **Generate Accessor** when you want to enable support for hierarchical UI components, such as databound trees which require a view link accessor with accessor generated in the master view object.

   For example, in Figure 6-5, the checkbox settings indicate that you'll be able to access a detail collection of rows from `OrdersVO` for the current row in `CustomerVO`, but not vice versa. In this case, this behavior is specified by the checkbox setting in the **Destination Accessor** group box for `OrdersVO` (the **Generate Accessor In View Object: CustomerVO** box is selected) and checkbox setting in the **Source Accessor** group box for `CustomerVO` (the **Generate Accessor In View Object: OrdersVO** box is not selected).

Figure 6-5 View Link Properties Control Name and Direction of Accessors



Source Accessor
View Object: CustomerVO
Generate Accessor
□ In View Object: OrdVO
□ In Entity: OrdEO
Accessor Name:
CustomerVO

Destination Accessor
View Object: OrdVO
Generate Accessor
☑ In View Object: CustomerVO
□ In Entity: CustomerEO
Accessor Name:
CustomerOrders

8. On the Edit Source Query page, preview the view link SQL predicate that will be used at runtime to access the master row in the source view object and click **Next**.

9. On the Edit Destination Query page, preview the view link SQL predicate that will be used at runtime to access the correlated detail rows from the destination view object for the current row in the source view object and click **Next**.

10. On the Application Module page, add the view link to the data model for the desired application module and click **Finish**.

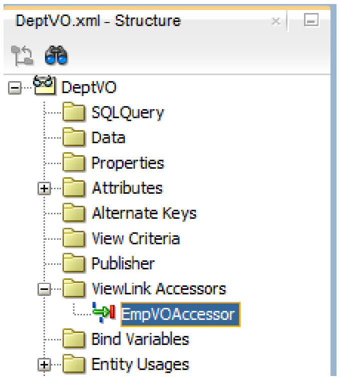
    By default the view link will not be added to the application module's data model. Later you can add the view link to the data model using the overview editor for the application module.

What Happens When You Create Master-Detail Hierarchies Using View Links

When you create a view link or an association-based view link, JDeveloper creates the XML document file that represents its declarative settings and saves it in the directory that corresponds to the name of its package. For example, if the view link is named `DeptToEmpFkLink` and it appears in the `views.links` package, then the XML file created will be `./views/links/DeptToEmpFkLink.xml` under the project's source path. This XML file contains the declarative information about the source and target attribute pairs you've specified and, in the case of an association-based view link, contains the declarative information about the association that relates the source and target view objects you've specified.

In addition to saving the view link component definition itself, JDeveloper also updates the XML definition of the *source* view object in the view link relationship to add information about the view link accessors that you may have defined. As a confirmation of this, you can select the source view object in the Applications window and inspect its details in the Structure window. As shown in Figure 6-6, you can see the default destination accessor `EmpVOAccessor` under the **ViewLink Accessors** node for the `DeptVO` source view object that accesses the destination `EmpVO` view object. This allows the source view object, using the view link accessor, to traverse the destination side of the view link. In addition to the view link accessor definition for the source view object, you can directly customize the view link to define a view link accessor on the destination view object, which provides access to row set of the source view object.

Figure 6-6 View Object with View Link Accessor in the Structure Window



How to Enable Active Master-Detail Coordination in the Data Model

When you enable programmatic navigation to a row set of correlated details by defining a view link, as described in How to Create a Master-Detail Hierarchy Based on Entity Associations, the view link plays a *passive* role, simply defining the information necessary to retrieve the coordinated detail row set when your code requests it. The view link accessor attribute is present and programmatically accessible in any result rows from any instance of the view link's source view object. In other words, programmatic access does not require modifying the application module's data model.

However, since master-detail user interfaces are such a frequent occurrence in enterprise applications, the view link can be also used in a more *active* fashion so you can avoid needing to coordinate master-detail screen programmatically. You opt to have this active master-detail coordination performed by *explicitly* adding an instance of a view-linked view object to your application module's data model.

To enable active master-detail coordination, open the application module in the overview editor and select the Data Model page.

Before you begin:

It may be helpful to have an understanding of the ways to create a master-detail hierarchy. For more information, see Working with Multiple Tables in a Master-Detail Hierarchy.

You may also find it helpful to understand the role of the application module. For more information, see About Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

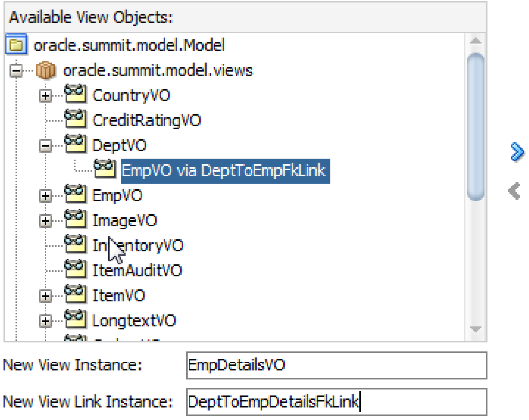
- Create the desired view objects, as described in How to Create an Entity-Based View Object and How to Create a Custom SQL Mode View Object.
- Create an application module, as described in How to Create an Application Module.

To add a detail instance of a view object:

1. In the Applications window, double-click the application module for which you define a new view instance.
2. In the overview editor, click the **Data Model** navigation tab.
3. In the Data Model page, expand the **View Object Instances** section and, in the **Available View Objects** list, select the detail view object node that is indented beneath the master view object.

   Note that the list shows the detail view object *twice*: once on its own, and once as a detail view object via the view link. For example, in Figure 6-7 you would select the detail view object `EmpVO via DeptToEmpFkLink` instead of the view object labeled as `EmpVO` (which, in this case, appears beneath the highlighted view object).

Figure 6-7 Detail View Object Selection from Available View Objects



New View Instance: EmpDetailsVO

New View Link Instance: DeptToEmpDetailsFkLink

4. In the **Name View Instance** field below the **Available View Objects** list, enter a name for the detail instance you're about to create.

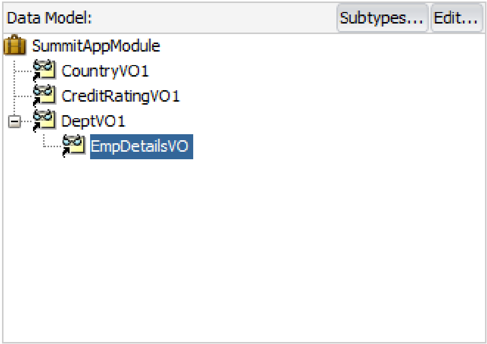
   For example, Figure 6-7 shows the name `EmpDetailsVO` for the instance of the `EmpVO` view object that is a detail view.

5. In the **Data Model** list, select the instance of the view object that you want to be the actively coordinating master.

6. Click **Add Instance** to add the detail instance to the currently selected master instance in the data model, with the name you've chosen.

   For example, in Figure 6-8, the **Data Model** list shows a master-detail hierarchy of view object instances with `EmpDetailsVO` as the detail view object.

Figure 6-8 Data Model with View Linked View Object



How to Test Master-Detail Coordination

To test active master-detail coordination, launch the Oracle ADF Model Tester on the application module by choosing **Run** from its context menu in the Applications window. The Oracle ADF Model Tester data model tree shows the view link instance that is actively coordinating the detail view object instance with the master view object instance. You can double-click the view link instance node in the tree to open a master-detail data view page in the Oracle ADF Model Tester. Then, when you use the toolbar buttons to navigate in the master view object — changing the view object's current row as a result — the coordinated set of details is automatically refreshed and the user interface stays in sync.

If you double-click another view object that is not defined as a master and detail, a second tab will open to show its data; in that case, since it is not actively coordinated by a view link, its query is not constrained by the current row in the master view object.

For information about editing the data model and running the Oracle ADF Model Tester, see Testing View Object Instances Using the Oracle ADF Model Tester.

How to Access the Detail Collection Using the View Link Accessor

To work with view links effectively, you should also understand that view link accessor attributes return a RowSet object and that you can access a detail collection using the view link accessor programmatically.

Accessing Attributes of Row by Name

At runtime, the getAttribute() method on a Row object allows you to access the value of any attribute of that row in the view object's result set by name. The view link accessor behaves like an additional attribute in the current row of the source view object, so you can use the same getAttribute() method to retrieve its value. The only practical difference between a regular view attribute and a view link accessor attribute is its data type. Whereas a regular view attribute typically has a scalar data type with a value like 303 or ngreenbe, the value of a view link accessor attribute is a row set of zero or more correlated detail rows. Assuming that curUser is a Row object from some instance of the Orders view object, you can write a line of code to retrieve the detail row set of order items:

```
RowSet items = (RowSet)curUser.getAttribute("OrderItems");
```

Note:

If you generate the custom Java class for your view row, the type of the view link accessor will be RowIterator. Since at runtime the return value will always be a RowSet object, it is safe to cast the view link attribute value to RowSet.

Programmatically Accessing a Detail Collection Using the View Link Accessor

Once you have retrieved the RowSet object of detail rows using a view link accessor, you can loop over the rows it contains just as you would loop over a view object's row set of results, as shown in the following example.

```
while (items.hasNext()) {
  Row curItem = items.next();
  System.out.println("--> (" + curItem.getAttribute("LineItemId") + ") " +
                     curItem.getAttribute("LineItemTotal"));
}
```

For information about creating a test client, see How to Access a Detail Collection Using the View Link Accessor.

Optimizing View Link Accessor Access to Display Master-Detail Data

You can enable caching of the view link accessor row set when you do not want the application to incur the small amount of overhead associated with reexecuting queries to create new detail row sets. For example, because **view accessor** row sets remain stable as long as the master row view accessor attribute remains unchanged, it would not be necessary to re-create a new row set for UI components, like the ADF Faces tree component, where data for each master node in a tree needs to retain its distinct set of detail rows.

You can enable retention of the view link accessor row set using the overview editor for the view object that is the source for the view link accessor. Select the **Retain Row Set** flag in the View Accessors page of the overview editor for the source view object.

> **Performance Tip:**
>
> When you expect user interface developers will use the view link to create databound master-detail components where the detail collections are stable, such as an ADF Faces tree component, enable the **Retain Row Set** flag. At runtime, this setting ensures the accessors for each detail collection will be executed once. The compromise for this improvement in performance is that accessed collections may occupy more memory space as compared to accessing the detail collections without the flag enabled.

To enable retention of the view link accessor row set:

1. In the Applications window, double-click the source view object that defines the view link.
2. In the overview editor, click the **View Accessors** navigation tab.
3. In the View Accessors page, expand the **View Link Accessors** section and select the **Retain Row Set** checkbox.

What You May Need to Know About View Link Accessors Versus Data Model View Link Instances

View objects support two different styles of master-detail coordination:

- View link *instances* for data model master-detail coordination, as described in Enabling a Dynamic Detail Row Set with Active Master-Detail Coordination.
- View link *accessor* attributes for programmatically accessing detail row sets on demand, as described in Programmatically Accessing a Detail Row Set Using View Link Accessor Attributes.
- You can combine both styles, as described in What Happens At Runtime: When You Combine the Programmatic Access Using View LInk Accessors.

Enabling a Dynamic Detail Row Set with Active Master-Detail Coordination

When you add a view link instance to your application module's data model, you connect two specific view object instances. The use of the view link instance indicates that you want active master-detail coordination between the two. At runtime the view link instance in the data model facilitates the eventing that enables this coordination. Whenever the current row is changed on the master view object instance, an event causes the detail view object to be refreshed by automatically invoking `executeQuery()` with a new set of bind parameters for the new current row in the master view object.

A key feature of this data model master-detail is that the master and detail view object instances are stable objects to which client user interfaces can establish bindings. When the current row changes in the master — instead of producing a *new* detail view object instance — the existing detail view object instance updates its default row set to contain the set of rows related to the new current master row. In addition, the user interface binding objects receive events that allow the display to update to show the detail view object's refreshed row set.

Another key feature that is exclusive to data model hierarchy is that a detail view object instance can have multiple master view object instances. For example, an `PaymentOptions` view object instance may be a detail of *both* a `Customers` and a `Orders` view object instance. Whenever the current row in *either* the `Customers` or `Orders` view object instance changes, the default row set of the detail `PaymentOptions` view object instance is refreshed to include the row of payment information for the current customer and the current order. See How to Create a Master-Detail Hierarchy With Multiple Masters for details on setting up a detail view object instance with multiple-masters.

Programmatically Accessing a Detail Row Set Using View Link Accessor Attributes

When you need to programmatically access the detail row set related to a view object row by virtue of a view link, you can use the **view link accessor** attribute. You specify the finder name of the view link accessor attribute from the overview editor for the view link. Click the **Edit** icon in the Accessors section of the Relationship page and in the Edit View Link Properties dialog, edit the name of the view link accessor attribute.

The following example shows the XML for the view link that defines the `_findername` value of the `<Attr>` element.

```
<ViewLinkDefEnd
    Name="Orders"
    Cardinality="1"
    Owner="devguide.advanced.multiplemasters.Orders"
    Source="true">
    <AttrArray Name="Attributes">
      <Item Value="devguide.advanced.multiplemasters.Orders.PaymentOptionId"/>
    </AttrArray>
    <DesignTime>
      <Attr Name="_minCardinality" Value="1"/>
      <Attr Name="_isUpdateable" Value="true"/>
      <Attr Name="_finderName" Value="Orders"/>
    </DesignTime>
</ViewLinkDefEnd>
```

Assuming you've named your accessor attribute *`AccessorAttrName`*, you can access the detail row set using the generic `getAttribute()` API like:

```
RowSet detail = (RowSet)currentRow.getAttribute("AccessorAttrName");
```

If you've generated a custom view row class for the master view object and exposed the getter method for the view link accessor attribute on the client view row interface, you can write strongly typed code to access the detail row set like this:

```
RowSet detail = (RowSet)currentRow.getAccessorAttrName();
```

Unlike the data model master-detail, programmatic access of view link accessor attributes does not require a detail view object instance in the application module's data model. Each time you invoke the view link accessor attribute, it returns a `RowSet` containing the set of detail rows related to the master row on which you invoke it.

Using the view link accessor attribute, the detail data rows are stable. As long as the attribute value(s) involved in the view link definition in the master row remain unchanged, the detail data rows will not change. Changing of the current row in the master does not affect the detail row set which is "attached" to a given master row. For this reason, in addition to being useful for general programmatic access of detail rows, view link accessor attributes are appropriate for UI objects like the tree control, where data for each master node in a tree needs to retain its distinct set of detail rows.

What Happens At Runtime: When You Combine the Programmatic Access Using View LInk Accessors

Oracle ADF needs to distinguish between the data model master-detail and view link accessor row sets. When you *combine* the use of data model master-detail with programmatic access of detail row sets using view link accessor, it is important to understand that they are distinct mechanisms. For example, imagine that you:

- Define `PersonsVO` and `OrdersVO` view objects
- Define a view link between them, naming the view link accessor `PersonsToOrders`
- Add instances of them to an application module's data model named `master` (of type `PersonsVO`) and `detail` (of type `OrdersVO`) coordinated actively by a view link instance.

If you find a person in the `master` view object instance, the `detail` view object instance updates as expected to show the corresponding orders. At this point, if you invoke a custom method that programmatically accesses the `PersonsToOrders` view link accessor attribute of the current `PersonsVO` row, you get a `RowSet` containing the set of `OrdersVO` rows. You might reasonably expect this programmatically accessed `RowSet` to have come from the `detail` view object instance in the data model, but this is not the case.

The `RowSet` returned by a view link accessor always originates from an *internally created* view object instance, not one you that added to the data model. This internal view object instance is created as needed and added with a system-defined name to the **root application module**.

The principal reason a distinct, internally created view object instance is used is to guarantee that it remains unaffected by developer-related changes to their own view objects instances in the data model. For example, if the view row were to use the detail view object in the data model for view link accessor `RowSet`, the resulting row set could be inadvertently affected when the developer dynamically:

1. Adds a `WHERE` clause with new named bind parameters

   If such a view object instance were used for the view link accessor result, unexpected results or an error could ensue because the dynamically added `WHERE` clause bind parameter values have not been supplied for the view link accessor's `RowSet`: they were only supplied for the default row set of the detail view object instance in the data model.

2. Adds an additional master view object instance for the detail view object instance in the data model.

   In this scenario, the semantics of the accessor would be changed. Instead of the accessor returning `OrdersVO` rows for the current `PersonsVO` row, it could all of a sudden start returning *only* the `OrdersVO` rows for the current `PersonsVO` that were created by a current logged in customer, for example.

3. Removes the detail view object instance or its containing **application module instance**.

   In this scenario, all rows in the programmatically accessed detail `RowSet` would become invalid.

Furthermore, Oracle ADF needs to distinguish between the data model master-detail and view link accessor row sets for certain operations. For example, when you create a new row in a detail view object, the framework automatically populates the attributes involved in the view link with corresponding values of the master. In the data model master-detail case, it gets these values from the current row(s) of the possibly multiple master view object instances in the data model. In the case of creating a new row in a `RowSet` returned by a view link accessor, it populates these values from the master row on which the accessor was called.

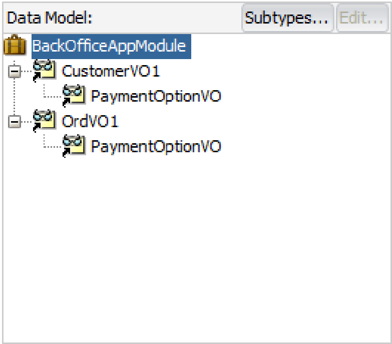
How to Create a Master-Detail Hierarchy With Multiple Masters

When useful, you can set up your data model to have multiple master view object instances for the same detail view object instance. Consider view objects named `Customers`, `Orders`, and `PaymentOptions` with view links defined between:

- `Customers` and `PaymentOptions`
- `Orders` and `PaymentOptions`

Figure 6-9 shows what the data model panel looks like when you've configured both `Customers` and `Orders` view object instances to be masters of the same `PaymentOptions` view object instance.

Figure 6-9 Multiple Master View Object Instances for the Same Detail



To set up the data model as shown in Figure 6-9 you use the overview editor for the application module and use the Data Model page.

Before you begin:

It may be helpful to have an understanding of view objects. For more information, see About View Objects.

To create a view instance with multiple master view objects:

1. Add an instance of the first master view object to the data model.

   Assume you name it `Customers`.
2. Add an instance of the second master view object to the data model.

   Assume you name it `Orders`.
3. Select the first master view object instance in the **Data Model** list
4. In the **Available View Objects** list, select the detail view object indented beneath the first master view object and enter the view object instance name in the **New Instance Name** field. Click **>** to shuttle it into data model as a detail of the existing `Customers` view object instance.
5. Select the second master view object instance in the **Data Model** list
6. In the **Available View Objects** list, select the detail view object indented beneath the second master view object and the **New Instance Name** field, enter the same view object instance name as the previously entered detail view object. Click **>** to shuttle it into data model as a detail of the existing `Orders` view object instance.

   An alert will appear: **An instance of a View Object with the name PaymentOptionsVO has already been used in the data model. Would you like to use the same instance?**
7. Click **Yes** to confirm you want the detail view object instance to *also* be the detail of the second view object instance.

How to Create a Master-Detail Hierarchy for Entity Objects Consisting of Transient-Only Attributes

When you link entity-based view objects to form master-detail hierarchies, the view objects and their respective entity usages are typically related by an association. At runtime, the association constructs an internal association view object that enables a query to be executed to enable the master-detail coordination. An exception to this scenario occurs when the entity object that participates in an association consists exclusively of nonpersistent attributes. This may occur when you define an entity object with transient attributes that you wish to populate programmatically at runtime. In this case, you can use the association overview editor that links the nonpersistent entity object to select an association view object to perform the query.

Before you begin:

It may be helpful to have an understanding of associations. For more information, see What Happens When You Create Entity Objects and Associations from Existing Tables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

- Create the entity-based view object for the nonpersistent entity object, as described in How to Create an Entity-Based View Object.
- Use the Create Association wizard to create an association between the nonpersistent entity object and a database-derived entity object. For details about creating an association, see Creating and Configuring Associations.

To customize an association for nonpersistent entity objects:

1. In the Applications window, double-click the association that you want to customize.
2. In the overview editor, click the **Tuning** navigation tab and then click the **Edit accessors** icon for the **Custom View Objects** section.
3. In the Custom Views dialog, select **Use Custom View Object** for the nonpersistent entity object.
4. In the **Select View Object** list, select the view object that you created based on the nonpersistent entity-object.
5. Click **OK**.

How to Find Rows of a Master View Object Using Row Finders

Row finders are objects that the application may use to locate specific rows within a row set using a view criteria. The row finder may be invoked on the master row set to match one or more criteria attributes supplied by the detail row set.

Currently, row finders that you define at design time can participate in these master-detail scenarios where non-row key attribute lookup is desired at runtime:

- When you expose the row finder in an ADF Business Components web service, the end user may initiate row updates on the specific rows of the master service view instance that match one or more row-finder mapped attribute values on the detail service view instance. For more information about this use case, see What You May Need to Know About View Criteria and Row Finder Usage.
- Programmatically, in the application, when you want to obtain a set of master view rows that match one or more row-finder mapped, non-key attribute values in the detail view instance. For more information about this use case, see Programmatically Invoking the Row Finder.

> **Note:**
>
> Row finders that you define on view objects are not currently supported by the ADF Business Components **data control** for use in a view project. Therefore row-finder mapped attributes of a view object that the application exposes as a collection in the **Data Controls panel** will not participate in row finder lookup operations.

The view criteria attributes defined by the view criteria can be any attribute that the detail view object defines and specifically need not be a row key attribute. For example, in a master-detail relationship, where `PersonVO` is the master view object and `AddressVO` is the detail view object, the attribute `EmailAddress` will locate the person row that matches the email address of the person in the `AddressVO` row set.

To create a row finder to locate rows of the master view object using criteria attributes supplied by the detail view object, perform the following steps:

1. Define an inline view criteria on the master view object to reference the detail view object and specify the criteria attributes as a view criteria items defined by bind variables.
2. Define an updatable transient attribute on the master view object to receive the value of each criteria attribute. At runtime, the transient attribute may be set programmatically or exposed in a web service payload to allow an end user to supply the criteria attribute value (for example, an email address).
3. Define the row finder on the master view object by selecting the view criteria and setting each criteria attribute's bind variable to a corresponding transient attribute from the master view object.

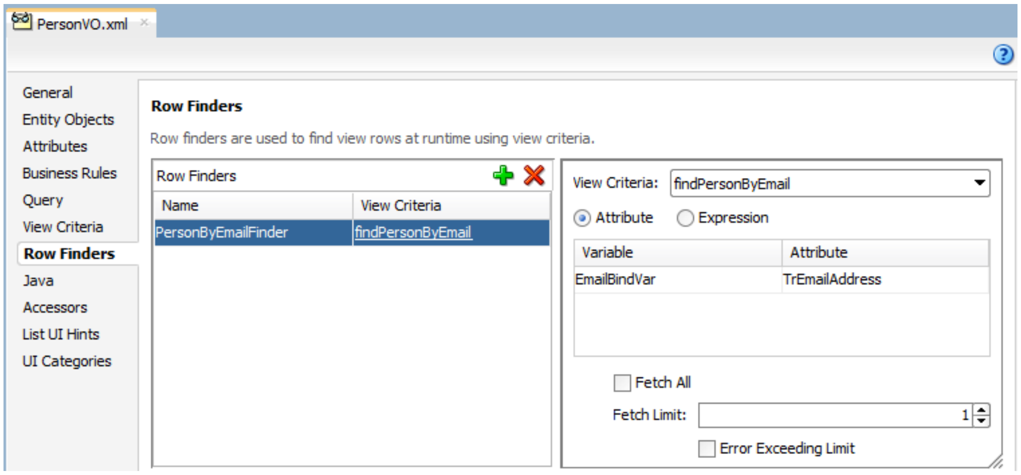
Defining a Row Finder on the Master View Object

Row finders that you define to filter the row set of a master view object are defined entirely on the master view object. The row finder matches the criteria attributes that you specified in the inline view criteria with values obtained at runtime. In order to receive the criteria attribute values, the master view object may define transient attributes that the application can set programmatically using row finder methods on the view object or that a web service payload may expose to receive end user-supplied values.

You use the Row Finders page of the master view object's overview editor to define the row finder. In the editor, you define a value source for each bind variable of the view criteria that you select. Attributes of the view object or attribute-value expressions are both valid sources for bind variables defined by the row finder.

Figure 6-10 shows the overview editor with a row finder that maps the view criteria bind variable `EmailBindVar` specified in the `findPersonByEmail` view criteria to the transient attribute `TrEmailAddress` defined by the master view object `PersonVO` as its value source.

Figure 6-10 View Object Overview Editor with Row Finder



Row Finders

Row finders are used to find view rows at runtime using view criteria.

Row Finders

Name	View Criteria
PersonByEmailFinder	findPersonByEmail

View Criteria: findPersonByEmail

● Attribute ○ Expression

Variable	Attribute
EmailBindVar	TrEmailAddress

□ Fetch All

Fetch Limit: 1

□ Error Exceeding Limit

> **Note:**
>
> You can also define row finders on view objects that do not participate in a master-detail hierarchy, as described in Working with Row Finders.

Before you begin:

It may be helpful to have an understanding of the row finder for master-detail view objects. For more information, see How to Find Rows of a Master View Object Using Row Finders.

It may be helpful to have an understanding of master-detail view objects. For more information, see About Master-Detail View Objects.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete these tasks:

- Create the desired master-detail view objects, as described in How to Create a Master-Detail Hierarchy Based on Entity Associations or How to Create a Master-Detail Hierarchy Based on View Objects Alone.
- Define an inline view criteria on the master view object, as described in Working with Master-Detail Related View Objects in View Criteria. The inline view criteria references the detail view object and specifies one or more detail attributes as view criteria items.
- Optionally, add updatable transient attributes to the master view object, as described in Adding Calculated and Transient Attributes to a View Object. The transient attribute may be set programmatically by the application or exposed in an ADF Business Components web service payload to solicit the value from an end user. The transient attributes must be defined as updatable to receive the criteria lookup value.

To create a row finder for a master view object:

1. In the Applications window, double-click the master view object that you want to customize with a new row finder.
2. In the overview editor, click the **Row Finders** navigation tab and then click the **Add Row Finder** button.
3. In the **Name** field, rename the row finder.

   For example, a row finder that you define to locate a person record by their email address, might be named `PersonByEmailFinder`.
4. Select the new row finder in the **Row Finders** list and then, in the **View Criteria** dropdown, select the view criteria that filters the view object row set.

   The desired row finder should appear highlighted, as shown in Figure 6-10. The view criteria list will be empty unless you have created a view criteria for the row finder to use.
5. When you want the end user of an ADF Business Components web service to supply a value, leave **Attribute** selected, select the bind variable from the list, and

then, in the **Attribute** dropdown, select the transient attribute from the master view object that supplies the bind variable value at runtime.

The transient attribute that you select will be used by the row finder to supply the criteria attribute value. For example, a PersonVO master view object that matches rows based on the email address in the AddressVO, might include a transient attribute that you define named TrEmailAddress.

Note: When you create the transient attribute in the overview editor for the view object, be sure to define the transient attribute as **Updatable** so it can receive the criteria lookup value.

6. Deselect **FetchAll** when you want to specify the number of rows that the row finder is allowed to match.

   When you enter a number of rows for **Fetch Limit**, you can also select **Error Exceeding Limit** to enable Oracle ADF to throw an exception when more matching rows exist in the database than the number you specify for **Fetch Limit**.

What Happens When You Create a Row Finder for a Master View Object

When you create a master view object row finder, the view object definition contains all the metadata required by the row finder, including the row finder definition itself. As the following example shows, the metadata for a row finder PersonByEmailFinder includes a bind variable EmailBindVar in the <Variable> element, a transient attribute TrEmailAddress in the <ViewAttribute> element, a view criteria findPersonByEmail and an inline view criteria AddressVONestedCriteria in the <ViewCriteria> element, and finally the row finder PersonByEmailFinder in the <RowFinders> element of the view object definition.

The row finder <VarAttributeMapping> subelement maps the view criteria bind variable EmailBindVar to the transient attribute TrEmailAddress of the master view object, which allows the end user to supply a value at runtime and allows the application to invoke the row finder with the required criteria attribute. The inline <ViewCriteriaItem> subelement sets the criteria attribute EmailAddress on the detail view object to the value of the bind variable.

At runtime, when the row finder is invoked on the master view object, one or more detail criteria attributes identify the matching rows in the master row set. In this example, the email address is used to match the person to which the email address belongs. The row finder locates the person record without the need to pass a row key value.

```
<ViewObject
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="PersonVO"
  SelectList="PersonEO.ID,
       PersonEO.FIRST_NAME
       PersonEO.LAST_NAME"
  FromList="PERSON PersonEO"
  ...
  <Variable
    Name="EmailBindVar"
    Kind="viewcriteria"
    Type="java.lang.String"/>
  <EntityUsage
    Name="PersonEO"
    Entity="model.entities.PersonEO"/>
    ...
  <ViewAttribute
    Name="TrEmailAddress"
    IsUpdateable="false"
    IsSelected="false"
    IsPersistent="false"
    PrecisionRule="true"

          Variable="EmailBindVar"
          Attribute="TrEmailAddress"/>
      </VarAttributeMap>
    </AttrValueRowFinder>
  </RowFinders>
</ViewObject>
```

Working with a Single Table in a Recursive Master-Detail Hierarchy

JDeveloper allows you to create a master-detail hierarchy based on a single view object when the source and target attribute exist in one table.

A recursive data model is one that utilizes a query that names source and destination attributes in a master-detail relationship based on a single table. In a typical master-detail relationship, the source attribute is supplied by the primary key attribute of the master view object and the destination attribute is supplied by foreign key attribute in the detail view object. For example, a typical master-detail relationship might relate the `DepartmentId` attribute on the `DEPARTMENT` table and the corresponding `DepartmentId` attribute on the `EMPLOYEE` table. However, in a recursive data model, the source attribute `EmployeeId` and the target attribute `ManagerId` both exist in the `EMPLOYEE` table. The query for this relationship therefore involves only a single view object. In this scenario, you create the view object for a single base entity object that specifies both attributes and then you define a self-referential view link to configure this view object as both the "source" and the "target" view object to form a master-detail hierarchy.

After you create the view link, there are two ways you can handle the recursive master-detail hierarchy in the data model project. You can either:

- Create a data model that exposes two instances of the same view object, one playing the role as master and the other playing the role as detail, actively coordinated by a view link instance. This can be useful when you anticipate needing to show a single level of master rows and detail rows at a time in two separate tables.
- Create a data model that exposes only a single instance of the view object, and use the view link accessor attribute in each row to access a row set of details. This is the more typical use case of the two because it allows you to display (or programmatically work with) the recursive master-detail hierarchy to any number of levels that exist in the data. For example, to show the recursive hierarchy in a `tree` or `treeTable` component, you would use this approach, as described in How to Display Master-Detail Objects in Trees.

How to Create a Recursive Master-Detail Hierarchy for an Entity-Based View Object

In a recursive master-detail hierarchy, the attributes of the view object that you select for the source and destination in the view link will typically be the same pair of attributes that define the self-referential association between the underlying entity object, if this association exists. While this underlying association is not required to create the view link, it does simplify the creation of the view link, so you will first create a foreign key association for the base entity object of the view object.

To create the recursive master-detail hierarchy:

1. Create an self-referential view link using the base entity object of the view object.
2. Expose the view object with a view criteria that will filter the view instance's results to include only those rows you want to see at the "root" of the hierarchy.

Creating an Association-Based, Self-Referential View Link

To create an association, you use the Create Association wizard. Then the association will appear as a selection choice when you use the Create View Link wizard. The view link will be self-referential because the association you select for the source and the destination view object names the *same* entity object, which is derived from a single database table.

Before you begin:

It may be helpful to have an understanding of the recursive data model. For more information, see Working with a Single Table in a Recursive Master-Detail Hierarchy.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

- When you create the view link JDeveloper won't be able to infer the association between the source and destination attributes of the entity object. To support the recursive hierarchy, you can use the Create Association wizard to create an association between the source attribute and the destination attribute. On the Entity Objects page, select the same entity object to specify the source and destination attributes and leave all other default selections unchanged in the wizard. For details about creating an association, see Creating and Configuring Associations.

  For example, assume the recursive master-detail hierarchy displays a list of employees based on their management hierarchy. In this scenario, you would create the association based on the `Employees` entity object. On the Entity Objects page of the Create Association wizard, you would select `Employees.EmployeeId` as the source attribute and `Employee.ManagerId` as the destination attribute. The entity object `Employees` supplies both attributes to ensure the association is self-referential.

To create an association-based, self-referential view link:

1. In the Applications window, right-click the project in which you want to create the view object and choose **New**.

   To avoid having to type in the package name in the Create View Link wizard, you can choose **New** and then **View Link** on the context menu of the **links** package node in the Applications window.

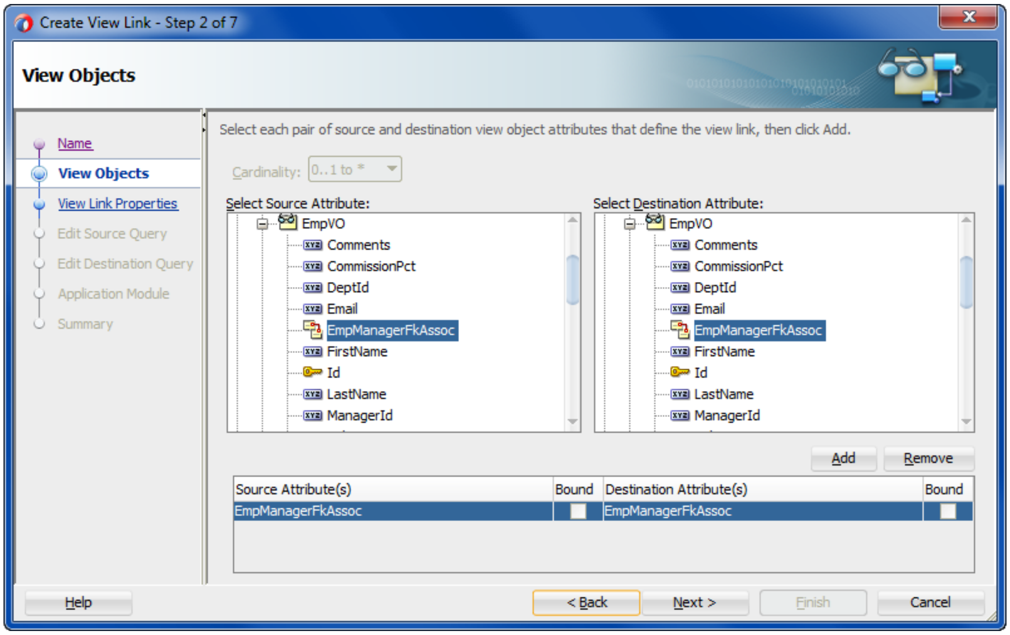
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **View Link**, and click **OK**.
3. In the Create View Link wizard, on the Name page, supply a package and a component name.
4. On the View Objects page, in the **Select Source Attribute** tree expand the source view object in the desired package. In the **Select Destination Attribute** tree expand the destination view object.

   For entity-based view objects, notice that in addition to the view object attributes, relevant associations also appear in the list.

5. Select the same association in both **Source** and **Destination** trees. Then click **Add** to add the association to the table below.

For example, Figure 6-11 shows the same `EmpManagersFkAssoc` association in both **Source** and **Destination** trees selected. The view link is self-referential because the definition of the association names the source and destination attribute on the *same* entity object (in this case, `Employees`).

Figure 6-11 Master and Detail Related by a Self-Referential Association Selection



Create View Link - Step 2 of 7

View Objects

Select each pair of source and destination view object attributes that define the view link, then click Add.

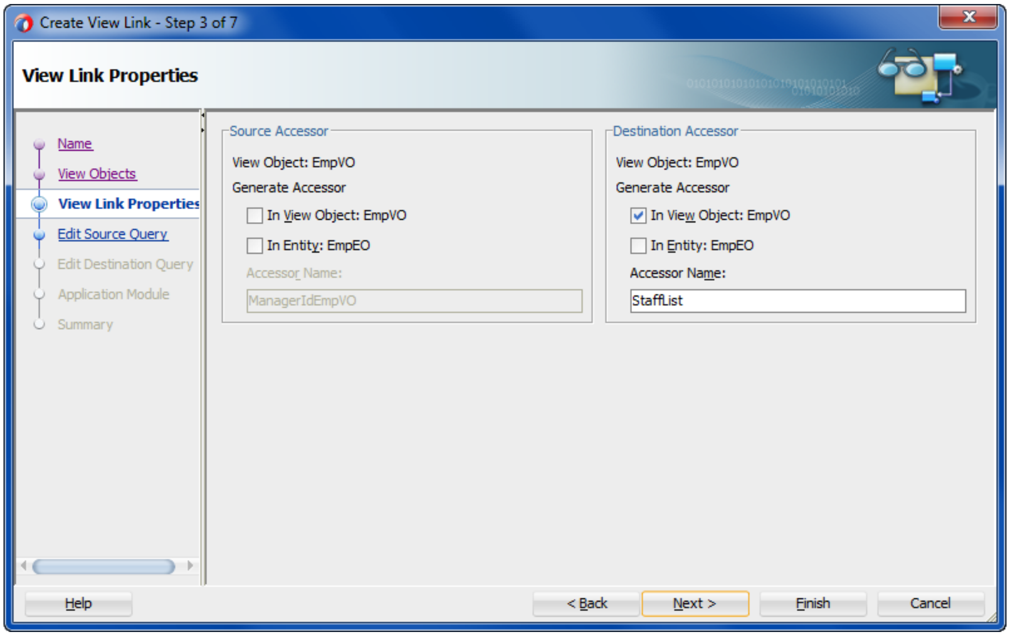
Cardinality: 0..1 to *

Source Attribute(s)	Bound	Destination Attribute(s)	Bound
EmpManagerFkAssoc	□	EmpManagerFkAssoc	□

6. On the View Link Properties page, leave the default selections unchanged, but edit the accessor name of the destination accessor to provide a meaningful name.

   For example, Figure 6-12 shows the destination accessor has been renamed from `EmployeesView` to `StaffList`. This name will be exposed in the binding editor when the user interface developer populates the ADF Faces tree component by selecting this accessor. The name you provide will make clear to the UI developer the purpose of the accessor; in this case, to generate a list of employees associated with each manager.

Figure 6-12 Renamed Destination Accessor in View LInk



Source Accessor

View Object: EmpVO

Generate Accessor

□ In View Object: EmpVO

□ In Entity: EmpEO

Accessor Name: ManagerIdEmpVO

Destination Accessor

View Object: EmpVO

Generate Accessor

☑ In View Object: EmpVO

□ In Entity: EmpEO

Accessor Name: StaffList

7. Click **Finish**.

Exposing the View Instance and Filter with a View Criteria

When you are ready to expose the view object in your project's data model, you will configure the view instance in the data model to use a view criteria to filter the initial value in the root of the tree. For example, assume the recursive master-detail hierarchy displays a list of employees based on their management hierarchy. In this scenario, you'll configure the view criteria's bind variable to specify the employee ID of the employee that you want to be the root value of the entire hierarchy. In this case, the root value of the recursive hierarchy of managers and employees would be the employee ID of the highest level manager in the organization.

Before you begin:

It may be helpful to have an understanding of the recursive data model. For more information, see Working with a Single Table in a Recursive Master-Detail Hierarchy.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for View Objects.

You will need to complete this task:

- Create the entity-based view object and create a view criteria that will filter the view instance's results to include only those rows you want to see at the "root" of the hierarchy. To create a view criteria that uses a bind variable to filter the view object, see Working with Named View Criteria.

  For example, in a recursive hierarchy of managers and employees, you would create the entity-based view object `EmployeesView`. After you create the view object in the Create View Object wizard, you can use the Query page of the overview editor to create a bind variable and view criteria which allow you to identify the employee or employees that will be seen at the top of the hierarchy.

If only a single employee should appear at the root of the hierarchy, then the view criteria in this scenario will filter the employees using a bind variable for the employee ID (corresponding to the source attribute) and the WHERE clause shown in the Create View Criteria dialog would look like `( (Employees.EMPLOYEE_ID = :TheEmployeeId ) )`, where `TheEmployeeId` is the bind variable name. For more information on creating a view criteria that uses a bind variable to filter the view object, see Creating a Data Source View Object to Control the Cascading List.

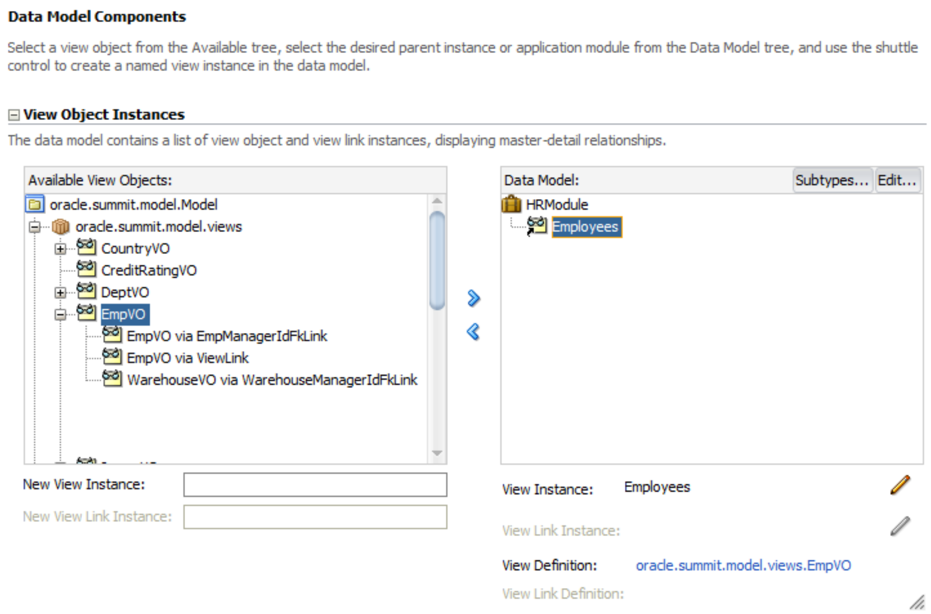
To define the view object instance in an existing application module:

1. In the Applications window, double-click the application module for which you want to define a new view instance.
2. In the overview editor, click the **Data Model** navigation tab.
3. In the Data Model page, expand the **View Object Instances** section and, in the **Available View Objects** list, select the view object definition that you defined the view criteria to filter.

   The **New View Instance** field below the list shows the name that will be used to identify the next instance of that view object that you add to the data model.
4. To change the name before adding it, enter a different name in the **New View Instance** field.
5. With the desired view object selected, shuttle the view object to the **Data Model** list.

   Figure 6-13 shows the view object `EmployeesView` has been renamed to `Employees` before it was shuttled to the **Data Model** list.

Figure 6-13 Data Model Displays Added View Object Instance



Data Model Components

Select a view object from the Available tree, select the desired parent instance or application module from the Data Model tree, and use the shuttle control to create a named view instance in the data model.

View Object Instances

The data model contains a list of view object and view link instances, displaying master-detail relationships.

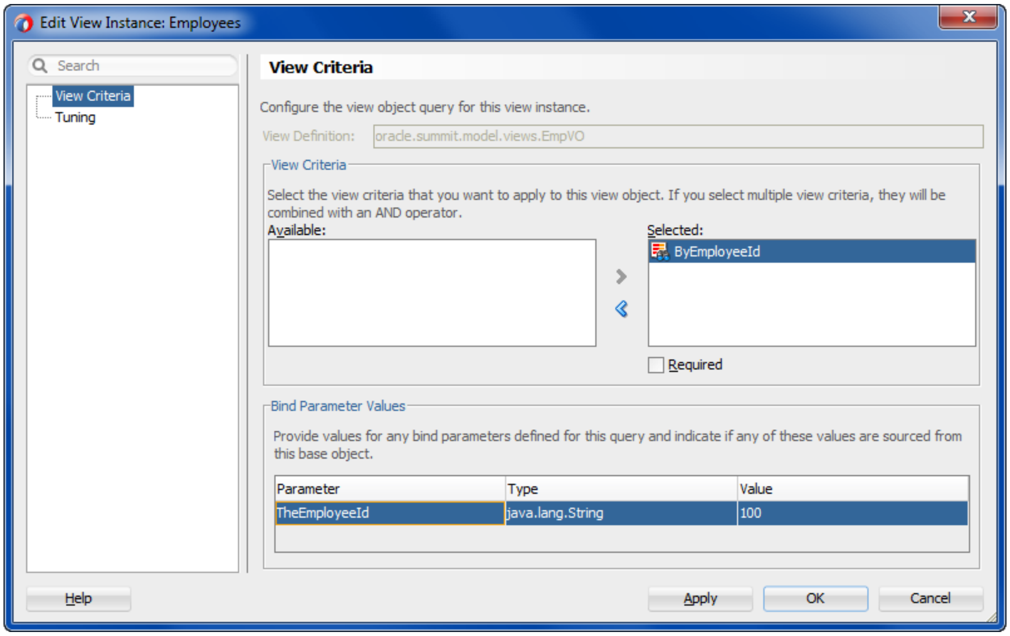
View Instance: Employees

View Definition: oracle.summit.model.views.EmpVO

6. To filter the view object instance so that you specify the root value of the hierarchy, select the view object instance you added and click **Edit**.
7. In the Edit View Instance dialog, shuttle the view criteria you created to the **Selected** list and enter the bind parameter value that corresponds to the root of the hierarchy.

Figure 6-14 shows the view object `ByEmployeeId` view criteria with the bind parameter `TheEmployeeId` set to the value `100` corresponding to the employee that is at the highest level of the hierarchy.

Figure 6-14 View Criteria Filters View Instance



View Criteria

Configure the view object query for this view instance.

View Definition: oracle.summit.model.views.EmpVO

View Criteria

Select the view criteria that you want to apply to this view object. If you select multiple view criteria, they will be combined with an AND operator.

Available:

Selected: ByEmployeeId

□ Required

Bind Parameter Values

Provide values for any bind parameters defined for this query and indicate if any of these values are sourced from this base object.

Parameter	Type	Value
TheEmployeeId	java.lang.String	100

8. Click **OK**.

What Happens When You Create a Recursive Master-Detail Hierarchy

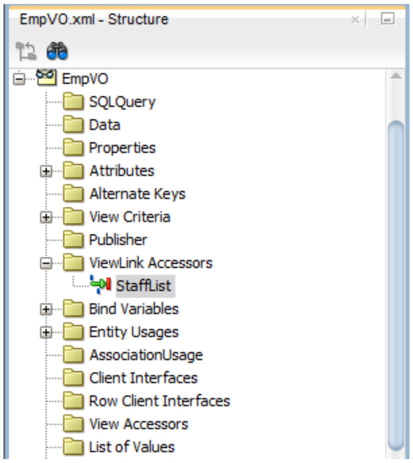
When you create an self-referential view link, JDeveloper creates the XML document file that represents its declarative settings and saves it in the directory that corresponds to the name of its package. This XML file contains the declarative information about the source and target attribute pairs that the association you selected specifies and contains the declarative information about the association that relates the source and target view object you selected.

The following example shows the `EmpManagerFkLink` defines the same view object `EmployeesView` for the source and destination in its XML document file.

```
<ViewLink
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="EmpManagerFkLink"
  EntityAssociation="test.model.EmpManagerFkAssoc">
  <ViewLinkDefEnd
    Name="EmployeesView1"
    Cardinality="1"
    Owner="test.model.EmployeesView"
    Source="true">
    <DesignTime>
      <Attr Name="_finderName" Value="ManagerIdEmployeesView"/>
      <Attr Name="_isUpdateable" Value="true"/>
    </DesignTime>
    <AttrArray Name="Attributes">
      <Item Value="test.model.EmployeesView.EmployeeId"/>
    </AttrArray>
  </ViewLinkDefEnd>
  <ViewLinkDefEnd
    Name="EmployeesView2"
    Cardinality="-1"
    Owner="test.model.EmployeesView">
    <DesignTime>
      <Attr Name="_finderName" Value="StaffList"/>
      <Attr Name="_isUpdateable" Value="true"/>
    </DesignTime>
    <AttrArray Name="Attributes">
      <Item Value="test.model.EmployeesView.ManagerId"/>
    </AttrArray>
  </ViewLinkDefEnd>
</ViewLink>
```

In addition to saving the view link component definition itself, JDeveloper also updates the XML definition of the view object to add information about the view link accessor you've defined. As a confirmation of this, you can select the view object in the Applications window and inspect its details in the Structure window. As shown in Figure 6-15, you can see the defined accessor under the **ViewLink Accessors** node for the `EmployeesView` view object of the `EmpManagerFkLink` view link.

Figure 6-15 View Object with View Link Accessor in the Structure Window



Working with Master-Detail Related View Objects in View Criteria

The ADF Business Components framework allows you to apply view criteria filters on master view objects using attributes of detail view objects.

View criteria provide a declarative way to define view object query filters that apply to the view object's own query. In certain cases you may need to filter the master view object using attributes of the detail view object. View criteria that involve master and detail view objects rely on the `EXISTS` operator and an inline view criteria to define the query filter. The `EXISTS` operator allows the inline view criteria to reference a detail view object and apply attributes that you select as criteria items. For example, a view criteria used in combination with a row finder can filter the master row set and locate specific rows in the row set using view criteria items from the detail view object.

You use the View Criteria page of the view object overview editor to define the view criteria on the master view object. For example, a view criteria `findPersonByEmail` that filters the rows in the master `PersonVO` using the `EmailAddress` attribute of the detail `AddressVO` might look similar to the one shown in the following example. In this example, the view criteria statement uses a bind variable `EmailBindVar` to obtain the value of the email attribute on the detail view object `AddressVO` at runtime.

```
( (EXISTS(SELECT 1 FROM ADDRESS AddressEONQ1 WHERE
    (UPPER(AddressEONQ1.EMAIL_ADDRESS LIKE UPPER (:EmailBindVar || '%') ) )
         AND
      (PersonEO.PERSON_ID = AddressEONQ1.PERSON_ID) ) ) )
```

Before you begin:

It may be helpful to have an understanding of the row finder that operates on a master view object. See How to Find Rows of a Master View Object Using Row Finders.

It may be helpful to have an understanding of view criteria. See Working with Named View Criteria.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See Additional Functionality for View Objects.

You will need to complete this task:

> Create the desired master-detail view objects, as described in How to Create a Master-Detail Hierarchy Based on Entity Associations or How to Create a Master-Detail Hierarchy Based on View Objects Alone.

To create an inline view criteria:

1. In the Applications window, double-click the master view object for which you want to customize with a new inline view criteria.

   The view object that you create the inline view criteria on must be a master view object in a master-detail hierarchy.

2. In the overview editor, click the **View Criteria** navigation tab and click the **Create New View Criteria** button.

3. In the Create View Criteria dialog, enter the name of the view criteria to identify its usage in your application.

   For example, to filter the person row set by an employee's email, you might specify a view criteria name like `findPersonByEmail`.

4. In the **Query Execution Mode** dropdown list, leave the default **Database** selected.

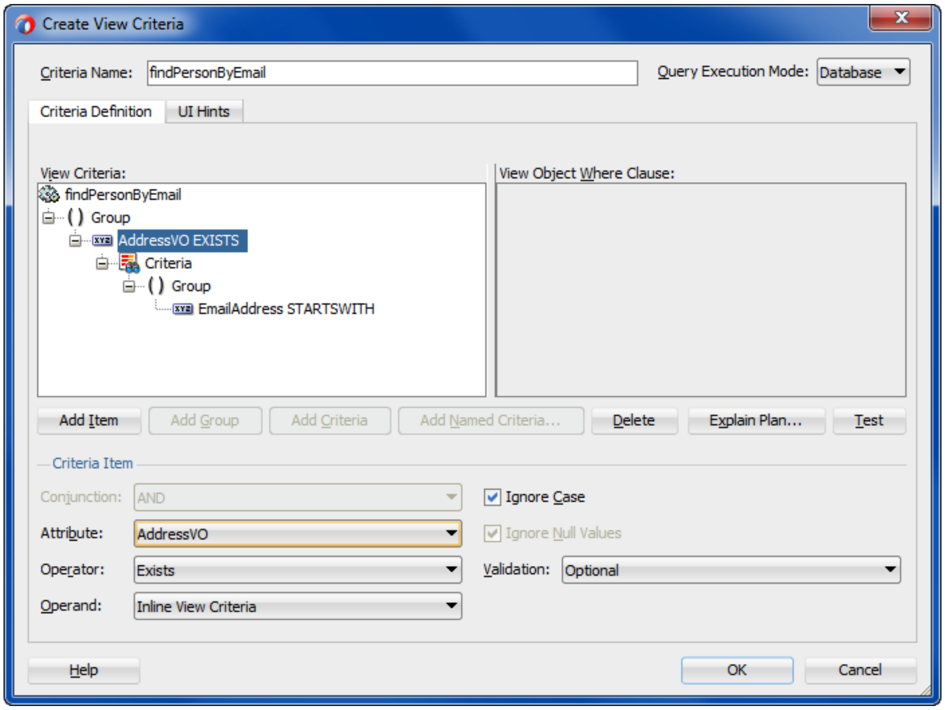
   The default mode allows the view criteria to filter the database table specified by the view object query.

5. In the Criteria Definition tab, click **Add Item** to define the view criteria.

6. In the view criteria hierarchy, select the unassigned view criteria item node beneath **Group** and, in the **Criteria Item** section, select the **Attribute** dropdown and select the detail view object from the list.

   When a view link exists for the current view object you are editing, you may select a detail view object to create a view criteria with a nested view criteria inline. The detail view object name will appear in the **Attribute** dropdown list. For example, `PersonVO` is linked to the `AddressVO` and a view criteria definition for findPersonByEmail filters the master view object PersonVO by attributes of the detail view object AddressVO, as shown in Figure 6-16.

Figure 6-16 Edit View Criteria Dialog with Inline View Criteria Specified



Criteria Name: findPersonByEmail

Query Execution Mode: Database

View Criteria:

```
findPersonByEmail
( ) Group
    AddressVO EXISTS
        Criteria
            ( ) Group
                EmailAddress STARTSWITH
```

Criteria Item

Conjunction: AND

☑ Ignore Case

Attribute: AddressVO

☑ Ignore Null Values

Operator: Exists

Validation: Optional

Operand: Inline View Criteria

7. Leave the default **Operator** and **Operand** selections unchanged.

   When you create an inline view criteria with a view object criteria item, the editor specifies the **Exists** operator and **Inline View Criteria** operand as the default choices. At runtime, the EXISTS operator tests for the presence of the attribute value in the detail view object and filter the rows in the master view object, as described in Working with Master-Detail Related View Objects in View Criteria.

8. In the view criteria hierarchy, select the new view criteria item node beneath **Group** and, in the **Criteria Item** section, enter the following:

   - In the **Attribute** dropdown, select the attribute from the detail view object that you want to filter by.

     The detail attribute is the attribute that will be used to filter the master view object. The value of this attribute can be supplied by the end user when a bind variable is defined for the criteria item.

   - In the **Operator** dropdown, select the desired filter operator.

   - In the **Operand** dropdown, select **Bind Variable** to specify the name of the bind variable for the detail attribute. If the variable was already defined for the view criteria, select it from the **Parameter** dropdown list. Otherwise, click **New** to display the New Variable dialog that lets you name a new bind variable on the view criteria.

     Note: When you select an existing bind variable from the dropdown list for use by the view criteria, do not select a bind variable that has been defined for the view object query (these will appear on the Query page of the overview editor). Select only bind variables that you define in the View Criteria page of the overview editor.

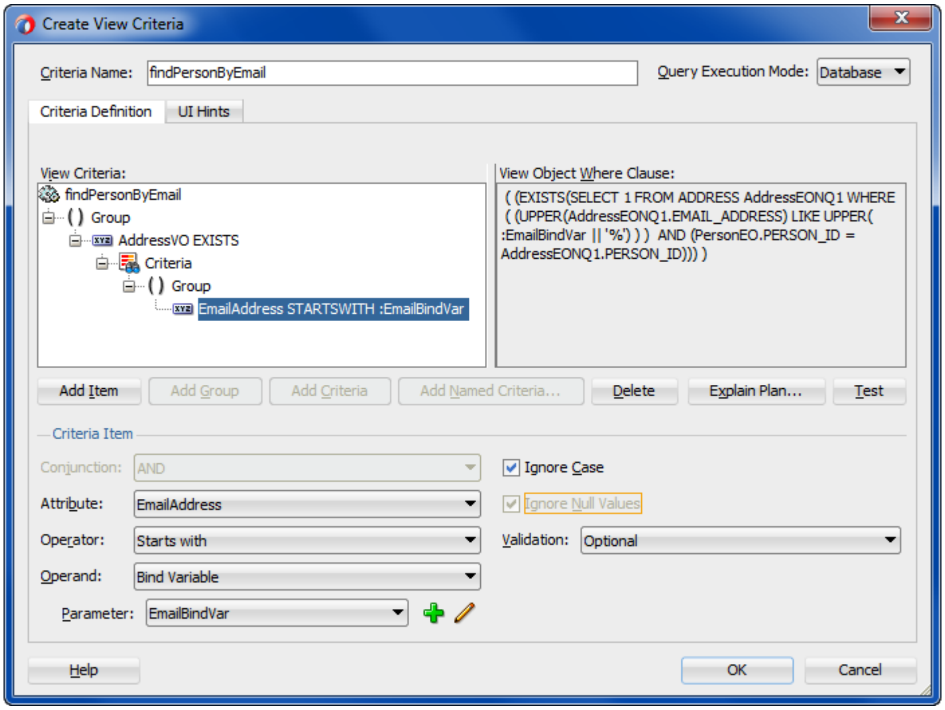
9. To disable case-sensitive filtering of the attribute based on the case of the runtime-supplied value, leave **Ignore Case** selected.

   This option is supported for attributes of type String only. The default disables case sensitive searches.

10. In the **Validation** dropdown list, leave the default **Optional** selected.

    Optional means the view criteria (or search field) is added to the `WHERE` clause only if the value is non-`NULL`. The default **Optional** for each new view criteria item means no exception will be generated for null values. For example, a `findPersonByEmail` view criteria definition filters the master view object `PersonVO` by the `Email` attribute of the detail view object `AddressVO`, and the value may be null, as shown in Figure 6-17.

Figure 6-17 Edit View Criteria Dialog with Bind Variable Criteria Item Specified



Criteria Name: findPersonByEmail

Query Execution Mode: Database

View Criteria:

findPersonByEmail
() Group
AddressVO EXISTS
Criteria
() Group
EmailAddress STARTSWITH :EmailBindVar

View Object Where Clause:

```
( (EXISTS(SELECT 1 FROM ADDRESS AddressEONQ1 WHERE
( (UPPER(AddressEONQ1.EMAIL_ADDRESS) LIKE UPPER(
:EmailBindVar || '%') ) )  AND (PersonEO.PERSON_ID =
AddressEONQ1.PERSON_ID))) )
```

Conjunction: AND

Attribute: EmailAddress

Operator: Starts with

Operand: Bind Variable

Parameter: EmailBindVar

☑ Ignore Case

☑ Ignore Null Values

Validation: Optional

11. Click **OK**.

12. In the View Criteria page of the overview editor, select the bind variable and in the **Details** section, leave the default settings unchanged:

    - Leave **Literal** selected but do not supply a default value. The value will be obtained from the end user at runtime.
    - Leave **Updatable** selected to allow the bind variable value to be defined through the user interface.

13. In the View Criteria page, click the **UI Hints** tab and specify hints like **Label**, **Format Type**, **Format** mask, and others.

    The view layer will use bind variable UI hints when you build user interfaces like search pages that allow the user to enter values for the named bind variables.

Note that formats are only supported for bind variables defined by the `Date` type or any numeric data type.

7
Defining Polymorphic View Objects

This chapter describes how to use inheritance in ADF Business Components to create an ADF view object that exposes multiple view row types in an Oracle ADF application. As an alternative to working with entity object inheritance, this chapter also describes how to define a view object inheritance hierarchy to generate heterogeneous view rows.
This chapter includes the following sections:

About Polymorphic View Objects

ADF Business Components allows you to work with polymorphic view objects that are based on entity objects with inherited attributes from an inheritance hierarchy. A polymorphic view object has a heterogeneous row set.

The **view object** lets you create a table represented by its base **entity object**. Typically, when you create the entity-based view object, you create it to work with entity rows of a single type like `Domestics`, which perhaps include specific attributes that pertain to domestic customers. At other times you may want to query and update rows based on an entity object inheritance hierarchy in the same row set. For example, in the same row set, you might work with attributes that are common to the inheritance hierarchy of `Customers`, `Domestics`, *and* `Internationals` entity objects, where `Domestics` and `Internationals` are subtype entity objects of the parent `Customers` entity object. Such a view object is called a **polymorphic view object**. For a client to properly use the polymorphic view object, the view object must know which entity object to delegate to for each row in its heterogeneous row set. To identify the row type, the polymorphic view object relies on a discriminator attribute to identify each row's corresponding table.

ADF Business Component supports these types of polymorphism:

- The entity object defines polymorphic subtypes, but the view object does not.

  This is useful when the backend business logic needs to be aware of the different types but the presentation layer needs to treat view instances as a single type. In this case, the view instance will contain the common set of attributes defined by the entity subtypes.

- Both the entity object and the view object usages define polymorphic subtypes.

  In this case, both the backend business logic and the presentation layer need to distinguish between the various subtypes.

- The entity object does not define polymorphic subtypes, but the view object usages do define polymorphic subtypes.

  In this case, the presentation layer needs to distinguish between the view subtypes, but the backend business logic is not unique.

When you create polymorphic view object based on inheritance of entity subtypes, the various entity subtypes are not exposed to the client. As far as the client is concerned, every row in the view object's result set has the same set of attributes and the same row type. This is accomplished because ADF Business Components ensures that the correct entity object row subtype is created based on the value of the discriminator attribute. In other words, with a polymorphic entity usage, only the entity row parts of a view row can change type, while the view row type is constant.

Whereas, when you create polymorphic view object based on the inheritance defined by a view object hierarchy (not entity subtypes), you configure the application module to allow one or more view row subtypes in the result. Only polymorphic view rows produce different subtypes of client-visible view row types. And, unlike view objects derived from polymorphic entity usages, only polymorphic view rows allow you to expose view row subtypes to the client with additional attributes.

> **Note:**
>
> To experiment with the examples that demonstrate the concept in this chapter, use the `SummitADF_Examples` workspace, as described in Running the Standalone Samples from the SummitADF_Examples Workspace. For information about how to obtain and install the Summit ADF standalone sample applications, see Setting Up the Summit Sample Applications for Oracle ADF.

Polymorphic Entity Usages and Polymorphic View Rows Usages

You can work with either type of polymorphism, or you can combine the two.

While often even more useful when used *together*, the view row polymorphism and the polymorphic entity usage features are distinct and can be used separately. In particular, the view row polymorphism feature can be used for read-only view objects, as well as for entity-based view objects. When you combine both mechanisms, you can have both the entity row part being polymorphic, as well as the view row type.

Note to use view row polymorphism with either view objects or entity objects, you must configure the discriminator attribute property separately for each. This is necessary because read-only view objects contain no related entity usages from which to infer the discriminator information.

A limitation exists when defining polymorphic view objects that requires view objects with discriminator attributes to be defined no more than one level deep. Your project may define a polymorphic view object with discriminator attributes to specify the row subtypes, but using another view object to specify further subrows based on the first polymorphic view object will cause the display of subrows to fail. When creating polymorphic view objects, limit the discriminator attribute definition to one level.

In summary, to create a view object with a polymorphic entity usage:

1. Configure an attribute to be the discriminator at the entity object level in the root entity object in an inheritance hierarchy.
2. Define a hierarchy of inherited entity objects, each of which overrides and provides a distinct value for the Subtype Value property of that entity object level discriminator attribute.
3. List the subclassed entity objects in a view object's list of subtypes.
4. Update the application module to expose the entity-based subtype view objects in this hierarchy in the application module's list of subtypes.

Whereas, to work with view row polymorphism:

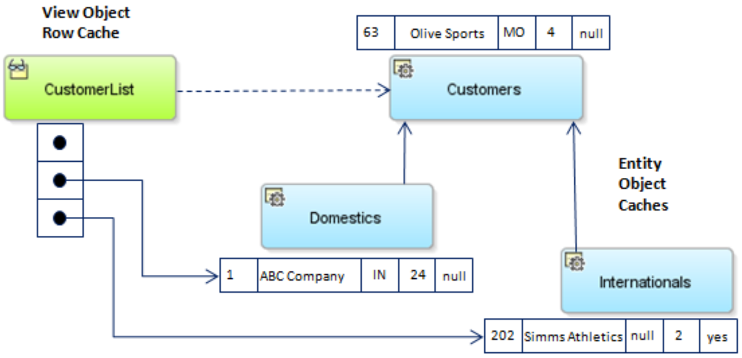
1. Configure an attribute to be the discriminator at the view object level in the base view object in an inheritance hierarchy.
2. Define a hierarchy of inherited view objects each of which provides a distinct value for the Subtype Value property of that discriminator attribute at the view object level (identified as `DefaultValue` for the attribute in the view object definition file).
3. Update the application module to expose the subclassed view objects in this hierarchy in the application module's list of subtypes.

Working with Polymorphic Entity Usages

You can use an ADF view object with a polymorphic entity usage to create a heterogeneous row set based on a base entity object and its subtypes as well.

A *polymorphic* entity usage is one that references a base entity object in an inheritance hierarchy and is configured to handle *subtypes* of that entity as well. Figure 7-1 shows the results of using a view object with a polymorphic entity usage. The entity-based `CustomerList` view object has the `Customers` entity object as its primary entity usage. The view object partitions each row retrieved from the database into an entity row with attributes specific to the various subtypes of `Customers`. It creates the appropriate entity row subtype based on consulting the value of the discriminator attribute. For example, if the `CustomerList` query retrieves one row for domestic company `ABC Company` and one row for international company `Simms Athletics`, the underlying entity rows would be as shown in the figure.

Figure 7-1 View Object with a Polymorphic Entity Usage Handles Entity Subtypes



> **Note:**
>
> The example in this section refers to the `oracle.summit.model.polymorphic` package in the `SummitADF_Examples` application workspace.

How to Create a Subtype View Object with a Polymorphic Entity Usage

The view object that you create with a polymorphic entity usage may inherit one or more of the attributes of the base entity object and the entity subtypes. Attributes that you select from the entity objects will be overridden by the view object attribute definitions. When an entity-based view object references an entity object with a discriminator attribute, then Oracle ADF enforces that the discriminator attribute is included in the query (in addition to the primary key attribute).

Before you begin:

It may be helpful to have an understanding of polymorphic view objects (also called in this section, subtype view objects). For more information, see About Polymorphic View Objects.

You will need to complete these tasks:

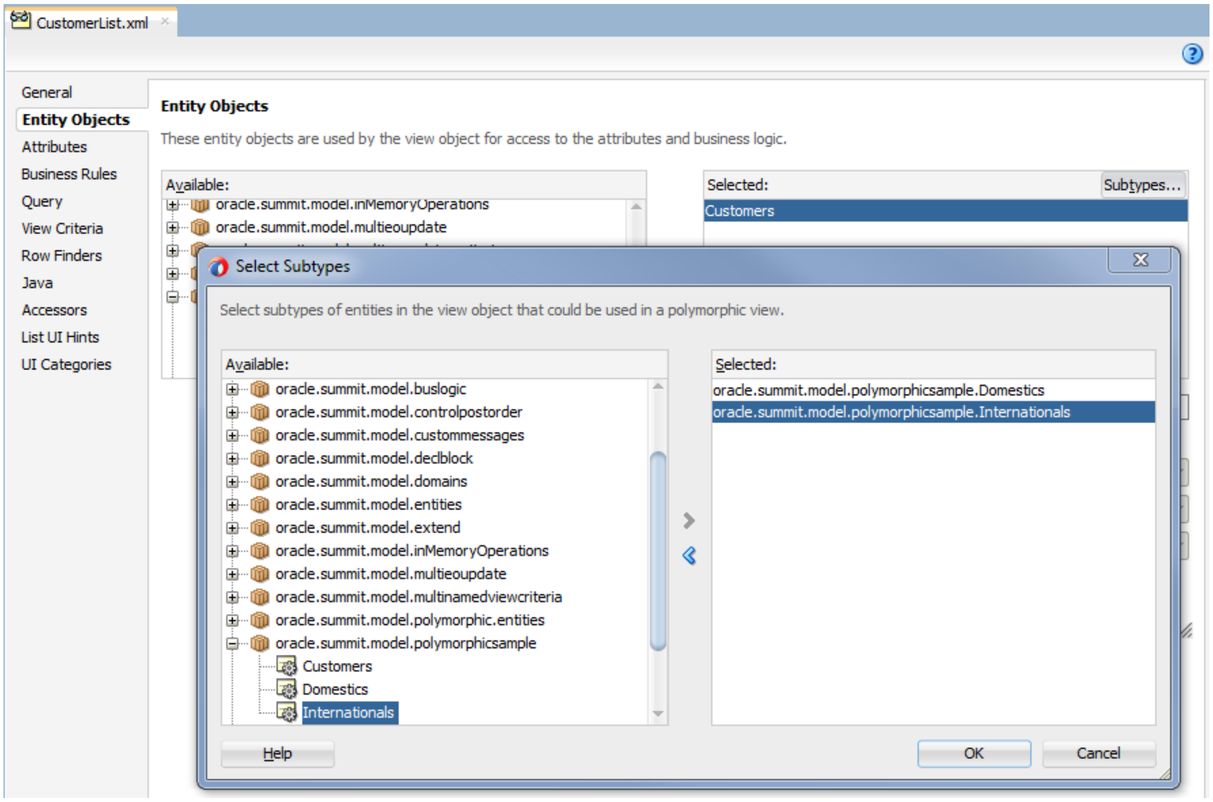
1. Create the base entity object and entity subtypes upon which the view objects will be based. For details about creating base entity objects and entity subtypes, see How to Create Entity Objects in an Inheritance Hierarchy.
2. Create an entity-based view object from the base entity object and select the attributes that are common to the subtype view objects. The base view object must contain the superset of attributes represented by each subtype view object. For details about creating an entity-based view object, see How to Create an Entity-Based View Object.
3. In the base view object that you create, select the entity subtype corresponding to each subtype view object that you will create. JDeveloper limits the subtype view objects that you may create to the polymorphic entity usage selections you make.

   To select entity subtypes in the base view object:

   a. Open the base view object in the overview editor and click the **Entity Objects** navigation tab.
   b. In the Entity Objects page, click **Subtypes** and in the Select Subtypes dialog, add the entity subtypes to the **Selected** list.

   For example, as Figure 7-2 shows, the entity subtype `Domestics` and `Internationals` have been selected to anticipate creating subtype view objects for each.

Figure 7-2 Entity Subtypes Define Possible Subtype View Objects



Entity Objects

These entity objects are used by the view object for access to the attributes and business logic.

Available:
oracle.summit.model.inMemoryOperations
oracle.summit.model.multieoupdate

Selected:
Customers

Select subtypes of entities in the view object that could be used in a polymorphic view.

Available:
oracle.summit.model.buslogic
oracle.summit.model.controlpostorder
oracle.summit.model.custommessages
oracle.summit.model.declblock
oracle.summit.model.domains
oracle.summit.model.entities
oracle.summit.model.extend
oracle.summit.model.inMemoryOperations
oracle.summit.model.multieoupdate
oracle.summit.model.multinamedviewcriteria
oracle.summit.model.polymorphic.entities
oracle.summit.model.polymorphicsample
Customers
Domestics
Internationals

Selected:
oracle.summit.model.polymorphicsample.Domestics
oracle.summit.model.polymorphicsample.Internationals

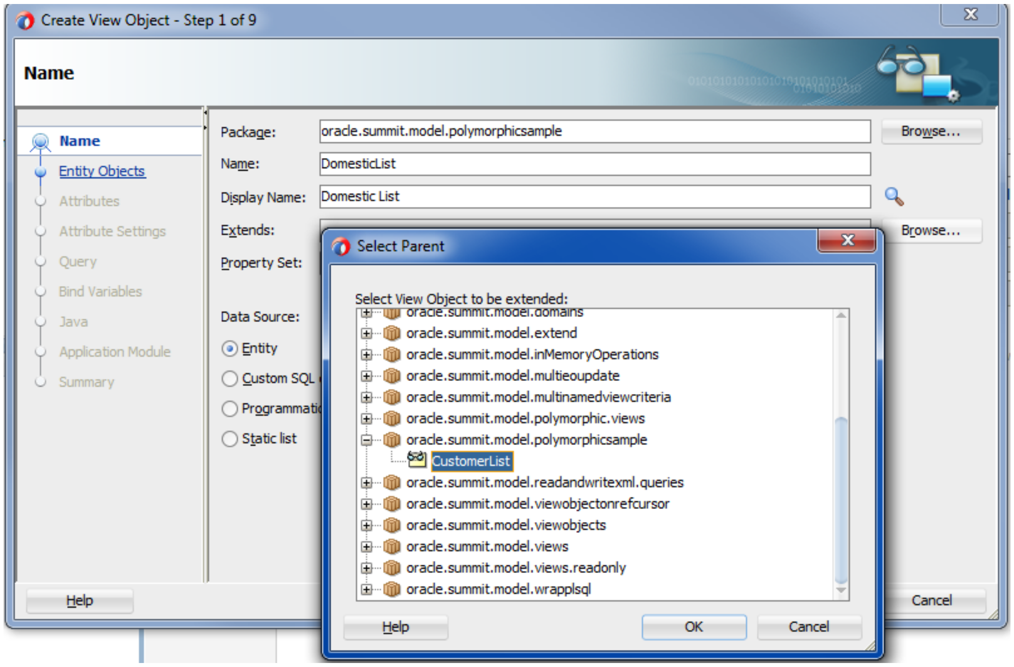
To create a subtype view object with a polymorphic entity usage:

1. In the Applications window, right-click your data model project and choose **New** and then **View Object**.
2. In the Create View Object wizard, name the subtype view object and then next to the **Extends** field, click **Browse**.

   For example, you might name the subtype view object `DomesticList` or `InternationalList` when the subtype view object extends a base view object `CustomerList`. In this case, the data model project would define a base `Customers` entity object in order to support the creation of subtype view objects with polymorphic entity usages for the `Domestics` and `Internationals` subtype entity objects.
3. In the Select Parent dialog, select the entity-based view object that you wish to extend and click **OK**.

   The view object you select is the base view object which defines the superset of attributes and is the view object that the subtype view object extends. For example, you select the base view object `CustomerList` to extend when you want to create the subtype view object `DomesticList`, as shown in Figure 7-3.

Figure 7-3 Subtype View Object Extends Base View Object



Package: oracle.summit.model.polymorphicsample

Name: DomesticList

Display Name: Domestic List

Extends:

Property Set:

Data Source:

● Entity

○ Custom SQL

○ Programmatic

○ Static list

Select View Object to be extended:

- oracle.summit.model.domains
- oracle.summit.model.extend
- oracle.summit.model.inMemoryOperations
- oracle.summit.model.multieoupdate
- oracle.summit.model.multinamedviewcriteria
- oracle.summit.model.polymorphic.views
- oracle.summit.model.polymorphicsample
  - CustomerList
- oracle.summit.model.readandwritexml.queries
- oracle.summit.model.viewobjectonrefcursor
- oracle.summit.model.viewobjects
- oracle.summit.model.views
- oracle.summit.model.views.readonly
- oracle.summit.model.wrapplsql

4. In the Create View Object wizard, make sure that **Entity** is selected as the data source and click **Next**.

5. In the Entity Objects page, in the **Available** list, locate the entity subtype that you want to define as the polymorphic entity usage for the subtype view object and click **Add**.

   The list of available entity subtypes is defined in the inheritance hierarchy of the base entity object, as explained in the prerequisites for this procedure. For example, when you create the subtype view object `DomesticList` for the base view object `CustomerList`, you would add `Domestics` as the entity subtype from the **Available** list, as shown in Figure 7-4.

☑ Updatable ☐ Reference

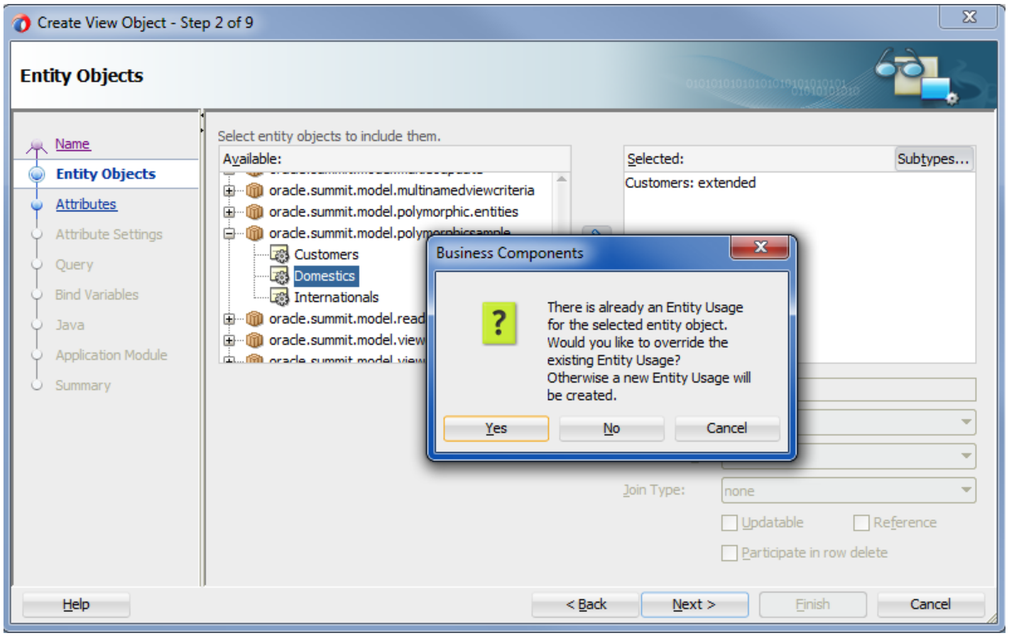
☑ Participate in row delete

6. In the Business Components dialog, click **Yes** to override the entity usage for your subtype view object with the desired polymorphic entity usage.

The Business Components dialog warns you that you will override the attributes of the base entity usage with the entity subtype, as shown in Figure 7-5.

Note that clicking **No** in the dialog will add an additional usage without overriding the attributes of the base entity usage. Normally, you click **Yes** to override the base entity usage with the desired entity subtype.

Figure 7-5 Polymorphic Entity Usage Overrides Subtype View Object



There is already an Entity Usage for the selected entity object. Would you like to override the existing Entity Usage? Otherwise a new Entity Usage will be created.

Join Type: none

☐ Updatable ☐ Reference

☐ Participate in row delete

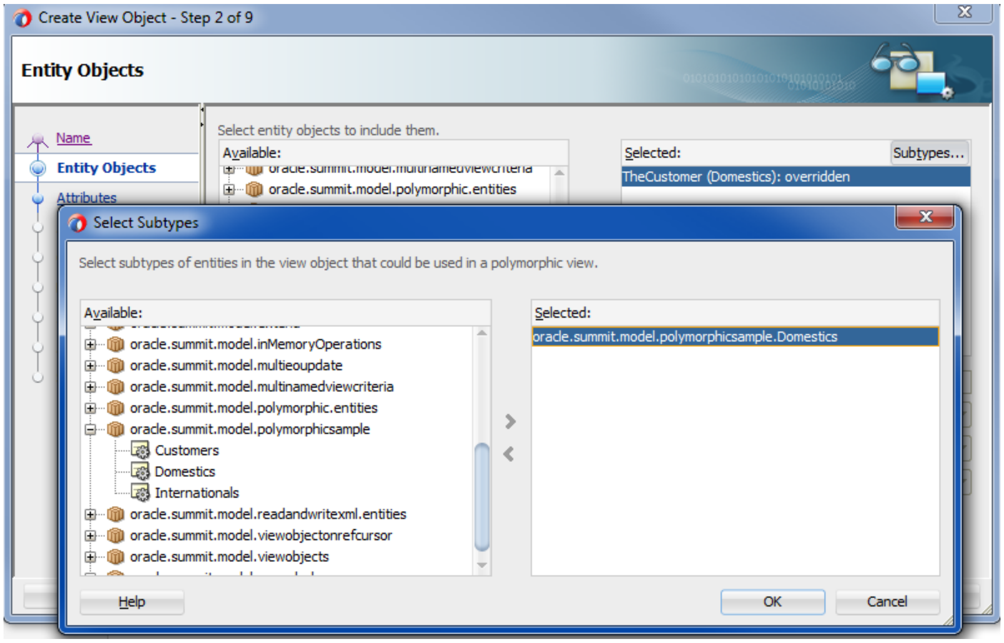
7. In the **Selected** list, select the overridden entity usage and click **Subtypes**.

8. In the Select Subtypes dialog, use the shuttle buttons to leave only the desired polymorphic entity subtype in the **Selected** list and click **OK**.

   The Select Subtypes dialog lets you specify the entity subtype to be referenced by the usages you have defined in the Entity Objects page of the Create View Object wizard. The list of available entity subtypes is defined by the base view object, as explained in the prerequisites for this procedure. Normally, you will pick the same entity subtype as the one you choose to override (as shown in Figure 7-5).

   For example, when you create the subtype view object `DomesticList`, you would select `Domestics` as the single entity subtype of the base entity object `Customers` (and deselect `Internationals` from the **Selected** list), as shown in Figure 7-6.

Figure 7-6 Subtype View Object with a Single Polymorphic Entity Usage Applied



Create View Object - Step 2 of 9

Entity Objects

Select entity objects to include them.

Available:
- oracle.summit.model.polymorphic.entities

Selected:
- TheCustomer (Domestics): overridden

Select Subtypes

Select subtypes of entities in the view object that could be used in a polymorphic view.

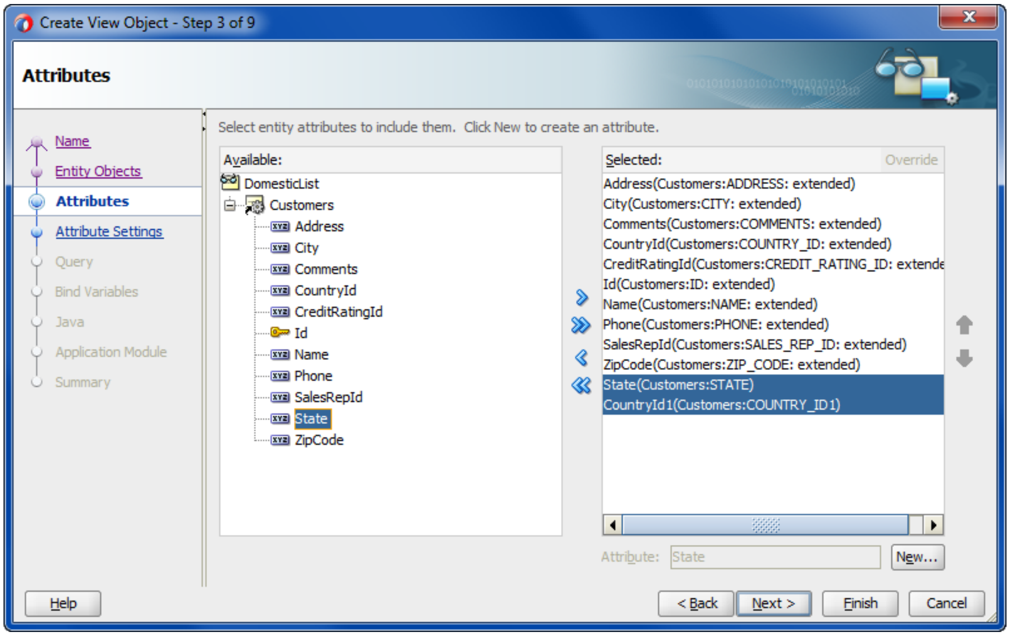
Available:
- oracle.summit.model.inMemoryOperations
- oracle.summit.model.multieoupdate
- oracle.summit.model.multinamedviewcriteria
- oracle.summit.model.polymorphic.entities
- oracle.summit.model.polymorphicsample
  - Customers
  - Domestics
  - Internationals
- oracle.summit.model.readandwritexml.entities
- oracle.summit.model.viewobjectonrefcursor
- oracle.summit.model.viewobjects

Selected:
- oracle.summit.model.polymorphicsample.Domestics

9. In the Create View Object wizard, in the Entity Objects page, click **Next** and on the Attributes page of the wizard, shuttle the desired attributes from the entity subtype to the **Selected** list.

   For example, for the `DomesticList` view object you would select the `State` attribute from the entity subtype `Domestics`, as shown in Figure 7-7.

Figure 7-7 View Object with a Entity Subtype Attribute Addition



Select entity attributes to include them. Click New to create an attribute.

Selected:

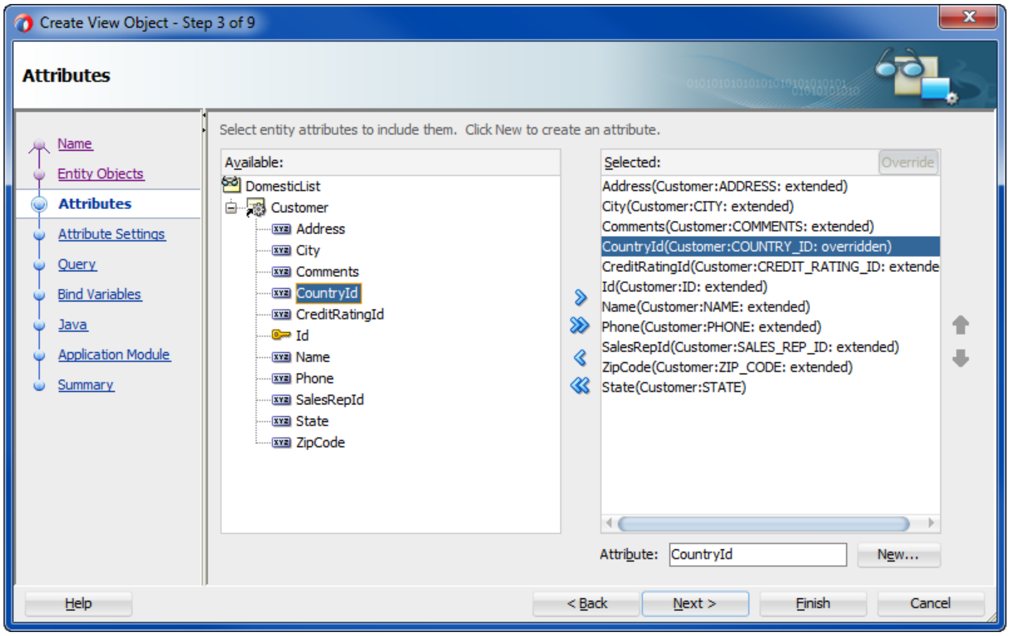
Address(Customers:ADDRESS: extended)
City(Customers:CITY: extended)
Comments(Customers:COMMENTS: extended)
CountryId(Customers:COUNTRY_ID: extended)
CreditRatingId(Customers:CREDIT_RATING_ID: extende
Id(Customers:ID: extended)
Name(Customers:NAME: extended)
Phone(Customers:PHONE: extended)
SalesRepId(Customers:SALES_REP_ID: extended)
ZipCode(Customers:ZIP_CODE: extended)
State(Customers:STATE)
CountryId1(Customers:COUNTRY_ID1)

Attribute: State

10. In the Attributes page, remove the primary key attribute so the extended view object defines a single primary key attribute and then select the discriminator attribute and click **Override** and click **Next**.

    For example, for the `DomesticList` view object you would remove the `CountryId` attribute from the subtype view object's selected list and override the `CountryId` attribute, as shown in Figure 7-8.

Figure 7-8 View Object with the Overridden Discriminator Attribute



Select entity attributes to include them. Click New to create an attribute.

Selected:

Address(Customer:ADDRESS: extended)
City(Customer:CITY: extended)
Comments(Customer:COMMENTS: extended)
CountryId(Customer:COUNTRY_ID: overridden)
CreditRatingId(Customer:CREDIT_RATING_ID: extende
Id(Customer:ID: extended)
Name(Customer:NAME: extended)
Phone(Customer:PHONE: extended)
SalesRepId(Customer:SALES_REP_ID: extended)
ZipCode(Customer:ZIP_CODE: extended)
State(Customer:STATE)

Attribute: CountryId

11. In the Attributes Settings page, select the discriminator attribute from the dropdown and enter the **Default Value** that defines the subtype and click **Finish** to complete the wizard.

For example, for the `DomesticList` view object you would enter `DOMESTIC`, as shown in Figure 7-9.

12. Repeat this procedure to create additional subtype view objects with unique polymorphic entity usages.

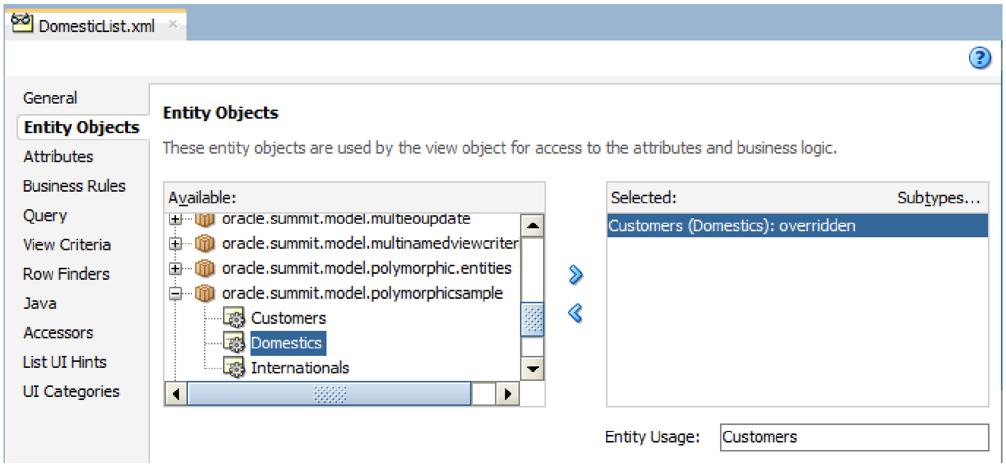
    For example, the `InternationalList` view object is a second subtype that extends `CustomerList`. It supplies the value `INTERNATIONAL` for the `CustomerTypeCode` discriminator attribute.

After creating the subtype view object, you must define the list of subtypes that participate in the view object polymorphism, as described in Updating the Application Module to Expose Subtype Usages. For example, the `CustomersModule` application module with view instance `CustomerList1` must be configured to name the subtype view objects `DomesticList` and `InternationalList`.

What Happens When You Create a Subtype View Object with a Polymorphic Entity Usage

The Entity Objects page of the overview editor identifies the selected entity object with the entity usage override. For example, the overview editor for the `DomesticList` view object identifies the overridden entity usage `Customers (Domestics): overridden` with the overriding subtype in parenthesis, as shown in Figure 7-10.

Figure 7-10 View Object Editor Shows Entity Usage is Overridden



Entity Objects

These entity objects are used by the view object for access to the attributes and business logic.

Customers (Domestics): overridden

Entity Usage: Customers

When you create an entity-based view object with a polymorphic entity usage, JDeveloper adds information about the allowed entity subtypes to the base view object's XML document. For example, when creating the `CustomerList` view object, the names of the allowed subtype entity objects are recorded in an `<AttrArray>` tag. The XML property `DiscrColumn` identifies `CountryTypeCode` as the base view object's polymorphic discriminator attribute like this:

```
<ViewObject Name="CustomerList" ... >
  <EntityUsage
    Name="Customers"
    Entity="oracle.summit.model.polymorphics.entities.Customers" >
  </EntityUsage>
  <AttrArray Name="EntityImports">
    <Item Value="oracle.summit.model.polymorphic.entities.Domestics" />
    <Item Value="oracle.summit.model.polymorphic.entities.Internationals" />
  </AttrArray>
...
  <ViewAttribute
    Name="CountryTypeCode"
    PrecisionRule="true"
    EntityAttrName="CountryTypeCode"
    EntityUsage="Customers"
    AliasName="COUNTRY_TYPE_CODE"
    DiscrColumn="true">
  </ViewAttribute>
   ...
</ViewObject>
```

Then, when you create a subtype view object with a polymorphic entity usage, JDeveloper adds information about the base view object to the subtype view object's XML document. For example, The following example shows the `DomesticList` subtype view object with the name of the base view object recorded in the `Extends` property. The XML property `DiscrColumn` identifies the overridden `CountryTypeCode` attribute as the polymorphic discriminator attribute, with a subtype value of `DOMESTIC`. Only the additional attribute `State`, specific to the subtype view object, appears in the XML document.

```
<ViewObject
  Name="DomesticList"
  Extends="oracle.summit.model.polymorphic.views.CustomerList"
  ...>
  <EntityUsage
    Name="Customers"
    Entity="oracle.summit.model.polymorphic.entities.Domestics"/>
  <AttrArray Name="EntityImports">
    <Item Value="oracle.summit.model.polymorphicsample.Domestics"/>
  </AttrArray>
  <ViewAttribute
    Name="CountryTypeCode"
    PrecisionRule="true"
    DiscrColumn="true"
    EntityAttrName="CountryTypeCode"
    EntityUsage="Customers"
    AliasName="COUNTRY_TYPE_CODE"
    DefaultValue="DOMESTIC">
    <DesignTime>
      <Attr Name="_OverrideAttr" Value="true"/>
    </DesignTime>
  </ViewAttribute>
  <ViewAttribute
    Name="State"
    PrecisionRule="true"
    EntityAttrName="State"
    EntityUsage="Customers"
    AliasName="STATE"/>
</ViewObject>
```

Similarly, the XML document for the `InternationalList` subtype view object names the same `CustomerList` base view object in the `Extends` property of its XML document, but defines the polymorphic discriminator attribute with a subtype value of `INTERNATIONAL` and the additional attribute `Language` specific to its subtype like this:

```
<ViewObject
  Name="InternationalList"
  Extends="oracle.summit.model.polymorphic.views.CustomerList"
  ... >
  <EntityUsage
     Name="Customers"
     Entity="oracle.summit.model.polymorphic.entities.Internationals"/>
  <AttrArray Name="EntityImports">
    <Item Value="oracle.summit.model.polymorphicsample.Internationals"/>
  </AttrArray>
  <ViewAttribute
    Name="CountryTypeCode"
    PrecisionRule="true"
    DiscrColumn="true"
    EntityAttrName="CountryTypeCode"
    EntityUsage="Customers"
    AliasName="COUNTRY_TYPE_CODE"
    DefaultValue="INTERNATIONAL">
    <DesignTime>
      <Attr Name="_OverrideAttr" Value="true"/>
    </DesignTime>
  </ViewAttribute>
  <ViewAttribute
    Name="Language"
    PrecisionRule="true"
    EntityAttrName="Language"
    EntityUsage="Customers"
    AliasName="LANGUAGE"/>
</ViewObject>
```

Note the <AttrArray> tag in the subtype view object definition identifies the allowed entity object for each subtype. Each subtype view object should therefore name a single subtype entity object. If the <AttrArray> tag of a subtype view object definition names more than one entity object, you may remove the unused one. This situation arises when using the Create View Object wizard to create the subtype view object but not reducing the list of default subtype entity objects in the Select Subtypes dialog, as shown in Figure 7-6. By default the dialog makes all subtype entity objects selected.

What You May Need to Know About Polymorphic Entity Usages

When you derive view objects from polymorphic entity usages, you will want to follow these best practices to allow the discriminator attribute to filter the query to only contain the expected subtypes.

Your Query Must Limit Rows to Expected Entity Subtypes

If your view object expects to work with only a *subset* of the available entity subtypes in a hierarchy, you need to include an appropriate WHERE clause that limits the query to only return rows whose discriminator column matches the expected entity type. You should not rely solely on the discriminator attribute to perform subtype filtering in the query. Without the addition of attributes to limit the query, the view object will effectively query all rows and cause the client to discard rows that do not match any discriminator values.

Exposing Selected Entity Methods in View Rows Using Delegation

By design, clients do not work directly with entity objects. Instead, they work indirectly with entity objects through the view rows of an appropriate view object that presents a relevant set of information related to the task as hand. Just as a view object can expose a particular set of the underlying *attributes* of one or more entity objects related to the task at hand, it can also expose a selected set of *methods* from those entities. You accomplish this by enabling a custom view row Java class and writing a method in the view row class that:

- Accesses the appropriate underlying entity row using the generated entity accessor in the view row, and
- Invokes a method on it

For example, assume that the Customers entity object contains a performCustomerFeature() method in its CustomersImpl class. To expose this method to clients on the CustomerList view row, you can enable a custom view row Java class and write the method, as shown in the following example.

```
// In CustomerListRowImpl.java
public void performCustomerFeature() {
  getTheCustomer().performCustomerFeature();
}
```

JDeveloper generates an entity accessor method in the view row class for each participating entity usage based on the entity usage *alias* name. Since the alias for the Customers entity in the CustomerList view object is "TheCustomer", it generates a getTheCustomer() method to return the entity row part related to that entity usage.

The code in the view row's `performCustomerFeature()` method uses this `getTheCustomer()` method to access the underlying `CustomersImpl` entity row class and then invokes *its* `performCustomerFeature()` method. This style of coding is known as **delegation**, where a view row method delegates the implementation of one of *its* methods to a corresponding method on an underlying entity object. When delegation is used in a view row with a polymorphic entity usage, the delegated method call is handled by appropriate underlying entity row subtype. This means that if the `CustomersImpl`, `DomesticsImpl`, and `InternationalsImpl` classes implement the `performCustomerFeature()` method in a different way, the appropriate implementation is used depending on the entity subtype for the current row.

After exposing this method on the client row interface, client programs can use the custom row interface to invoke custom business functionality on a particular view row. The following example shows the interesting lines of code from a `TestEntityPolymorphism` class. It iterates over all the rows in the `CustomerList` view object instance, casts each one to the custom `CustomerListRow` interface, and invokes the `performCustomerFeature()` method.

```
CustomerList customerlist = (CustomerList)am.findViewObject("CustomerList");
customerlist.executeQuery();
while (customerlist.hasNext()) {
  CustomerListRow customer = (CustomerListRow)customerlist.next();
  System.out.print(customer.getEmail()+"->");
  customer.performCustomerFeature();
}
```

Running the client code in the previous example produces the following output:

```
austin->## performCustomerFeature as Domestics
hbaer->## performCustomerFeature as Internationals
:
sking->## performCustomerFeature as Domestic
:
```

Rows related to `Customers` entities display a message confirming that the `performCustomerFeature()` method in the `CustomersImpl` class was used. Rows related to `Domestics` and `Internationals` entities display a different message, highlighting the different implementations that the respective `DomesticsImpl` and `InternationalsImpl` classes have for the inherited `performCustomerFeature()` method.

Creating New Rows With the Desired Entity Subtype

In a view object with a polymorphic entity usage, when you create a new view row it contains a new entity row part whose type matches the base entity usage. To create a new view row with one of the entity *subtypes* instead, use the `createAndInitRow()` method.

The following example shows two custom methods in the `CustomerList` view object's Java class that use `createAndInitRow()` to allow a client to create new rows having entity rows either of `Domestics` or `Internationals` subtypes. To use the `createAndInitRow()`, as shown in the example, create an instance of the `NameValuePairs` object and set it to have an appropriate value for the discriminator attribute. Then, pass that `NameValuePairs` to the `createAndInitRow()` method to create a new view row with the appropriate entity row subtype, based on the value of the discriminator attribute you passed in.

```
// In CustomerListImpl.java
public CustomerListRow createCustomersRow() {
  NameValuePairs nvp = new NameValuePairs();
  nvp.setAttribute("CustomerTypeCode","DOMESTIC");
  return (CustomerListRow)createAndInitRow(nvp);
}
public CustomerListRow createInternationalsRow() {
  NameValuePairs nvp = new NameValuePairs();
  nvp.setAttribute("CustomerTypeCode","INTERNATIONAL");
  return (CusotmersListRow)createAndInitRow(nvp);
}
```

If you expose methods like this on the view object's custom interface, then at runtime, a client can call them to create new view rows with appropriate entity subtypes. The following example shows the interesting lines relevant to this functionality from a `TestEntityPolymorphism` class. First, it uses the `createRow()`, `createDomesticsRow()`, and `createInternationalsRow()` methods to create three new view rows. Then, it invokes the `performCustomerFeature()` method from the `CustomerListRow` custom interface on each of the new rows.

```
// In TestEntityPolymorphism.java
CustomerListRow newCustomer = (CustomerListRow)CustomerList.createRow();
CustomerListRow newDomestic  = Customerlist.createDomesticsRow();
CustomerListRow newInternational = Customerlist.createInternationalsRow();
newCustomer.performCustomerFeature();
newDomestic.performCustomerFeature();
newInternational.performCustomerFeature();
```

As expected, each row handles the method in a way that is specific to the subtype of entity row related to it, producing the results:

```
## performCustomerFeature as Customer
## performCustomerFeature as Domestic
## performCustomerFeature as International
```

Working with Polymorphic View Rows

ADF Business Components allows you to configure a view object to have polymorphic view rows. This allows the client to access different view row types with specific view row interfaces.

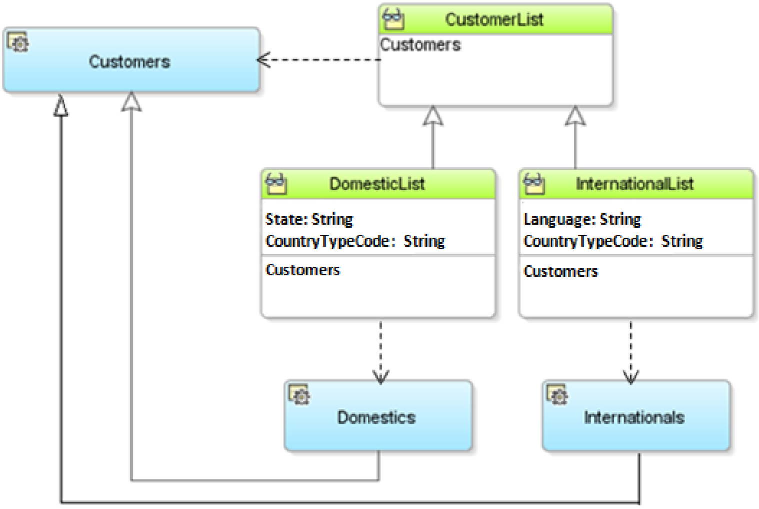
In the example shown in Working with Polymorphic Entity Usages, the polymorphism occurs "behind the scenes" at the entity object level. Since the client code works with all view rows using the same `CustomerListRow` interface, it cannot distinguish between rows based on a `Domestics` entity object from those based on a `Customers` entity object. The code works with all view rows using the same set of view row attributes and methods common to all types of underlying entity subtypes.

If you configure a view object to support polymorphic view rows, then the client can work with different types of view rows using a view row interface specific to the type of row it is. By doing this, the client can access view attributes or invoke view row methods that are specific to a given subtype as needed. Figure 7-11 illustrates the hierarchy of view objects that enables this feature for the `CustomerList` example considered above. `DomesticList` and `InternationalList` are child view objects that extend the base (or parent) `CustomerList` view object. Notice that each one includes an additional attribute specific to the subtype of `Customers` they have as their entity usage. `DomesticList` includes an additional `State` attribute, while `InternationalList` excludes the `State` attribute and includes the `Language` attribute. When configured for view row polymorphism, a client can work with the results of the `CustomerList` view object using:

- `CustomerListRow` interface for view rows related to customers
- `DomesticListRow` interface for view rows related to domestic customers
- `InternationalListRow` interface for view rows related to international customers

As you'll see, this allows the client to access the additional attributes and view row methods that are specific to a given subtype of view row.

Figure 7-11 Hierarchy of View Object Subtypes Enables View Row Polymorphism



Note:

The example in this section refers to the `oracle.summit.model.polymorphicvo` package in the `SummitADF_Examples` application workspace.

How to Create a View Object with Polymorphic View Rows

The view object that you create with polymorphic view rows may inherit one or more of the attributes from a hierarchy of view objects, each with their own base entity object. Attributes that you select from the extended view objects will be overridden by the polymorphic view row definitions in the parent view object.

To create a view object with polymorphic view rows:

1. In the Application Navigator, double-click the view object that you want to be the base view object in the inheritance hierarchy.

   For example, the `CustomerList` view object is the base for `DomesticList` view object.

2. In the overview editor for the view object, click the **Attributes** navigation tab and select the discriminator attribute that distinguishes which view row interface to use for the view row, and then click the **Edit selected attribute(s)** button.

   For example, the `CustomerTypeCode` is the discriminator attribute for `CustomerList`.

3. In the Edit Attribute dialog, select the **Discriminator** checkbox, enter a **Default Value**, and click **OK**.

   You must supply a value for the **Default Value** field that matches the attribute value for which you expect the base view object's view row interface to be used. For example, in the `CustomerList` view object, you would mark the `CustomerTypeCode` attribute as the discriminator attribute and supply a default value of `CUSTOMER`.

4. In the overview editor for the view object, in the Attributes page, delete all attributes that are specific to the subtype view object.

   For example, the attribute `States` would be removed from the base view object since it is used exclusively by the `DomesticList` subtype view object.

5. In the overview editor, click the **Java** navigation tab, and enable a custom view row class for the base view object, and expose at least one method on the client row interface. This can be one or all of the view row attribute accessor methods, as well as any custom view row methods.

6. Create the subtype new view object that *extends* the base view object:

   a. In the Application Navigator, right-click the base view object and choose **New Extended Object**, and in the Create Extended Object dialog, name the subtype view object.

      In this example, the `CustomerList` view object is the base and the subtype view object is named `DomesticList`.

   b. In the overview editor for the subtype view object, click the **Attributes** navigation tab and choose **Add Attribute From Entity** from the **Add** button dropdown, and then, in the Attributes dialog, add the attributes that are specific to the subtype view object and click **OK**.

      In this example, the subtype `DomesticList` defines the additional attribute `State`.

   c. In the Attributes page of the overview editor, select the discriminator attribute for the view row, and click **Override** and then click the **Edit selected attribute(s)** button.

   d. In the Edit Attribute dialog, give the discriminator attribute a *distinct* **Default Value** to define the subtype of the extended view object and click **OK**.

      For example, the `DomesticList` view object provides the value `DOMESTIC` for the `CustomerTypeCode` discriminator attribute.

   e. In the overview editor, click the **Java** navigation tab, and enable a custom view row class for the extended view object.

      If appropriate, add additional custom view row methods or override custom view row methods inherited from the parent view object's row class.

   f. Repeat to add additional extended view objects as needed.

For example, the InternationalList view object is a second one that extends CustomerList. It supplies the value INTERNATIONAL for the CustomerTypeCode discriminator attribute.

After setting up the view object hierarchy, you must define the list of view object subtypes that participate in the view row polymorphism, as described in Updating the Application Module to Expose Subtype Usages. For example, the CustomersModule application module with view instance CustomerList1 must be configured to name the subtype view objects DomesticList and InternationalList.

What Happens When You Create a View Object With Polymorphic View Rows

When you create the base view object that you use to define child view objects with polymorphic view row definitions, JDeveloper adds information about the discriminator attribute to the base view object's XML document. For example, when creating the CustomerList view object, the XML property DiscrColumn identifies CountryTypeCode as the base view object's polymorphic discriminator attribute, with a subtype value of CUSTOMER like this:

```
<ViewObject
  Name="CustomerList" ... >
  <EntityUsage
    Name="Customers"
    Entity="oracle.summit.model.polymorphics.entities.Customers" >
  </EntityUsage>
...
  <ViewAttribute
    Name="CountryTypeCode"
    PrecisionRule="true"
    EntityAttrName="CountryTypeCode"
    EntityUsage="Customers"
    AliasName="COUNTRY_TYPE_CODE"
    DiscrColumn="true"
    DefaultValue="CUSTOMER">
  </ViewAttribute>
   ...
</ViewObject>
```

Then, when you create a child view object with a polymorphic view row definition, JDeveloper adds information about the view row definition to the child view object's XML document. For example, The following example shows the DomesticList child view object with the name of the base view object recorded in the Extends property. The XML property DiscrColumn identifies the overridden CountryTypeCode attribute as the polymorphic discriminator attribute, with a subtype value of DOMESTIC. Only the additional attribute State, specific to the subtype, appears in the XML document of the child view object.

```
<ViewObject
  Name="DomesticList"
  Extends="oracle.summit.model.polymorphic.views.CustomerList"
  ...>
  <ViewAttribute
    Name="CountryTypeCode"
    PrecisionRule="true"
    DiscrColumn="true"
    EntityAttrName="CountryTypeCode"
    EntityUsage="Customers"
    AliasName="COUNTRY_TYPE_CODE"
    DefaultValue="DOMESTIC">
    <DesignTime>
      <Attr Name="_OverrideAttr" Value="true"/>
    </DesignTime>
  </ViewAttribute>
  <ViewAttribute
    Name="State"
    PrecisionRule="true"
    EntityAttrName="State"
    EntityUsage="Customers"
    AliasName="STATE"/>
</ViewObject>
```

Similarly, the XML document for the InternationalList child view object names the same base view object in the Extends property of its XML document, but defines the polymorphic discriminator attribute with a subtype value of INTERNATIONAL and the additional attribute Language specific to its subtype like this:

```
<ViewObject
  Name="InternationalList"
  Extends="oracle.summit.model.polymorphic.views.CustomerList"
  ... >
  <ViewAttribute
    Name="CountryTypeCode"
    PrecisionRule="true"
    DiscrColumn="true"
    EntityAttrName="CountryTypeCode"
    EntityUsage="Customers"
    AliasName="COUNTRY_TYPE_CODE"
    DefaultValue="INTERNATIONAL">
    <DesignTime>
      <Attr Name="_OverrideAttr" Value="true"/>
    </DesignTime>
  </ViewAttribute>
  <ViewAttribute
    Name="Language"
    PrecisionRule="true"
    EntityAttrName="Language"
    EntityUsage="Customers"
    AliasName="LANGUAGE"/>
</ViewObject>
```

Note that unlike the polymorphic entity usage example described in What Happens When You Create a Subtype View Object with a Polymorphic Entity Usage, view instances with polymorphic view rows use inheritance and overriding attributes to distinguish, for example, between rows based on a Domestics entity object from those based on a Customers entity object. Thus, the definition of allowed subtype entity objects is absent from the XML document of the view objects in the polymorphic view row case (but defined in <AttrArray> tags in the polymorphic entity usage case).

What You May Need to Know About Polymorphic View Rows

When you work with polymorphic view rows, you can interact with the row types to customize the attributes to display or to delegate to methods specific to the entity subtypes of the view rows.

Selecting Subtype-Specific Attributes in Extended View Objects

When you create an extended view object, it inherits the entity usage of its parent. If the parent view object's entity usage is based on an entity object with subtypes in your domain layer, you may want your extended view object to work with one of these subtypes instead of the inherited parent entity usage type. Two reasons you might want to do this are:

- To select attributes that are *specific* to the entity subtype
- To be able to write view row methods that delegate to methods *specific* to the entity subtype

In order to do this, you need to override the inherited entity usage to refer to the desired entity subtype. To do this, perform these steps in the overview editor for your extended view object.

To override the entity usage for the view object:

1. In the Applications window, double-click the view object that contains the entity usage that you want to override.
2. In the overview editor, click the **Entity Objects** navigation tab and verify that you are working with an extended entity usage.

   For example, when creating the `DomesticList` view object that extends the `DomesticList` view object, the entity usage with the alias `TheCustomer` will initially display in the **Selected** list as: **TheCustomer(Customers): extended**. The type of the entity usage is in parenthesis, and the "extended" label confirms that the entity usage is currently inherited from its parent.
3. Select the desired entity *subtype* in the **Available** list that you want to override the inherited one. It must be a subtype entity of the existing entity usage's type.

   For example, you would select the `Domestics` entity object in the **Available** list to override the inherited entity usage based on the `Customers` entity type.
4. Click **>** to shuttle it to the **Selected** list
5. Acknowledge the alert that appears, confirming that you want to override the existing, inherited entity usage.

When you have performed these steps, the **Selected** list updates to reflect the overridden entity usage. For example, for the `DomesticList` view object, after overriding the `Customers`-based entity usage with the `Domestics` entity subtype, it updates to show: **TheCustomer (Domestics): overridden**.

After overriding the entity usage to be related to an entity subtype, you can then use the **Attributes** tab of the editor to select additional attributes that are specific to the subtype. For example, the `DomesticsList` view object includes the additional attribute named `State` that is specific to the `Domestics` entity object.

Delegating to Subtype-Specific Methods After Overriding the Entity Usage

After overriding the entity usage in an extended view object to reference a subtype entity, you can write view row methods that delegate to methods specific to the subtype entity class.

The following example shows the code for a `performInternationalFeature()` method in the custom view row class for the `InternationalList` view object. It casts the return value from the `getTheCustomer()` entity row accessor to the subtype `InternationalsImpl`, and then invokes the `performInternationalFeature()` method that is specific to `Internationals` entity objects.

```
// In InternationalListRowImpl.java
public void performInternationalFeature() {
   InternationalsImpl international = (InternationalsImpl)getTheCustomer();
   international.performInternationalFeature();
}
```

> **Note:**
>
> You need to perform the explicit cast to the entity subtype here because JDeveloper does not yet take advantage of the JDK feature called covariant return types that would allow a subclass like `InternationalListRowImpl` to override a method like `getTheCustomer()` and change its return type.

Working with Different View Row Interface Types in Client Code

The following example shows the interesting lines of code from a `TestViewRowPolymorphism` class that performs the following steps:

1. Iterates over the rows in the `CustomerList` view object.

   For each row in the loop, it uses Java's `instanceof` operator to test whether the current row is an instance of the `DomesticListRow` or the `InternationalListRow`.

2. If the row is a `DomesticListRow`, then cast it to this more specific type and:
   - Call the `performDomesticFeature()` method specific to the `DomesticListRow` interface, and
   - Access the value of the `State` attribute that is specific to the `DomesticList` view object.

3. If the row is a `InternationalListRow`, then cast it to this more specific type and:
   - Call the `performInternationalFeature()` method specific to the `InternationalListRow` interface, and
   - Access the value of the `Language` attribute that is specific to the `InternationalList` view object.

4. Otherwise, just call a method on the `CustomerListRow`

```
// In TestViewRowPolymorphism.java
ViewObject vo = am.findViewObject("CustomerList");
vo.executeQuery();
// 1. Iterate over the rows in the CustomerList view object
while (vo.hasNext()) {
  CustomerListRow Customer = (CustomerListRow)vo.next();
  System.out.print(Customer.getEmail()+"->");
  if (Customer instanceof DomesticListRow) {
    // 2. If the row is a DomesticListRow, cast it
    DomesticListRow mgr = (DomesticListRow)Customer;
    mgr.performDomesticFeature();
    System.out.println("State: "+domestic.getState());
  }
  else if (Customer instanceof InternationalListRow) {
    // 3. If the row is an InternationalListRow, cast it
    InternationalListRow international = (InternationalListRow)Customer;
    international.performInternationalFeature();
    System.out.println("Speaks English: "+international.getLanguage());
  }
  else {
    // 4. Otherwise, just call a method on the CustomerListRow
    Customer.performCustomerFeature();
  }
}
```

Running the code in the previous example produces the following output:

```
daustin->## performInternationalFeature called
English spoken: Yes
hbaer->## performCustomerFeature as Customer
:
sking->## performDomesticFeature called
State: CA
:
```

This illustrates that by using the view row polymorphism feature the client was able to distinguish between view rows of different types and access methods and attributes specific to each subtype of view row.

What You May Need to Know About the Discriminator Attribute

You can choose to include or exclude a discriminator attribute in the query that an ADF view object uses to reference an entity object.

When a view object references an entity object with a discriminator attribute, you can decide whether or not that discriminator attribute should be included in the query (in addition to the primary key attribute) by selecting the **Polymorphic Discriminator** checkbox for the inherited discriminator attribute in the **Details** tab on the Attributes page of the overview editor for the view object.

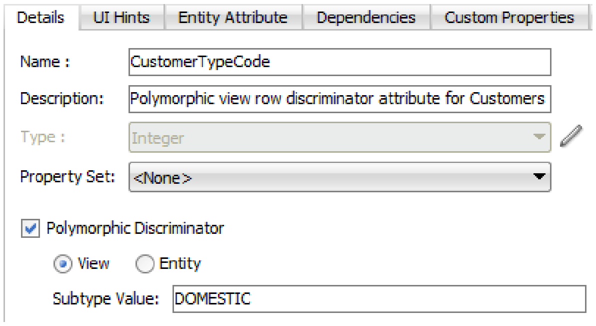
When you decide to enable the checkbox, you can then use the **Polymorphic Discriminator** options in the **Details** tab to configure whether or not the view object is defined as a subtype view object:

- Enabling the option **View** means you want to enable polymorphic view rows.
- Enabling the option **Entity** means you want to ignore the discriminator capability of the view row and will instead instantiate the attribute with a default value.

  The **Entity** option is useful in situations where a discriminator attribute is inherited by an entity-based view object with multiple backing entity objects and yet polymorphic view rows are not desired.

Figure 7-12 shows the Details tab for the DomesticList view object enables its CustomerTypeCode discriminator attribute inherited from the Customers entity object. The **View** selection indicates that this discriminator attribute participates in view object polymorphism and the value DOMESTIC determines the subtype view object's row type.

Figure 7-12 Discriminator Attribute Selection Enables View Row Polymorphism



Name : CustomerTypeCode

Description: Polymorphic view row discriminator attribute for Customers

Type : Integer

Property Set: <None>

☑ Polymorphic Discriminator

● View ○ Entity

Subtype Value: DOMESTIC

Updating the Application Module to Expose Subtype Usages

You can specify the list of view object subtypes for the base view object instance in an ADF application module definition.

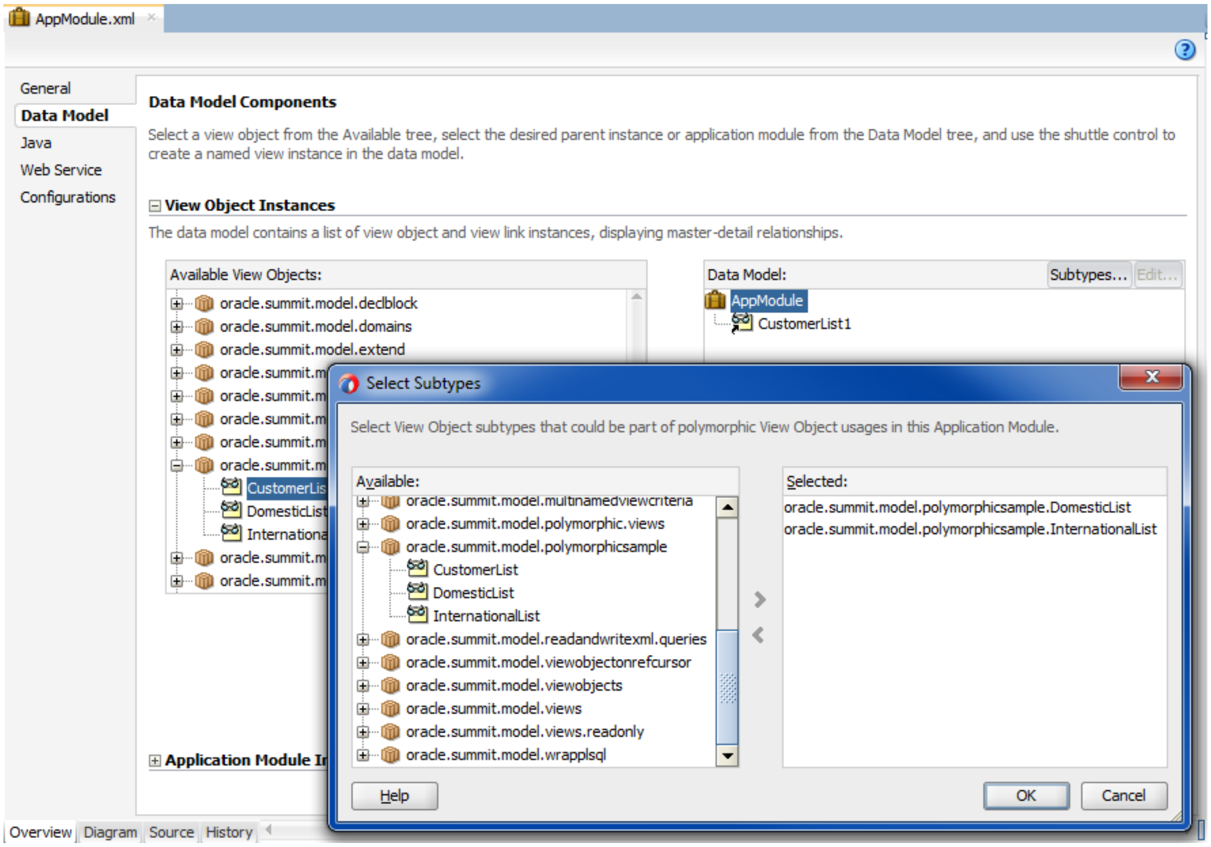
After creating the view object hierarchy using either view row polymorphism or entity object polymorphism, you need to define the list of view object subtypes that participate in the view object polymorphism at runtime. To accomplish this, you update the application module definition to specify the subtype view objects for the base view instance. At runtime, ADF creates polymorphic view rows based on the definitions of the invoked view instance's named subtypes.

How to Expose Subtype Usages on the Data Model

After creating the view object hierarchy using either view row polymorphism or entity object polymorphism, you need to define the list of view object subtypes that participate in the view object polymorphism. To accomplish this, you update the application module definition to specify the subtype view objects for the base view instance.

As Figure 7-13 shows, the data model that exposes the base view object usage `CustomerList1` remains unchanged, while the Select Subtypes dialog is used to define the possible polymorphic view object usages of the base view object.

Figure 7-13   Updating the Application Module Definition with Subtype View Objects



Select a view object from the Available tree, select the desired parent instance or application module from the Data Model tree, and use the shuttle control to create a named view instance in the data model.

The data model contains a list of view object and view link instances, displaying master-detail relationships.

Select View Object subtypes that could be part of polymorphic View Object usages in this Application Module.

Overview
Diagram
Source
History

Before you begin:

It may be helpful to have an understanding of polymorphic view objects. For more information, see Working with Polymorphic View Rows.

When you want to create subtype view objects based on polymorphic entity usages, which the view objects derive from the inheritance of the entity subtypes, create the subtype view objects that extend the base entity-based view object. For more information, see Working with Polymorphic Entity Usages.

When you want to create subtype view objects based on polymorphic view rows, which derive from a view object hierarchy that you define, create the subtype view objects with polymorphic discriminator attribute. For more information, see Working with Polymorphic View Rows.

To add subtype view objects to the application module definition:

1. In the overview editor for the application module, click the **Data Model** navigation tab and add an instance of the base view object to the data model of an application module.

   For example, when the `CustomerList` view object supports two subtypes: `DomesticList` and `InternationalList` view objects, the `AppModule` application module will have base view instance `CustomerList1`.

2. In the Data Model page, expand the **View Object Instances** section and in the **Data Model** list, click the **Subtypes** button.

You do not need to make a view instance selection in **Data Model** list to click the button.

3. In the **Subtypes** dialog, shuttle the desired view object subtypes of the base view instance from the **Available** to the **Selected** list, and click **OK**.

   For example, for the `CustomerList1` view instance with subtype view objects `DomesticList` and `InternationalList`, you would shuttle both view objects to the **Selected** list, as shown in Figure 7-13.

What Happens When You Add Subtype View Objects to the Application Module

When you add a subtype view object to the application module, JDeveloper adds information about the allowed view subtypes to the application module's XML document. For example, when defining a view instance `CustomerList1` with two possible subtype usages, the names of the allowed subtype view objects are recorded in an `<AttrArray>` tag like this:

```
<AppModule
  ...
  <ViewUsage
    Name="CustomerList1"
    ViewObjectName="oracle.summit.model.polymorphicsample.CustomerList"/>
  <AttrArray Name="ViewImports">
    <Item Value="oracle.summit.model.polymorphicsample.DomesticList"/>
    <Item Value="oracle.summit.model.polymorphicsample.InternationalList"/>
  </AttrArray>
</AppModule>
```

8

Testing View Instance Queries

This chapter describes how to interactively test ADF view objects query results using the Oracle ADF Model Tester provided in JDeveloper. This chapter also explains how to use the ADF Business Components API to access view object instances in a test client outside of JDeveloper.
This chapter includes the following sections:

About View Instance Queries

Use the Oracle ADF Model Tester to achieve interactive ADF application module testing of the data model.

JDeveloper includes an interactive **application module** testing tool that you can use to test all aspects of its data model without having to use your application user interface or write a test client program. Running the Oracle ADF Model Tester can often be the quickest way of exercising the data functionality of your business service during development.

> **Note:**
>
> When you want to test an application module programmatically, you can write a test client. See How to Create a Command-Line Java Test Client.

View Instance Use Cases and Examples

Using the Oracle ADF Model Tester, you can simulate an end user interacting with your **application module data model** before you have started to build any custom user interface of your own. Even *after* you have your UI pages constructed, you will come to appreciate using the Oracle ADF Model Tester to assist in diagnosing problems when they arise. You can reproduce the issues in the Oracle ADF Model Tester to discover if the issue lies in the view or controller layers of the application, or is instead a problem in the business service layer application module itself.

Additional Functionality for Testing View Instances

You may find it helpful to understand other **Oracle ADF** features before you start working with view instances. Following are links to other functionality that may be of interest.

- For details about using debugging tools when you run the Oracle ADF Model Tester, see Using the Oracle ADF Model Tester for Testing and Debugging.
- For details about creating a data model consisting of **view object instances**, see Implementing Business Services with Application Modules.
- For a quick reference to the most common code that you will typically write, use, and override in your custom **ADF Business Components** classes, see Most Commonly Used ADF Business Components Methods.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Creating an Application Module to Test View Instances

Define an ADF application module and build a data model using view object instances. Use the Oracle ADF Model Tester to test the application module if required.

Before you can test view objects that you create in your data model project, you must create an application module where you will define instances of the view objects you want to test. The application module is the transactional component that the Oracle ADF Model Tester (or UI client) will use to work with application data. The set of view objects used by an application module defines its **data model**, in other words, the set of data that a client can display and manipulate through a user interface.

To test the view objects you added to an application module, use the Oracle ADF Model Tester, which is accessible from the Applications window. For details about using the Oracle ADF Model Tester, see Testing View Object Instances Using the Oracle ADF Model Tester.

How to Create the Application Module with Individual View Object Instances

To create an application module that will define instances of individual view objects, use the Create Application Module wizard, which is available in the New Gallery.

Before you begin:

It may be helpful to have an understanding of application modules. For more information, see Creating an Application Module to Test View Instances.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Testing View Instances.

You will need to complete this task:

> Create the desired view objects, as described in How to Create an Entity-Based View Object and How to Create a Custom SQL Mode View Object.

To create an application module to test individual view object instances:

1. In the Applications window, right-click the project in which you want to create the application module and choose **New** and then **Application Module**.
2. In the Create Application Module wizard, in the Name page, provide a package name and an application module name. Click **Next**.

3. On the Data Model page, include instances of the view objects you have previously defined and edit the view object instance names to be exactly what you want clients to see. Then click **Finish**.

   Instead of accepting the default instance name shown in the Data Model page, you can change the instance name to something more meaningful (for example, instead of the default name `OrderItems1` you can rename it to `AllOrderItems`).

How to Create the Application Module with Master-Detail View Object Instances

You can also use the Create Application Module wizard to create a hierarchy of view objects for an application module, based on a **master-detail relationship** that the view objects represent.

Before you begin:

It may be helpful to have an understanding of application modules. For more information, see Creating an Application Module to Test View Instances.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Testing View Instances.

You will need to complete this task:

> Create hierarchical relationships between view objects, as described in Working with Multiple Tables in a Master-Detail Hierarchy.

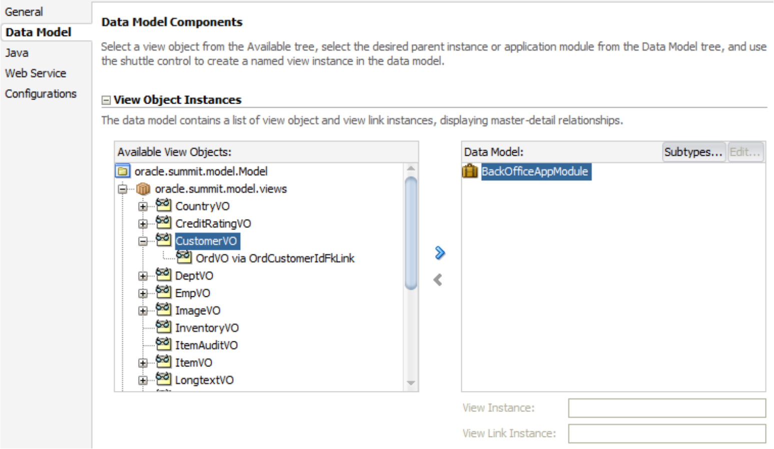
To create an application module based on view object relationships:

1. In the Applications window, right-click the project in which you want to create the application module and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Application Module**, and click **OK**.
3. In the Create Application Module wizard, select the **Data Model** node.
4. In the **Available View Objects** list, select the instance of the view object that you want to be the actively coordinating master.

   The master view object will appear with a plus sign in the list indicating the available view links for this view object. The **view link** must exist to define a master-detail hierarchy.

   For example, Figure 8-1 shows `PersonsVO` selected and renamed `AuthenticatedUser` in the **New View Instance** field.

Figure 8-1 Master View Object Selected



Data Model Components

Select a view object from the Available tree, select the desired parent instance or application module from the Data Model tree, and use the shuttle control to create a named view instance in the data model.

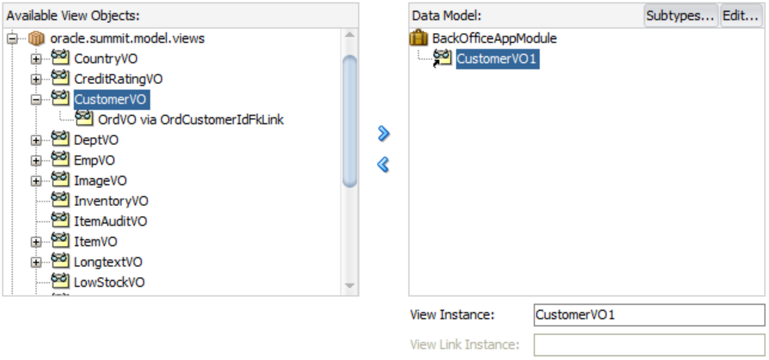
View Object Instances

The data model contains a list of view object and view link instances, displaying master-detail relationships.

5. Shuttle the selected master view object to the **Data Model** list

   For example, Figure 8-2 shows the newly created master view instance `AuthenticatedUser` in the **Data Model** list after you add it to the list.

Figure 8-2 Master View Instance Created

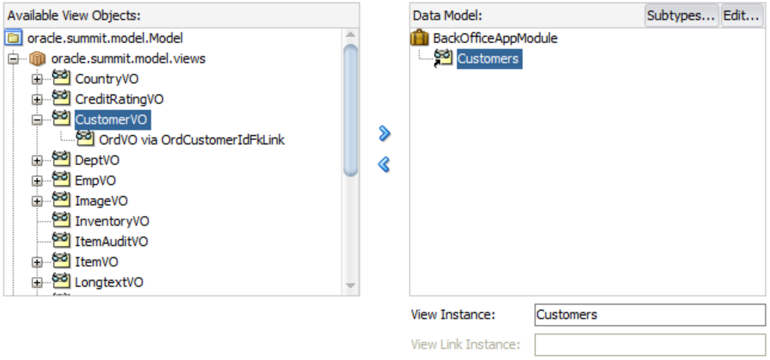


View Instance: CustomerVO1

6. In the **Data Model** list, leave the newly created master view instance selected, so that it appears highlighted. This will be the target of the detail view instance you will add. Then locate and select the detail view object beneath the master view object in the **Available View Objects** list.

   For example, Figure 8-3 shows the detail `OrdersVO` indented beneath master `PersonsVO` with the name `OrdersVO via PersonsToOrders`. The name identifies the view link `PersonsToOrders`, which defines the master-detail hierarchy between `PersonsVO` and `OrdersVO`. The detail view instance is renamed to `MyOrders`.

Figure 8-3 Detail View Object Selected



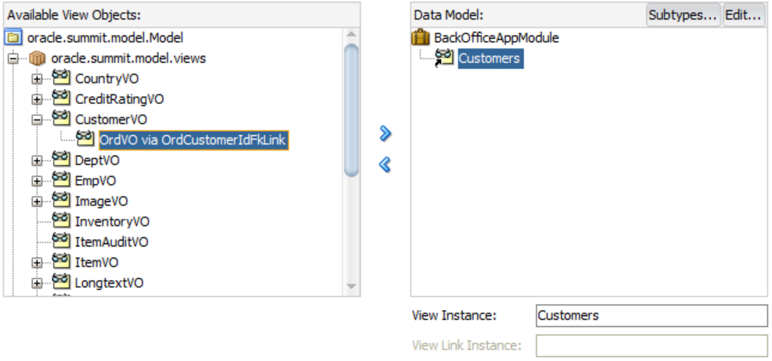
View Instance: Customers

View Link Instance:

7. To add the detail instance to the previously added master instance, shuttle the detail view object to the **Data Model** list below the selected master view instance.

   Figure 8-4 shows the newly created detail view instance `MyOrders` is a detail of the `AuthenticatedUser` in the data model.

Figure 8-4 Master View Instance Created



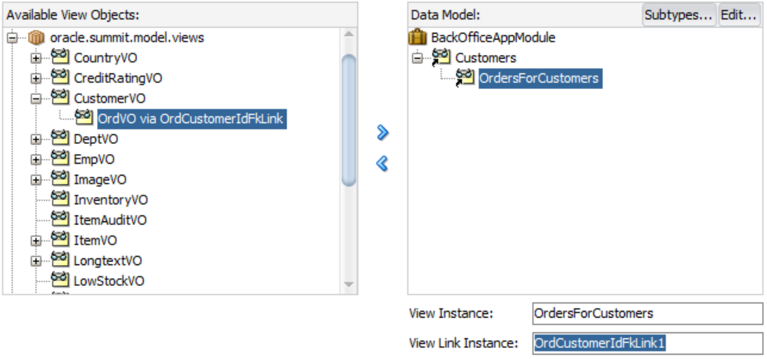
View Instance: Customers

View Link Instance:

8. To add another level of hierarchy, select the newly added detail in the **Data Model** list, then shuttle over the new detail which itself has a master-detail relationship with the previously added detail instance.

   Your data model can contain as many levels of hierarchy as your view object relationships support. For example, Figure 8-5 shows the **Data Model** list with instance `AuthenticatedUser` (renamed for `PersonsVO`) as the master of `MyOrders` (renamed for `OrdersVO via PersonsToOrders`), which in turn is a master for `MyOrderItems` (renamed from `OrderItemsVO via OrdersToOrderItems`). The detail view object `MyOrderItems` is the last level of the hierarchy possible because this view object is itself not a master for another view object.

Figure 8-5   Master-Detail-Detail Hierarchy Created



View Instance: OrdersForCustomers

View Link Instance: OrdCustomerIdFkLink1

Testing View Object Instances Using the Oracle ADF Model Tester

Use Oracle ADF Model Tester to test and diagnose the ADF application module using simulated end user interaction before building a custom user interface.

Using the Oracle ADF Model Tester, you can simulate an end user interacting with your **application module data model** before you have started to build any custom user interface of your own. Even *after* you have your UI pages constructed, you will come to appreciate using the Oracle ADF Model Tester to assist in diagnosing problems when they arise. You can reproduce the issues in the Oracle ADF Model Tester to discover whether the problem lies in the view or controller layers of the application, or whether there is instead a problem in the business service layer application module itself.

How to Run the Oracle ADF Model Tester

To test the view objects you added to an application module, use the Oracle ADF Model Tester, which is accessible from the Applications window. When you run the tester from the Applications window, the default application module configuration is used to connect to the database.

Before you begin:

It may be helpful to have an understanding of the Oracle ADF Model Tester. For more information, see Testing View Object Instances Using the Oracle ADF Model Tester.

You may also find it helpful to understand how to use debugging tools when you run the tester. For more information, see Using the Oracle ADF Model Tester for Testing and Debugging.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Testing View Instances.

To test view objects using an application module configuration:

1. In the Applications window, right-click the application module that you want to run and choose **Run**.

Alternatively, choose **Debug** when you want to run the application in the Oracle ADF Model Tester with debugging enabled. JDeveloper opens the debugger process panel in the Log window and the various debugger windows. For example, when debugging using the Oracle ADF Model Tester, you can view status message and exceptions, step in and out of source code, and manage breakpoints.

For information about receiving diagnostic messages specific to ADF Business Component debugging, see How to Enable ADF Business Components Debug Diagnostics.

2. In the Oracle ADF Model Tester, to execute a view object, expand the data model tree and double-click the desired view object node.

   Note that the view object instance may already appear executed in the testing session. In this case, the Oracle ADF Model Tester data view page on the right already displays query results for the view object instance. The fields in the Oracle ADF Model Tester data view page of a read-only view object will always appear disabled since the data it represents is not editable. For example, in Figure 8-6, data for the view instance `Products` appears in the tester. Fields like **Product Id**, **Language**, and **Category** appear disabled because the attributes themselves are not editable.

Figure 8-6 Testing the Data Model in the Oracle ADF Model Tester

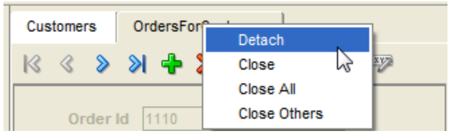
Name:BackOfficeAppModule.Customers Definition:oracle.summit.model.views.CustomerVO

3. Right-click a node in the data model tree to display the context menu for that node. For example, on a view object node you can reexecute the query if needed, to remove the view object from the data model tree, and perform other tasks.

4. Right-click the tab of an open data viewer to display the context menu for that tab, as shown in Figure 8-7. For example, you can close the data viewer or open it in a separate window.

Figure 8-7 Context Menu for Data Viewer Tabs in the Oracle ADF Model Tester



How to Run the Oracle ADF Model Tester Using Configurations

To test the view objects you added to an application module, use the Oracle ADF Model Tester, and run it using a specific configuration. The configuration you select will determine the database connection used by the tester.

Before you begin:

It may be helpful to have an understanding of the Oracle ADF Model Tester. For more information, see Testing View Object Instances Using the Oracle ADF Model Tester.

You may also find it helpful to understand how to use debugging tools when you run the tester. For more information, see Using the Oracle ADF Model Tester for Testing and Debugging.

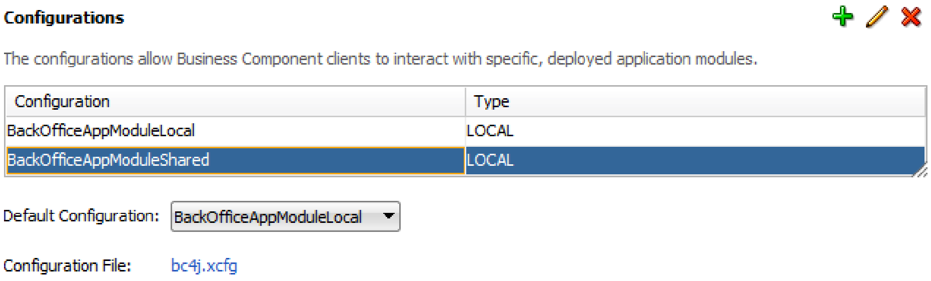
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Testing View Instances.

To test view objects using a specific application module configuration:

1. In the Applications window, double-click the application module that you want to run.
2. In the overview editor, click the **Configurations** navigation tab.
3. In the Configurations page, select the desired application module configuration from the **Default Configuration** dropdown list that you want to use to run the Oracle ADF Model Tester.

   By default, an application module has only its default configurations, named `*AppModuleName*Local` and `*AppModuleName*Shared`. For example, Figure 8-8 shows the `BackOfficeAppModuleShared` configuration is selected to connect to the database.

Figure 8-8 Configuration Selection in Application Module Overview Editor



Configurations

The configurations allow Business Component clients to interact with specific, deployed application modules.

Configuration	Type
BackOfficeAppModuleLocal	LOCAL
BackOfficeAppModuleShared	LOCAL

Default Configuration: BackOfficeAppModuleLocal

Configuration File: bc4j.xcfg

4. Right-click the selected configuration and choose **Run**.

Alternatively, choose **Debug** when you want to run the application in the Oracle ADF Model Tester with debugging enabled. JDeveloper opens the debugger process panel in the Log window and the various debugger windows. For example, when debugging using the Oracle ADF Model Tester, you can view status message and exceptions, step in and out of source code, and manage breakpoints.

For information about receiving diagnostic messages specific to ADF Business Component debugging, see How to Enable ADF Business Components Debug Diagnostics.

How to Test Language Message Bundles and UI Hints

When your application defines alternative languages in your resource message bundles, you can configure the Oracle ADF Model Tester to recognize these languages. In the Oracle ADF Model Tester, you can then display the **Locale** menu and select among the available language choices.

To specify a default language for the Oracle ADF Model Tester:

1. In the main menu, choose **Tools** and then **Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and select **Tester**.
3. In the Oracle ADF Model Tester page, add any locale for which you have created a resource message bundle to the **Selected** list.

Alternatively, you can configure the default language choice by setting ADF Business Components runtime configuration properties for a specific application module configuration. These runtime properties also determine which language the Oracle ADF Model Tester will display as the default. To set runtime configuration properties, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink. In the application module configuration overview editor (on the `bc4j.xcfg` file), select the **Properties** tab and click **Add Property** to select the following properties from the Add Property dialog and click **OK**.

- `jbo.default.country`
- `jbo.default.language`

Then, in the **Properties** list enter the desired country code for the country and language. For example, to specify the Italian language, you would enter `IT` and `it` for these two properties:

- `jbo.default.country` = `IT`
- `jbo.default.language` = `it`

Testing the language message bundles in the Oracle ADF Model Tester lets you verify that the translations of the UI hints are correctly located. Or, if the message bundle defines date formats for specific attributes, the tool lets you verify that date formats change (like `04/12/2013` to `12/04/2013`).

How to Test Entity-Based View Objects Interactively

You test entity-based view objects interactively in the same way as read-only ones. Just add instances of the desired view objects to the data model of some application module, and then test that application module using the Oracle ADF Model Tester.

You'll find the Oracle ADF Model Tester invaluable for quickly testing and debugging your application modules. Table 8-1 gives an overview of the operations that the Oracle ADF Model Tester toolbar buttons perform when you display an entity-based view object.

Table 8-1 Oracle ADF Model Tester Toolbar Buttons

Button	Operation	Usage
⏮ ◀ ▶ ⏭	**Move to ... row**	Changes the current row displayed by the Oracle ADF Model Tester. Moves to the first, previous, next, or last row.
➕	**Insert a new row**	Creates and inserts a new row.
✕	**Delete the current row**	Deletes the current row.
✓	**Save changes to the database**	Posts and commits changes that you made in the ADF Business Components cache.
↺	**Discard all changes since last save**	Discards changes that you made in the ADF Business Components cache and restores the original values, rolling back any changes posted to the database.
🔍	**Specify view criteria**	Displays the View Criteria dialog that you can use to create and apply **view criteria** to the master view object instance.

Table 8-1 (Cont.) Oracle ADF Model Tester Toolbar Buttons

Button	Operation	Usage
✓	**Validate row**	Validates the current row by applying validation rules defined for all **entity object** instances. Disabled unless at least one field is editable.
✎	**Edit bind variables**	Displays the Bind Variable dialog that you can use to enter values for bind parameters used in the view object query. Disabled unless the view object query uses bind parameters in the query statement.

To test the entity-based view objects you added to an application module, use the Oracle ADF Model Tester, which is accessible from the Applications window.

Before you begin:

It may be helpful to have an understanding of the Oracle ADF Model Tester. See Testing View Object Instances Using the Oracle ADF Model Tester.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See Additional Functionality for Testing View Instances.

To test entity-based view objects using an application module configuration:

1. In the Applications window, right-click the application module that you want to test and choose **Run**.
2. In the Oracle ADF Model Tester, expand the data model tree and double-click the desired entity-based view object node.

   Unlike the fields of a read-only view object, the fields displayed in the data view page will appear enabled, because the data it represents is editable.
3. To update individual values and perform validation checks on the entered data, use the editable fields.

   In the case of a view instance with referenced entities, you can change the foreign key value and observe that the referenced part changes.
4. To perform row-level operations, such as navigate rows, create row, remove row, and validate the current row, use the toolbar buttons.

   For further discussion about simulating end-user interaction in the data view page, see How to Simulate End-User Interaction in the Oracle ADF Model Tester.

How to Update the Oracle ADF Model Tester to Display Project Changes

Normally, changes that you make to the data model project will not be picked up automatically by running the Oracle ADF Model Tester. You can, however, force the Oracle ADF Model Tester to reload metadata from the data model project any time you want to synchronize the displayed data model and the data model project. This option is an alternative to quitting the Oracle ADF Model Tester, editing your project, and rerunning the Oracle ADF Model Tester to view the latest changes.

Using the **Reload Application** option saves time, especially as you work iteratively between the Oracle ADF Model Tester and JDeveloper. For example, while running the Oracle ADF Model Tester you might determine the need to modify the data model with a new view instance or you might find that a view instance is missing an LOV attribute definition. You can return to JDeveloper and use the Business Components overview editors to make the changes that alter the data model metadata. Then, after you recompile the project (a necessary step), you can return to the Oracle ADF Model Tester to reload the updated metadata from the project's class path.

Before you begin:

It may be helpful to have an understanding of the Oracle ADF Model Tester. For more information, see Testing View Object Instances Using the Oracle ADF Model Tester.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Testing View Instances.

To reload the data model metadata in the running Oracle ADF Model Tester:

1. In the Applications window, right-click the application module and choose **Run**.
2. In the Oracle ADF Model Tester, test the data model and determine any changes you want to make. Do not exit the Oracle ADF Model Tester.
3. In JDeveloper, make the desired changes and recompile the data model project. (For example, you can right-click the data model project in the Applications window and choose **Make** to complete the recompile step.)

   Although the metadata changes that you make are not involved in compiling the project, the compile step is necessary to copy the metadata to the class path and to allow the Oracle ADF Model Tester to reload it.
4. Return to the Oracle ADF Model Tester and click the **Reload the Application Metadata** button above the data model tree. The Oracle ADF Model Tester closes all open windows.

   Alternatively, you can choose **Reload Application** from the **File** menu of the Oracle ADF Model Tester.
5. Reopen the desired windows and view your changes.

What Happens When You Use the Oracle ADF Model Tester

When you launch the Oracle ADF Model Tester, JDeveloper starts the tool in a separate process and the Oracle ADF Model Tester appears. The tree at the left of the dialog displays all of the view object instances in your application module's data model. After you double-click the desired view object instance, the Oracle ADF Model Tester will display a data view page to inspect the query results. For example, Figure 8-9 shows the view instance `Products` that has been double-clicked in the expanded tree to display the data for this view instance in the data view page on the right.

The data view page will appear disabled for any read-only view objects you display because the data is not editable. But even for a read-only view object, the tool affords some useful features:

- You can validate that the UI hints based on the Label Text hint and format masks are defined correctly.
- You can also scroll through the data using the toolbar buttons.
- You can enter Query-by-Example criteria to find a particular row whose data you want to inspect. By clicking the **Specify View Criteria** button in the toolbar, the View Criteria dialog displays the list of available Query-by-Example criteria.

  For example, as shown in Figure 8-9, you can select a view criteria like `FindByProductNameCriteria` and enter a query criteria like "`P%`" for a `ProductName` attribute and click **Find** to narrow the search to only those products with a name that begins with the letter `P`.

The Oracle ADF Model Tester becomes even more useful when you create entity-based view objects that allow you to simulate inserting, updating, and deleting rows, as described in How to Test Entity-Based View Objects Interactively.

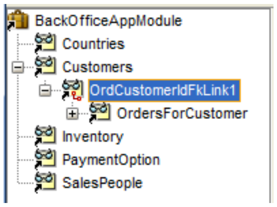
ZipCode:

How to Simulate End-User Interaction in the Oracle ADF Model Tester

When you launch the Oracle ADF Model Tester, the tree at the left of the display shows the hierarchy of the view object instances that the data model of your application module defines. If the data model defines master-detail view instance relationships, the tree will display them as parent and child nodes. A node between the master-detail view instances represent the view link instance that performs the active master-detail coordination as the current row changes in the master. For example, in Figure 8-10 the tree is expanded to show the master-detail relationship between the master `Products` view instance and the detail `WarehouseStockLevels` view instance. The selected node, `ProductsToWarehouseStockLevels1`, is the view link instance that defines the master-detail relationship.

Figure 8-10 Application Module Data Model in the Oracle ADF Model Tester



Double-clicking the view link instance executes the master object and displays the master-detail data in the data view page. For example, in Figure 8-11, double-clicking the `ProductsToWarehouseStockLevels1` view link instance in the tree executes the `Products` master view instance in the top portion of the data view page and the `WarehouseStockLevels` view instance in the bottom portion of the data view page. Additional context menu items on the view object node allow you to reexecute the query if needed, remove the view object from the data model panel, and perform other tasks.

In the master-detail data view page, you can scroll through the query results. Additionally, because instance of entity-based view objects are fully editable, Instead of displaying *disabled* UI controls showing read-only data for a read-only view object, the data view page displays editable fields. You are free to experiment with creating, inserting, updating, validating, committing, and rolling back.

Figure 8-11 Master-Detail Data View Page in the Oracle ADF Model Tester

1002	1	01-12-2012		15	$1,249.91

For example, you can view multiple levels of master-detail hierarchies, opening multiple data view pages at the same time. Use the **Detach** context menu item to open any tab into a separate window and visualize multiple view object's data at the same time.

Using just the master-detail data view page, you can test several functional areas of your application.

Testing Master-Detail Coordination

When you click the navigation buttons on the Oracle ADF Model Tester toolbar, you can see that the rows for the current master view object are correctly coordinated. For example, Figure 8-11 shows a master-detail hierarchy with products and warehouses. If you click the **Next Row** button in the master panel, the master panel will display the next product (identified by a product ID) and the detail panel will update to display the list of warehouses and quantities available for the product.

Testing UI Hints

The entity-based view object attributes inherit their UI hints from those on the underlying entity object attribute. The prompts displayed in the data view page help you see whether you have correctly defined a user-friendly label text UI hint for each attribute. For details on setting up the hint on your entity object, see Defining UI Hints for View Objects.

Testing Business Domain Layer Validation

Depending on the validation rules you have defined, you can try entering invalid values to trigger and verify validation exceptions. For example, when you have defined a range validation rule, enter a value outside the range and see an error similar to:

```
(oracle.jbo.AttrSetValException) Valid product codes are between 100 and 999
```

Click the rollback button in the toolbar to revert data to the previous state.

Testing View Objects That Reference Entity Usages

By scrolling through the data — or using the **Specify View Criteria** button in the Oracle ADF Model Tester toolbar to search — you can verify whether you have correctly altered the `WHERE` clause in an entity-based view object's query to use an outer join. The rows should appear as expected.

You also can try changing a primary key attribute of a master view object. This will allow you to verify that the corresponding reference information is automatically updated to reflect the new primary key value.

Use the Oracle ADF Model Tester to verify that UI hints defined at the view object level override the ones it would normally inherit from the underlying entity object. If you notice that several attributes share the same label text, you can edit the UI hint for the desired attributes at the view object level. For example, you can set the **Label Text** hint to **Member Since** for the `RegisteredDate` attribute and **Provisioned?** for the `ProvisionedFlag` attribute.

Testing Row Creation and Default Value Generation

When displaying an entity-based view object, click the **Create Row** button in the Oracle ADF Model Tester toolbar for the view object instance to create a new blank row. Any fields that have a declarative default value will appear with that value in the blank row. If the `DBSequence`-valued attribute is used, a temporary value will appear in the new row. After entering all the required fields, click the **Commit** button to commit the transaction. The actual, trigger-assigned primary key should appear in the field after successful commit.

Testing That New Detail Rows Have Correct Foreign Keys

If you click **Create Row** in the Oracle ADF Model Tester toolbar to try adding a new row to an existing detail entity-based view object instance, you'll notice that the view link automatically ensures that the foreign key attribute value in the new row is set to the value of the current master view instance row.

How to Test Multiuser Scenarios in the Oracle ADF Model Tester

When view objects and entity objects cooperate at runtime, two exceptions can occur when you run the application in a multiuser environment. To anticipate these exceptions, you can simulate a multiuser environment for testing purposes using the Oracle ADF Model Tester. For example, when the application displays edit forms for view object queries, what is the expected behavior when two users attempt to modify the same attribute in their forms?

To understand the expected behavior, open two instances of the Oracle ADF Model Tester on the application module to simulate two users editing the same view object attribute. Keep both instances open and perform the following two tests to demonstrate how multiuser exceptions can arise:

- In one instance of the Oracle ADF Model Tester, modify an attribute of an existing view object and tab out of the field. Then, in the other tester instance, try to modify the same view object attribute in some way. You'll see that the second user gets the `oracle.jbo.AlreadyLockedException`.

  You can then change the value of `jbo.locking.mode` to be `pessimistic` on the Properties page of the Oracle ADF Model Tester Connect dialog and try repeating the test (the default mode is set to `optimistic`). You'll see the error occurs for the second user immediately after changing the value instead of after committing the change.
- In one instance of the Oracle ADF Model Tester, modify an attribute of an existing view object and tab out of the field. Then, in the other tester instance, retrieve (but don't modify) the same view object attribute. Back in the first window, commit the change. If the second user then tries to modify that same attribute, you'll see that the second user gets the `oracle.jbo.RowInconsistentException`. The row has been modified and committed by another user since the second user retrieved the row into the entity cache.

How to Customize Configuration Options Before Running the Tester

Using the overview editor for the application module, you can select a predefined configuration to run the tool using that named set of runtime configuration properties. The Configurations page of the overview editor also lets you open the overview editor for application module configurations (defined in the `bc4j.xcfg` file) to specify properties of the configuration before running the tester.

To display the application module configuration overview editor, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink. In the application module configuration overview editor, select the **Properties** tab and click **Add Property** to select the desired property from the Add Property dialog and click **OK**.

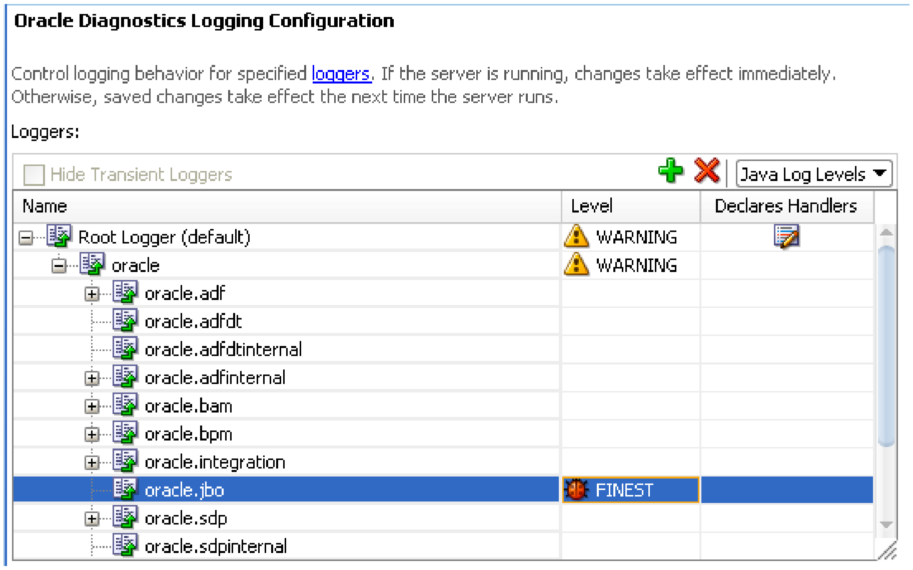
For example, you could alter the default language for the UI hints by editing the configuration and choosing the **Properties** tab to add and then set the following two properties with the desired country code (in this case, IT for Italy):

- jbo.default.country = IT
- jbo.default.language = it

How to Enable ADF Business Components Debug Diagnostics

When launching the Oracle ADF Model Tester, if you have configured diagnostic logging for the oracle.jbo logger, JDeveloper will direct ADF Business Components debug diagnostics messages to the JDeveloper Log window. Figure 8-12 shows the oracle.jbo logger set to a log level of FINEST to enable ADF Business Components debug diagnostics.

Figure 8-12 Configuring a Logger for ADF Business Components Debugging



Oracle Diagnostics Logging Configuration

Control logging behavior for specified loggers. If the server is running, changes take effect immediately. Otherwise, saved changes take effect the next time the server runs.

Loggers:

□ Hide Transient Loggers

Name	Level	Declares Handlers
Root Logger (default)	WARNING	
oracle	WARNING	
oracle.adf		
oracle.adfdt		
oracle.adfdtinternal		
oracle.adfinternal		
oracle.bam		
oracle.bpm		
oracle.integration		
oracle.jbo	FINEST	
oracle.sdp		
oracle.sdpinternal		

The oracle.jbo logger can be configured either before running the application or while the application is running in Integrated WebLogic Server. The logging will begin without the need to restart the server. You do not need to run the application in debug mode to log diagnostic messages.

With the oracle.jbo logger configured, the next time you run the Oracle ADF Model Tester and double-click the view object, you'll see detailed diagnostic output in the Log window, as shown in the following example. Configuring the oracle.jbo logger with a log level FINEST will allow you to visualize everything the ADF Business Components framework components are doing for your application.

```
   :
[355] Oracle SQLBuilder: Registered driver: oracle.jdbc.OracleDriver
[356] Creating a new pool resource
[357] **** DBTransactionImpl establishNewConnection
[358] Successfully logged in
[359] JDBCDriverVersion: xx.xx.x.x-Production
[360] DatabaseProductName: Oracle
```

```
[361] DBTransactionImpl initTransaction
[362] Replacing: null with: StoreServiceAM_AddressesPageDef
[363] Replacing: null with: StoreServiceAM_MostPopularProductsByCategoriesPageDef
...
[537] Orders ViewRowSetImpl.execute caused params to be "un"changed
[538] Column count: 41
[539] ViewObject: Orders Created new QUERY statement
[540] Orders>#q computed SQLStmtBufLen: 952, actual=865, storing=895
[541] SELECT OrderEO.ORDER_ID, OrderEO.ORDER_DATE, OrderEO.ORDER_SHIPPED_DATE,
       FROM ORDERS OrderEO ORDER BY OrderEO.ORDER_DATE desc
[542] Bind params for ViewObject: Orders
```

For backward compatibility, it remains possible to enable ADF Business Components debug diagnostics on the data model project using the Java system property `jbo.debugoutput=console`. To set the property, open the Run/Debug/Profile page in the Project Properties dialog for your data model project. Click **Edit** to edit the chosen run configuration, and add `-Djbo.debugoutput=console` to the **Java Options** field in the page. Other legal values for this property are `silent` (the default, if not specified) and `file`. If you choose the file option, diagnostics are written to the system `temp` directory.

Other legal values for the `-Djbo.debugoutput` system property are `silent` (the default, if not specified) and `file`. If you enter the `file` option, diagnostics are written to the system `temp` directory.

What Happens at Runtime: How View Objects and Entity Objects Cooperate

On their own, view objects and entity objects simplify two important jobs that every enterprise application developer needs to do:

- Work with SQL query results
- Modify and validate rows in database tables

Entity-based view objects can query any selection of data that you want the end user to be able to view and modify. Any data the end user is allowed to change will be validated and saved by your reusable business domain layer. The key ingredients you provide as the developer are the ones that only *you* can know:

- You decide what business logic should be enforced in your business domain layer
- You decide what queries describe the data you need to put on the screen

These are the things that make *your* application unique. The built-in functionality of your entity-based view objects handles the rest of the implementation details.

> **Note:**
>
> Understanding row keys and what role the entity cache plays in the transaction are important concepts that help to clarify the nature of the entity-based view objects. These two concepts are addressed in ViewObject Interface Methods for Working with the View Object's Default RowSet.

What Happens at Runtime: After a View Object Executes Its Query

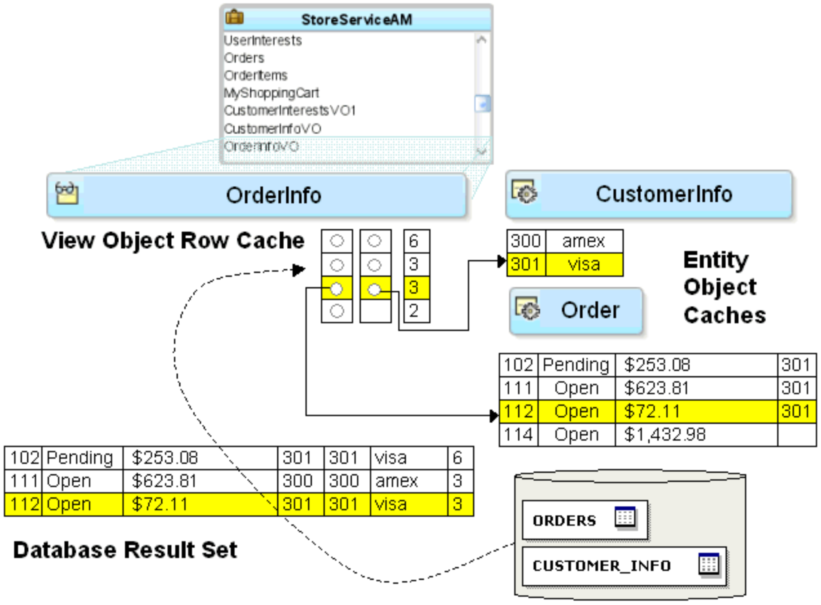
After adding an instance of an entity-based view object to the application module's data model, you can see what happens at runtime when you execute the query. Like a read-only view object, an entity-based view object sends its SQL query straight to the database using the standard Java Database Connectivity (JDBC) API, and the database produces a result set. In contrast to its read-only counterpart, however, as the entity-based view object retrieves each row of the database result set, it partitions the row attributes based on which entity usage they relate to. This partitioning occurs by creating an entity object row of the appropriate type for each of the view object's entity usages, populating them with the relevant attributes retrieved by the query, and storing each of these entity rows in its respective entity cache. Then, rather than storing duplicate copies of the data, the view row simply *points* at the entity row parts that comprise it.

Figure 8-13 illustrates how the entity cache partitions the result set attributes of two entity-based view objects. In this example, the highlighted row in the database result set is partitioned into an `Order` entity row with primary key `112` and a `CustomerInfo` entity row with primary key `301`.

As described in The Role of the Entity Cache in the Transaction, the entity row that is brought into the cache using `findByPrimaryKey()` contains *all* attributes of the entity object. In contrast, an entity row created by partitioning rows from the entity-based view object's query result contains values only for attributes that appear in the query. It does *not* include the complete set of attributes. This partially populated entity row represents an important runtime performance optimization.

Since the ratio of rows retrieved to rows modified in a typical enterprise application is very high, you can save memory by bringing only the attributes into memory that you need to display instead of bringing all attributes into memory all the time.

Figure 8-13 Entity Cache Partitions View Rows into Entity Rows



○	○	6
○	○	3
○	○	3
○		2

300	amex
301	visa

102	Pending	$253.08	301
111	Open	$623.81	301
112	Open	$72.11	301
114	Open	$1,432.98	

102	Pending	$253.08	301	301	visa	6
111	Open	$623.81	300	300	amex	3
112	Open	$72.11	301	301	visa	3

By partitioning queried data this way into its underlying entity row constituent parts, the first benefit you gain is that all of the rows that include some data queried will display a consistent result when changes are made in the current transaction. In other words, if one view object allows the PaymentType attribute of customer 301 to be modified, then all rows in any entity-based view object showing the PaymentType attribute for customer 301 will update instantly to reflect the change. Since the data related to customer 301 is stored exactly once in the CustomerInfo entity cache in the entity row with primary key 301, any view row that has queried the order's PaymentType attribute is just pointing at this single entity row.

Luckily, these implementation details are completely hidden from a client working with the rows in a view object's row set. The client works with a view row, getting and setting the attributes, and is unaware of how those attributes might be related to entity rows behind the scenes.

What Happens at Runtime: After a View Row Attribute Is Modified

When a user attempts to update the attribute of a view row, a series of steps occur to automatically coordinate this view row attribute modification with the underlying entity row. These steps ensure that a validation rule defined on the entity-mapped attribute will be triggered before the value is changed.

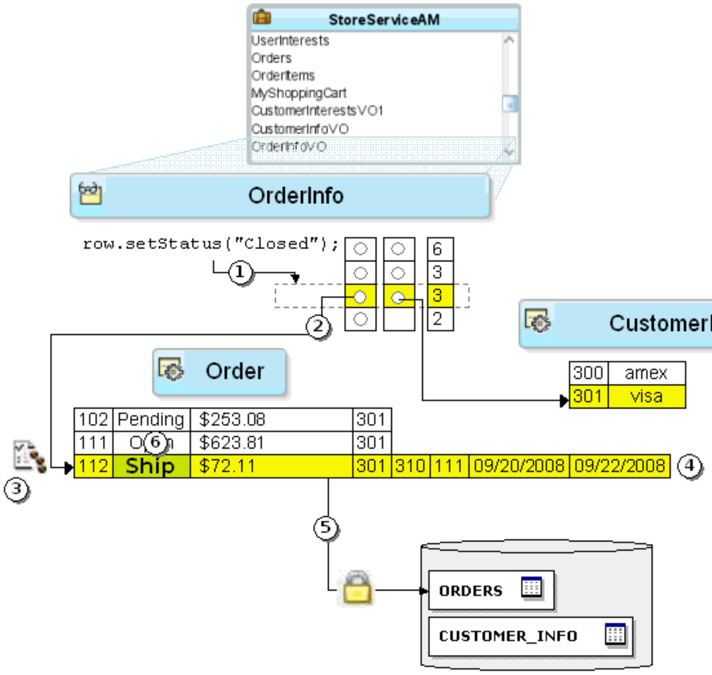
Figure 8-14 illustrates the basic steps that occur at runtime when the user attempts to update an entity-mapped attribute. In this example, the modified attribute Status is mapped to an entity usage where a validation rule is defined.

1. The user attempts to set the Status attribute to the value Ship.
2. Since Status is an entity-mapped attribute from the Order entity usage, the view row delegates the attribute set to the appropriate underlying entity row in the Order entity cache having primary key 112.
3. Any attribute-level validation rules on the Status attribute of the Order entity object are evaluated and the modification attempt will fail if any rule does not succeed.

   Assume that some validation rule for the Status attribute programmatically references the ShipDate attribute (for example, to enforce a business rule that an Order cannot be shipped the same day it is placed). The ShipDate was not one of the Order attributes retrieved by the query, so it is not present in the partially populated entity row in the Order entity cache.
4. To ensure that business rules can always reference all attributes of the entity object, the entity object detects this situation and "faults-in" the entire set of Order entity object attributes for the entity row being modified using the primary key (which must be present for each entity usage that participates in the view object).
5. After the attribute-level validations all succeed, the entity object attempts to acquire a lock on the row in the ORDERS table before allowing the first attribute to be modified.
6. If the row can be locked, the attempt to set the Status attribute in the row succeeds and the value is changed in the entity row.

> **Note:**
>
> The `jbo.locking.mode` configuration property controls how rows are locked. The default value is `optimistic`. Typically, Fusion web applications will use the default setting `optimistic`, so that rows aren't locked until transaction commit time. In `pessimistic` locking mode, the row must be lockable before any change is allowed to it in the entity cache.

Figure 8-14 View Row Attribute Updates Delegate to the Entity



What Happens at Runtime: After a Foreign Key Attribute is Changed

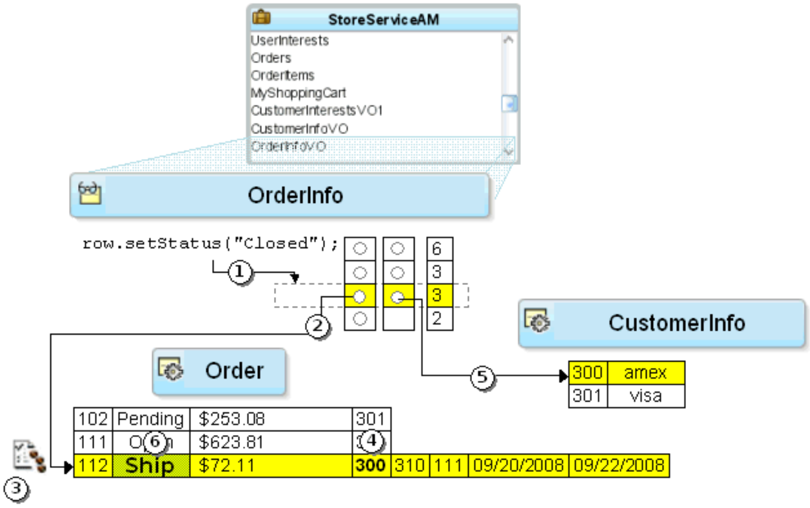
When a user attempts to update a foreign key attribute, a series of steps occur to automatically coordinate this view row attribute modification with the underlying entity row. These steps ensure that a validation rule defined on the foreign key, entity-mapped attribute will be triggered before the value is changed. They also ensure that the view row for the changed foreign key attribute reflects the correct attributes of all referenced entity objects.

Figure 8-15 illustrates the basic steps that occur at runtime when the user attempts to update a foreign key, entity-mapped attribute. In this example, the modified attribute `CustomerInfoId` is mapped to an entity usage `Order` where the attribute is associated with another entity object `CustomerInfo`.

1. The user attempts to set the `CustomerInfoId` attribute to the value `300`.
2. Since `CustomerInfoId` is an entity-mapped attribute from the `Order` entity usage, the view row delegates the attribute set to the appropriate underlying entity row in the `Order` entity cache, which has primary key `112`.

3. Any attribute-level validation rules on the `CustomerInfoId` attribute of the `Order` entity object are evaluated and the modification attempt will fail if any rule does not succeed.
4. The row is already locked, so the attempt to set the `CustomerInfoId` attribute in the row succeeds and the value is changed in the entity row.
5. Since the `CustomerInfoId` attribute on the `Order` entity usage is associated with the `CustomerInfo` entity object, this change of foreign key value causes the view row to replace its current entity row part for customer `301` with the entity row corresponding to the new `CustomerInfoId = 300`. This effectively makes the view row for order `112` point to the entity row for `300`, so the value of the `PaymentType` in the view row updates to reflect the correct reference information for this newly assigned customer.

Figure 8-15 After Updating a Foreign Key, View Row Points to a New Entity



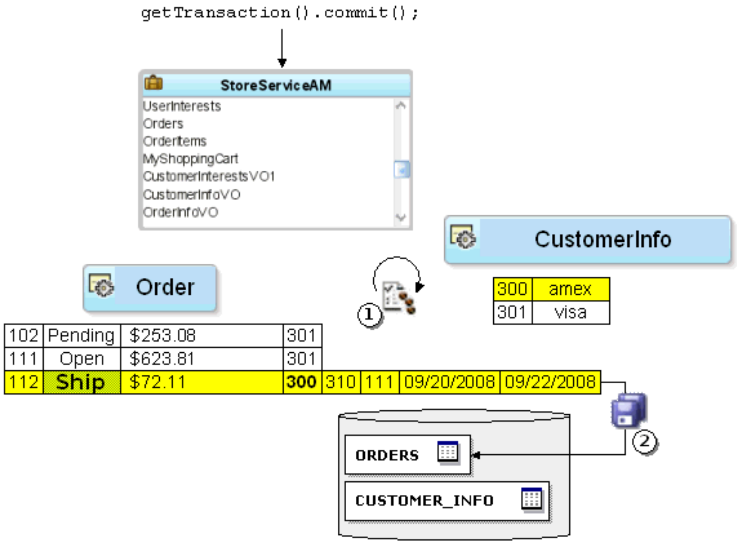
What Happens at Runtime: After a Transaction is Committed

Suppose the user is satisfied with the changes, and commits the transaction. As shown in Figure 8-16, there are two basic steps:

1. The `Transaction` object validates any invalid entity rows in its pending changes list.
2. The entity rows in the pending changes list are saved to the database.

The figure depicts a loop in Step 1 before the act of validating one modified entity object might programmatically affect changes to other entity objects. Once the transaction has processed its list of invalid entities on the pending changes list, if the list has entities, the transaction will complete another pass. It will attempt up to ten passes through the list. If by that point there are still invalid entity rows, it will throw an exception because this typically means you have an error in your business logic that needs to be investigated.

Figure 8-16 Committing the Transaction Validates Invalid Entities, Then Saves Them



What Happens at Runtime: After a View Object Requeries Data

When you reexecute a view object's query, by default the view rows in its current row set are "forgotten" in preparation for reading in a fresh result set. This view object operation does not directly affect the entity cache, however. The view object then sends the SQL to the database and the process begins again to retrieve the database result set rows and partition them into entity row parts.

> **Note:**
>
> Typically when the view object requeries data, you expect it to retrieve the latest database information. If instead you want to avoid a database roundtrip by restricting your view object to querying only over existing entity rows in the cache, or over existing rows already in the view object's row set, see Performing In-Memory Sorting and Filtering of Row Sets.

How Unmodified Attributes are Handled During Requery

As part of the entity row partitioning process during a requery, if an attribute on the entity row is unmodified, then its value in the entity cache is updated to reflect the newly queried value.

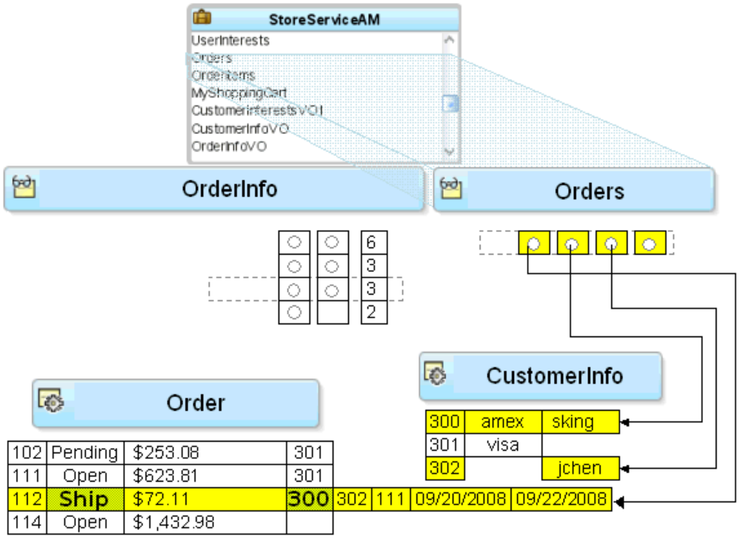
How Modified Attributes are Handled During Requery

However, if the value of an entity row attribute has been *modified* in the current transaction, then during a requery the entity row partitioning process does not refresh its value. Uncommitted changes in the current transaction are left intact so the end-user's logical unit of work is preserved. As with any entity attribute value, these pending modifications continue to be consistently displayed in any entity-based view object rows that reference the modified entity rows.

> **Note:**
>
> End-user row inserts and deletes are also managed by the entity cache, which permits new rows to appear and deleted rows to be skipped during requerying. For more information about new row behavior, see Maintaining New Row Consistency Between View Objects Based on the Same Entity.

For example, Figure 8-17 illustrates the scenario where a user "drills down" to a different page that uses the `Orders` view object instance to retrieve all details about order `112` and that this happens in the context of the current transaction's pending changes. That view object has two entity usages: a primary `Orders` usage and a reference usage for `CustomerInfo`. When its query result is partitioned into entity rows, it ends up pointing at the same `Order` entity row that the previous `OrderInfo` view row had modified. This means the end user will correctly see the pending change, that the order is assigned to `sking` in this transaction.

Figure 8-17 Entity Cache Merges Sets of Entity Attributes from Different View Objects



How Overlapping Subsets of Attributes are Handled During Requery

Two different view objects can retrieve two *different* subsets of reference information and the results are merged whether or not they have matching sets of attributes. For example, Figure 8-17 also illustrates the situation, where the `Orders` view object queries the user's `Email`, while the `OrderInfo` view object queried the user's `PaymentOption`. The figure shows what happens at runtime: if while partitioning the retrieved row, the entity row part contains a different set of attributes than does the partially populated entity row that is already in the cache, the attributes get "merged". The result is a partially populated entity row in the cache with the *union* of the overlapping subsets of user attributes. In contrast, for `jchen` (user 302), who wasn't in the cache already, the resulting new entity row contains only the `Email` attribute, but not the `PaymentOption`.

What You May Need to Know About Optimizing View Object Runtime Performance

The view object provides tuning parameters that let you control how SQL is executed and how data is fetched from the database. These tuning parameters play a significant role in the runtime performance of the view object. If the fetch options are not tuned correctly for the application, then your view object may fetch an excessive amount of data and may make too many roundtrips to the database.

You can use the **Tuning** section of the General page of the overview editor to configure the fetch options shown in Table 8-2.

Table 8-2 Parameters to Tune View Object Performance

Fetch Tuning Parameters	Usage
Fetch Mode	The default fetch option is the **All Rows** option, which will be retrieved **As Needed** (`FetchMode="FETCH_AS_NEEDED"`) or **All at Once** (`FetchMode="FETCH_ALL"`), depending on which option is desired. The **As Needed** option ensures that an `executeQuery()` operation on the view object initially retrieves only as many rows as necessary to fill the first page of a display, whose number of rows is set based on the view object's range size.
Fetch Size	In conjunction with the **Fetch Mode** option, the **in Batches of** field controls the number of records fetched at one time from the database (`FetchSize` in the view object XML). The default value is 1, which will give poor performance unless only one row will be fetched. The suggested configuration is to set this value to *n*+3 where *n* is the number of rows to be displayed in the user interface. For more information about how this parameter may affect memory requirements, see Consider Whether Fetching One Row at a Time is Appropriate.

Table 8-2 (Cont.) Parameters to Tune View Object Performance

Fetch Tuning Parameters	Usage
Max Fetch Size	The default max fetch size for a view object is -1, which means that there is no limit to the number of rows the view object can fetch. In cases where the result set should contain only *n* rows of data, the option **Only up to row number** should be selected and set to *n*. The developer can alternatively call `setMaxFetchSize(n)` to set this programmatically or manually add the parameter `MaxFetchSize` to the view object XML. For view objects whose `WHERE` clause expects to retrieve a single row, set the option **At Most One Row**. This way the view object knows you don't expect any more rows and it will skip its normal test for that situation. As mentioned earlier, setting a maximum fetch size of 0 (zero) makes the view object insert-only. In this case, no select query will be issued, so no rows will be fetched. When you want to specify a global threshold for all view object queries in the application, you can configure the **Row Fetch Limit** property in the `adf-config.xml` file. Setting this property means you can avoid changing the **Max Fetch Size** for individual query operations. If you do specify a fetch limit for individual view objects, the **Row Fetch Limit** setting will be ignored in those cases. For more details about **Row Fetch Limit**, see Using Fetch Size to Limit the Maximum Number of Records Fetched for a View Object.
Forward-only Mode	If a data set will only be traversed going forward, then forward-only mode can help performance when iterating through the data set. This can be configured by programmatically calling `setForwardOnly(true)` on the view object. Setting forward-only will also prevent caching previous sets of rows as the data set is traversed.

When you tune view objects, you should also consider these issues:

- Large data sets: View objects provide a mechanism to page through large data sets such that a user can jump to a specific page in the results. This is configured by calling `setRangeSize(n)` followed by `setAccessMode(RowSet.RANGE_PAGING)` on the view object where *n* is the number of rows contained within one page. When the user navigates to a specific page in the data set, the application can call `scrollToRangePage(P)` on the view object to navigate to page *P*. Range paging fetches and caches only the current page of rows in the view object row cache at the cost of another query execution to retrieve each page of data. Range paging is not appropriate where it is beneficial to have all fetched rows in the view object row cache (for example, when the application needs to read all rows in a dataset for an LOV or page back and forth in records of a small data set.

- Spillover: There is a facility to use the data source as "virtual memory" when the JVM container runs out of memory. By default, this is disabled and can be turned on as a last resort by setting `jbo.use.pers.coll=true`. Enabling spillover can have a large performance impact.
- SQL platform: If the generic SQL92 SQL platform is used to connect to generic SQL92-compliant databases, then some view object tuning options will not function correctly. The parameter that choosing the generic SQL92 SQL platform affects the most is the fetch size. When SQL92 SQL platform is used, the fetch size defaults to 10 rows regardless of what is configured for the view object. You can set the SQL platform when you define the database connection or you can define it as global project setting in the `adf-config.xml` file. By default, the SQL platform will be `Oracle`. To manually override the SQL platform, you can also pass the parameter `-Djbo.SQLBuilder="SQL92"` to the JVM upon startup.

Additionally, you have some options to tune the view objects' associated SQL for better database performance:

- Bind variables: If the query associated with the view object contains values that may change from execution to execution, use bind variables. Using bind variables in the query allows the query to reexecute without needing to reparse the query on the database. You can add bind variables to the view object in the Query page of the overview editor for the view object. For more information, see Working with Bind Variables.
- Query optimizer hints: The view object can pass hints to the database to influence which execution plan to use for the associated query. The optimizer hints can be specified in the **Retrieve from the Database** group box in the Tuning section of the overview editor for the view object. For information about optimizer hints, see Specify a Query Optimizer Hint if Necessary.

Testing View Object Instances Programmatically

You can use client programs to test an ADF application module programmatically.

When you are ready to test a working application module containing at least one view object instance, you can build a simple test client program to illustrate the basics of working programmatically with the data in the contained view object instances.

From the point of view of a client accessing your application module's data model, the API's to work with a read-only view object and an entity-based view object are identical. The key functional difference is that entity-based view objects allow the data in a view object to be fully updatable. The application module that contains the entity-based view objects defines the unit of work and manages the transaction. This section presents test client programs that work with the `SummitADF_Examples` workspace to illustrate:

- Iterating master-detail-detail hierarchy
- Finding a row and updating a foreign key value
- Creating a new order
- Retrieving the row key identifying a row

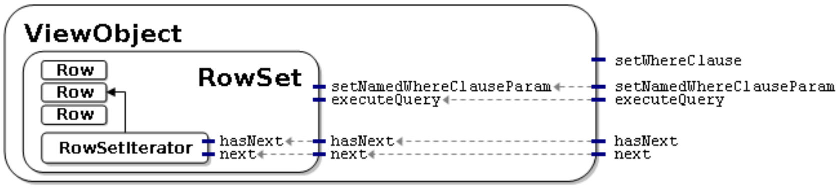
ViewObject Interface Methods for Working with the View Object's Default RowSet

The `ViewObject` interface in the `oracle.jbo` package provides the methods to easily perform any data-retrieval task. Some of these methods used in the example include:

- `executeQuery()`, to execute the view object's query and populate its row set of results
- `setWhereClause()`, to add a dynamic predicate at runtime to narrow a search
- `setNamedWhereClauseParam()`, to set the value of a named bind variable
- `hasNext()`, to test whether the **row set iterator** has reached the last row of results
- `next()`, to advance the row set iterator to the next row in the row set
- `getEstimatedRowCount()`, to count the number of rows a view object's query would return

Typically, when you work with a view object, you will work with only a single row set of results at a time. To simplify this overwhelmingly common use case, as shown in Figure 8-18, the view object contains a default `RowSet`, which, in turn, contains a default `RowSetIterator`. The default `RowSetIterator` allows you to call all of the data-retrieval methods directly on the `ViewObject` component itself, knowing that they will apply automatically to its default row set.

Figure 8-18 ViewObject Contains a Default RowSet and RowSetIterator



> **Note:**
>
> Defining Polymorphic View Objects presents situations when you might want a single view object to produce *multiple* distinct row sets of results. You can also find scenarios for creating *multiple* distinct row set iterators for a row set. Most of the time, however, you'll need only a single iterator.

The phrase "working with the rows in a view object," when used in this guide more precisely means working with the rows in the view object's default row set. Similarly, the phrase "iterate over the rows in a view object," more precisely means you will use the default row set iterator of the view object's default row set to loop over its rows.

The Role of the Key Object in a View Row or Entity Row

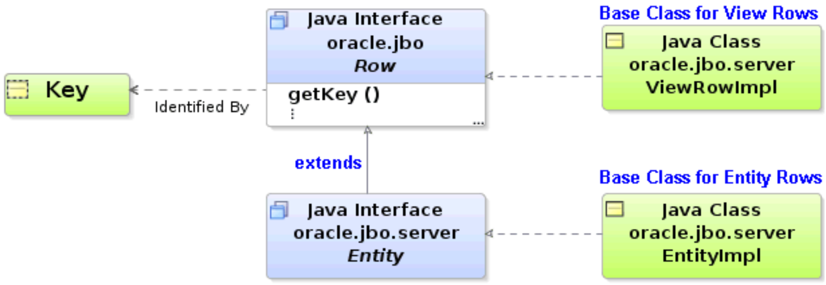
When you work with view rows you use the `Row` interface in the `oracle.jbo` package. As shown in Figure 8-19, the interface contains a method called `getKey()` that you can use to access the Key object that identifies any row. Notice that the Entity interface in the oracle.jbo.server package extends the Row interface. This relationship provides a concrete explanation of why the term *entity row* is so appropriate. Even though an entity row supports additional features for encapsulating business logic and handling database access, you can still treat any entity row as a Row.

An entity-based view object delegates the task of finding rows by key to its underlying entity row parts.

Recall that both view rows and entity rows support either single-attribute or multiattribute keys, so the Key object related to any given Row will encapsulate all of the attributes that comprise its key. Once you have a Key object, you can use the findByKey() method on any row set to find a row based on its Key object. When you use the findByKey() method to find a view row by key, the view row proceeds to use the entity definition's findByPrimaryKey() method to find each entity row contributing attributes to the view row key.

In the case of a read-only view object with no underlying entity row to which to delegate this task, the view object implementation automatically enables the manageRowsByKey flag when at least one primary key attribute is detected. This ensures that the findByKey() method is successful in the case of read-only view objects. If the manageRowsByKey flag is not enabled, then UI operations like setting the current row with the key, which depend on the findByKey() method, would not work.

Figure 8-19 Any View Row or Entity Row Supports Retrieving Its Identifying Key



Note:

When you define an entity-based view object, by default the primary key attributes for all of its entity usages are marked with their **Key Attribute** property set to true. In any *nonupdatable* reference entity usages, you should disable the **Key Attribute** property for the key attributes. Since view object attributes related to the primary keys of *updatable* entity usages must be part of the composite view row key, their **Key Attribute** property cannot be disabled.

The Role of the Entity Cache in the Transaction

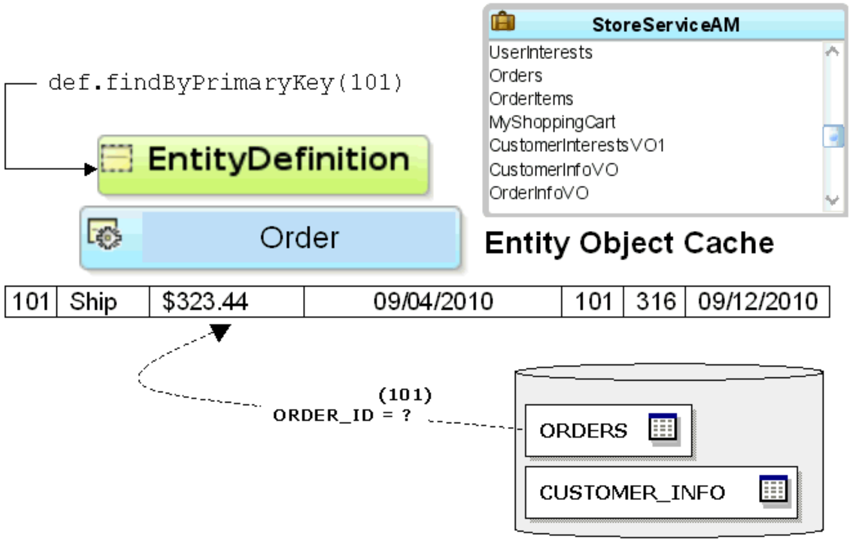
An application module is a transactional container for a logical unit of work. At runtime, it acquires a database connection using information from the named configuration you supply, and it delegates transaction management to a companion Transaction object.

Since a logical unit of work may involve finding and modifying multiple entity rows of different types, the `Transaction` object provides an entity cache as a "work area" to hold entity rows involved in the current user's transaction. Each entity cache contains rows of a single entity type, so a transaction involving two or more entity objects holds the working copies of those entity rows in separate caches.

By using an entity object's related entity definition, you can write code in an application module to find and modify existing entity rows. As shown in Figure 8-20, by calling `findByPrimaryKey()` on the entity definition for the `Order` entity object, you can retrieve the row with that key. If it is not already in the entity cache, the entity object executes a query to retrieve it from the database. This query selects all of the entity object's persistent attributes from its underlying table, and finds the row using an appropriate `WHERE` clause against the column corresponding to the entity object's primary key attribute. Subsequent attempts to find the same entity row by key during the same transaction will find it in the cache, preventing the need for a trip to the database. In a given entity cache, entity rows are indexed by their primary key. This makes finding an entity row in the cache a fast operation.

When you access related entity rows using association accessor methods, they are also retrieved from the entity cache. If related entity rows are not in the cache, then they are retrieved from the database. Finally, the entity cache is also the place where new entity rows wait to be saved. In other words, when you use the `createInstance2()` method on the entity definition to create a new entity row, it is added to the entity cache.

Figure 8-20 Entity Cache Stores Entity Rows During the Transaction



When an entity row is created, modified, or removed, it is automatically enrolled in the transaction's list of pending changes. When you call `commit()` on the `Transaction` object, it processes its pending changes list, validating new or modified entity rows that might still be invalid. When the entity rows in the pending list are all valid, the `Transaction` issues a database `SAVEPOINT` and coordinates saving the entity rows to the database. If all goes successfully, it issues the final database `COMMIT` statement. If anything fails, the `Transaction` performs a `ROLLBACK TO SAVEPOINT` to allow the user to fix the error and try again.

The Transaction object used by an application module represents the working set of entity rows for a single end-user transaction. By design, it is *not* a shared, global cache. The database engine itself is an extremely efficient shared, global cache for multiple, simultaneous users. Rather than attempting to duplicate all the work of fine-tuning that has gone into the database's shared, global cache functionality, ADF Business Components consciously embraces it. To refresh a single entity object's data from the database at any time, you can call its refresh() method. You can setClearCacheOnCommit() or setClearCacheOnRollback() on the Transaction object to control whether entity caches are cleared at commit or rollback. The defaults are false and true, respectively. The Transaction object also provides a clearEntityCache() method you can use to programmatically clear entity rows of a given entity type (or all types). When you clear an entity cache, you allow entity rows of that type to be retrieved from the database fresh the next time they are either found by primary key or retrieved by an entity-based view object.

How to Create a Command-Line Java Test Client

To the create a test client program, use the Create Java Class wizard, which is accessible from the New Gallery.

Generating a Test Client with Skeleton Code

When you use the Create Java Class wizard to create the test client program, JDeveloper will open your program file in the source editor and allow you to add code from a predefined code template to complete the test client.

Before you begin:

It may be helpful to have an understanding of programmatic testing. For more information, see Testing View Object Instances Programmatically.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Testing View Instances.

To generate a skeleton Java test client:

1. In the Applications window, right-click the project in which you want to create the test client and choose **New** and then **Java Class**.
2. In the Create Java Class dialog, enter a class name and a package name and ensure that the **Extends** field shows java.lang.Object.
3. In **Optional Attributes**, deselect **Constructors from Superclass** and select **Main Method**.
4. Click **OK**.

   The .java file opens in the source editor to show the skeleton code, as shown in the following example. In this example, TestClient is the class name and oracle.summit.model.test is the package name.

```
package oracle.summit.model.test;

public class TestClient {
  public static void main(String[] args) {
     TestClient testClient = new TestClient();
  }
}
```

Modifying the Skeleton Code to Create the Test Client

After you generate skeleton code for the test client, you can proceed to edit the file using the skeleton code template you created.

Before you begin:

It may be helpful to have an understanding of programmatic testing. For more information, see Testing View Object Instances Programmatically.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Testing View Instances.

You will need to complete this task:

Create create the test client skeleton code, as described in Generating a Test Client with Skeleton Code.

To insert the skeleton code:

1. Place the cursor on a blank line inside the body of the `main()` method and type the name of your test client class and then press Ctrl + Enter.
2. Type the characters `bc4jclient` and then press Ctrl + Enter.
3. Adjust the values of the `amDef` and`config` variables to reflect the names of the application module definition and the configuration that you want to use, respectively.

   For the example below, the changed lines look like this:

   ```
   String amDef = "oracle.summit.model.viewobjects.AppModule";
   String config = "AppModuleLocal";
   ```
4. Finally, change the view object instance name in the call to `findViewObject()` to the one you want to work with. Specify the name exactly as it appears in the **Data Model** tree on the Data Model page of the overview editor for the application module.

   the changed line looks like this:

   ```
   ViewObject customerList = am.findViewObject("SCustomerView1");
   ```

Your skeleton test client for your application module should contain source code like what you see in the following example.

> **Note:**
>
> The examples throughout Working Programmatically with an Application Module's Client Interface expand this test client sample code to illustrate calling custom application module service methods, too.

```
package oracle.summit.model.viewobjects;

import oracle.jbo.ApplicationModule;
import oracle.jbo.Row;
import oracle.jbo.RowSet;
```

```
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;

public class TestClient {

  public static void main(String[] args) {
    String  amDef = "oracle.summit.model.viewobjects.AppModule";
    String  config = "AppModuleLocal";
    ApplicationModule am =
                      Configuration.createRootApplicationModule(amDef,config);
    // 1. Find the Customer view object instance.
    ViewObject customerList = am.findViewObject("SCustomerView1");
    // Work with your appmodule and view object here
    Configuration.releaseRootApplicationModule(am,true);
  }
}
```

The method call `createRootApplicationModule()` allows test clients to create an **application module instance** where the **ADF Model** layer is unavailable. Normally, in the Fusion web applications your code finds the view object on the application module through **ADF binding** objects. For more information about how to work with the ADF Model layer, see How to Access an Application Module Client Interface in a Fusion Web Application.

Replace `// Work with your appmodule and view object here` , with code that will execute the view objects you want to test. For example, to execute the view object's query, display the number of rows it will return, and loop over the result to fetch the data and print it out to the console, you can adapt the code shown in the following example for your data model project components.

```
    // 2. Execute the query
    customerList.executeQuery();
    // 3. Iterate over the resulting rows
    while (customerList.hasNext()) {
        Row customer = customerList.next();
        // 4. Print the customer's name
        System.out.println("Customer: " + customer.getAttribute("Name"));
        // 5. Get related rowset of Orders using view link accessor attribute
        RowSet orders = (RowSet)customer.getAttribute("SOrdView");
        // 6. Iterate over the Orders rows
        while (orders.hasNext()) {
            Row order = orders.next();
            // 7. Print out some order attribute values
              System.out.println(" ["+order.getAttribute("CustomerId")+"] "+
                                   order.getAttribute("Id")+": "+
                                   order.getAttribute("Total"));
              if(!order.getAttribute("OrderFilled").equals("Y")) {
                  // 8. Get related rowset of OrderItems
                  RowSet items = (RowSet)order.getAttribute("SItemView");
                  // 9. Iterate over the OrderItems rows
                  while (items.hasNext()) {
                     Row item = items.next();
                     // 10. Print out some order items attributes
                     System.out.println("  "+item.getAttribute("ItemId")+": "+
                                          item.getAttribute("Price"));
                }
            }
        }
    }
```

The first line calls the `executeQuery()` method to execute the view object's query. This produces a row set of zero or more rows that you can loop over using a `while` statement that iterates until the view object's `hasNext()` method returns `false`. Inside the loop, the code puts the current `Row` in a variable named `customer`, then invokes the `getAttribute()` method twice on that current `Row` object to get the value of the `Name` and `Orders` attributes to print order information to the console. A second `while` statement performs the same task for the line items of the order.

What Happens When You Run a Test Client Program

The call to `createRootApplicationModule()` on the `Configuration` object returns an instance of the application module to work with. As you might have noticed in the debug diagnostic output, the ADF Business Components runtime classes load XML documents as necessary to instantiate the application module and the instance of the view object component that you've defined in its data model at design time. The `findViewObject()` method on the application module finds a view object instance by name from the application module's data model. After the loop described in Modifying the Skeleton Code to Create the Test Client, the test client executes `releaseRootApplicationModule()` on the `Configuration` object. This signals that you're done using the application module and it allows the framework to clean up resources, like the database connection that was used by the application module.

What You May Need to Know About Running a Test Client

The `createRootApplicationModule()` and `releaseRootApplicationModule()` methods are very useful for command-line access to application module components. However, you typically won't need to write these two lines of code in the context of an ADF-based web application. The ADF Model layer cooperates automatically with the ADF **business services layer** to acquire and release ADF application module components for you in those scenarios. For more information about how to work with the ADF Model layer, see How to Access an Application Module Client Interface in a Fusion Web Application.

How to Count the Number of Rows in a Row Set

The `getEstimatedRowCount()` method is used on a `RowSet` to determine how many rows it contains:

```
long numOrders = orders.getEstimatedRowCount();
```

The implementation of the `getEstimatedRowCount()` initially issues a `SELECT COUNT(*)` query to calculate the number of rows that the query will return. The query is formulated by "wrapping" your view object's entire query in a statement like:

```
SELECT COUNT(*) FROM ( ... your view object's SQL query here ... )
```

The `SELECT COUNT(*)` query allows you to access the count of rows for a view object without necessarily retrieving all the rows themselves. This approach permits an important optimization for working with queries that return a large number of rows, or for testing how many rows a query *would* return before proceeding to work with the results of the query.

Once the estimated row count is calculated, subsequent calls to the method do not reexecute the `COUNT(*)` query. The value is cached until the next time the view object's query is executed, since the fresh query result set returned from the database could potentially contain more, fewer, or different rows compared with the last time the query was run. The estimated row count is automatically adjusted to account for pending changes in the current transaction, adding the number of relevant new rows and subtracting the number of removed rows from the count returned.

You can also override `getEstimatedRowCount()` to perform a custom count query that suits your application's needs.

How to Access a Detail Collection Using the View Link Accessor

Once you've retrieved the `RowSet` of detail rows using a **view link accessor**, as described in Programmatically Accessing a Detail Collection Using the View Link Accessor, you can loop over the rows it contains using the same pattern used by the view object's row set of results, as shown in the following example.

```
while (orders.hasNext()) {
  Row curOrder = orders.next();
  System.out.println("--> (" + curOrder.getAttribute("Id") + ") " +
                     curOrder.getAttribute("Total"));
}
```

The following example shows the `main()` method sets a dynamic `WHERE` clause to restrict the `CustomerView` view object instance to show only customers whose `credit_rating_id` has the value `4`. Additionally, the `executeAndShowResults()` method accesses the view link accessor attribute (`SOrdView`) and prints out the order `Id` and `Total` attribute for each customer.

To access the a detail collection using a view link accessor, follow these basic steps (as illustrated in the following example):

1. Find the master view object instance.
2. Execute the query.
3. Iterate over the master view object rows.
4. Get the related row set of the detail view object using the view link accessor attribute.
5. Iterate over the detail view object rows.
6. Optionally, do something with the detail row set attributes.

> **Performance Tip:**
>
> If the code you write to loop over the rows does not need to display them, then you can call the `closeRowSet()` method on the row set when you're done. This technique will make memory use more efficient. The next time you access the row set, its query will be reexecuted.

```
package oracle.summit.model.viewobjects;

import oracle.jbo.ApplicationModule;
import oracle.jbo.Row;
import oracle.jbo.RowSet;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;
```

```
public class TestClient2 {
    public static void main(String[] args) {
            String        amDef = "oracle.summit.model.viewobjects.AppModule";
            String config = "AppModuleLocal";
            ApplicationModule am =
                Configuration.createRootApplicationModule(amDef, config);
            ViewObject vo = am.findViewObject("SCustomerView1");
          // Add an extra where clause with a new named bind variable
            vo.setWhereClause("credit_rating_id = :theCreditRating");
            vo.defineNamedWhereClauseParam("theCreditRating", null, null);
            vo.setNamedWhereClauseParam("theCreditRating", "4");
          // Show results when :theCreditRating = '4'
          executeAndShowResults(vo);
          Configuration.releaseRootApplicationModule(am, true);
        }
        private static void executeAndShowResults(ViewObject vo) {
          System.out.println("---");
          vo.executeQuery();
          while (vo.hasNext()) {
            Row curCustomer = vo.next();
            // Access the row set of details using the view link accessor attr.
            RowSet orders = (RowSet)curCustomer.getAttribute("SOrdView");
            long numOrders = orders.getEstimatedRowCount();
            System.out.println(curCustomer.getAttribute("Id") + " " +
                               curCustomer.getAttribute("Name")+" ["+
                               numOrders+" orders]");
            while (orders.hasNext()) {
              Row curOrder = orders.next();
              System.out.println("--> (" + curOrder.getAttribute("Id") + ") " +
                                 curOrder.getAttribute("Total"));
            }
          }
        }
}
```

Running `TestClient2.java` produces output in the Log window, as shown in the following example. Each customer is listed, and for each customer that has some orders, the order ID and total appears beneath their name.

```
---
202 Simms Athletics [11 orders]
--> (98) 595
--> (113) 4990
--> (114) 567
--> (115) 866.7
--> (116) 3661.24
--> (117) 17489
212 Hamada Sport [22 orders]
--> (108) 149570
--> (196) 761
--> (197) 516.75
...
```

If you run `TestClient2.java` with debug diagnostics enabled, you will see the SQL queries that the view object performed. The view link `WHERE` clause predicate is used to automatically perform the filtering of the detail service request rows for the current row in the `CustomerView` view object.

How to Iterate Over a Master-Detail-Detail Hierarchy

To iterate over a master-detail with an additional level of nesting, follow these basic steps (as illustrated in the following example):

1. Find the master view object instance.
2. Executes the query.
3. Iterate over the resulting rows.
4. Optionally, do something with the attributes of the master row set.
5. Get the related row set of the detail view object using the view link accessor attribute.
6. Iterate over the detail row set rows.
7. Optionally, do something with the attributes of the detail row set.
8. Get the related row set of the second detail view object using the view link accessor attribute.
9. Iterates over the second detail row set rows.
10. Optionally, do something with the second detail row set attributes.

Other than having one additional level of nesting, the following example uses the same API's used in the `TestClient` program that was iterating over master-detail read-only view objects in How to Access a Detail Collection Using the View Link Accessor.

If you use JDeveloper's **Refactor > Duplicate** functionality on an existing `TestClient.java` class, you can quickly "clone" it to create a `TestClient2.java` class. For example, the `TestClient.java` class described in How to Access a Detail Collection Using the View Link Accessor is suited to this technique.

```
package oracle.summit.model.viewobjects;

import oracle.jbo.ApplicationModule;
import oracle.jbo.Row;
import oracle.jbo.RowSet;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;

public class TestClient {
    public static void main(String[] args) {
        TestClient testClient = new TestClient();
        String amDef = "oracle.summit.model.viewobjects.AppModule";
        String config = "AppModuleLocal";
        ApplicationModule am =

Configuration.createRootApplicationModule(amDef,config);
        // Work with your appmodule and view object here
        // 1. Find the Customer view object instance.
        ViewObject customerList = am.findViewObject("SCustomerView1");
        // 2. Execute the query
          customerList.executeQuery();
          // 3. Iterate over the resulting rows
          while (customerList.hasNext()) {
              Row customer = customerList.next();
              // 4. Print the person's email
              System.out.println("Customer: " + customer.getAttribute("Name"));
              // 5. Get related rowset of Orders using view link accessor attr.
              RowSet orders = (RowSet)customer.getAttribute("SOrdView");
              // 6. Iterate over the Orders rows
              while (orders.hasNext()) {
                  Row order = orders.next();
                  // 7. Print out some order attribute values
                    System.out.println(" ["+order.getAttribute("CustomerId")+"]
"+
                                          order.getAttribute("Id")+": "+
                                          order.getAttribute("Total"));
                    if(order.getAttribute("OrderFilled").equals("Y")) {
                        // 8. Get related rowset of Items
                        RowSet items = (RowSet)order.getAttribute("SItemView");
                        // 9. Iterate over the Items rows
                        while (items.hasNext()) {
                           Row item = items.next();
                           // 10. Print out some order items attributes
                           System.out.println("  "+
                                                item.getAttribute("ItemId")+":
$"+

                                                item.getAttribute("Price"));
                      }
                  }
              }
          }
    }
}
```

Running the program produces the output shown in the following example.

```
Customer: Unisports
 [201] 97: 84000
  210: $9
  211: $1500
Customer: Simms Athletics
 [202] 98: 595
  212: $85
 [202] 113: 4990
  328: $9
 [202] 114: 567
  329: $28
  330: $40.95
  331: $25
...
```

How to Find a Row and Update a Foreign Key Value

To find a row and update a foreign key value, follow these basic steps (as illustrated in the following example):

1. Find the view object instance.
2. Construct a `Key` object to look up the row for the view instance.
3. Use `findByKey()` to find the row.
4. Optionally, do something with the row's attribute.

The following example shows the `main()` method finds and updates a foreign key value to find a row of the `Orders` view object instance. The sample then prints out the existing value of the `OrderStatusCode` attribute before changing the value on the row.

```
package oracle.summit.model.viewobjects;

import java.text.ParseException;
import java.text.SimpleDateFormat;

import java.util.Calendar;
import java.util.Date;

import oracle.jbo.ApplicationModule;
import oracle.jbo.JboException;
import oracle.jbo.Key;
import oracle.jbo.Row;
import oracle.jbo.RowSet;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;

public class TestClient3 {
    public TestClient3() {
        super();
    }

    public static void main(String[] args) {
        String amDef = "oracle.summit.model.viewobjects.AppModule";
        String config = "AppModuleLocal";
        ApplicationModule am =
                         Configuration.createRootApplicationModule(amDef, 
config);
        // 1. Find the Orders view object instance
        ViewObject vo = am.findViewObject("SOrdView1");
        // 2. Construct a new Key to find Order # 100
        Key orderKey = new Key(new Object[] { 100 });
        // 3. Find the row matching this key
        Row[] ordersFound = vo.findByKey(orderKey, 1);
        if (ordersFound != null && ordersFound.length > 0) {
            Row order = ordersFound[0];
            // 4. Print some order information
            Date dateOrdered = (Date) order.getAttribute("DateOrdered");
            String orderDate = dateOrdered.toString();
            System.out.println("Order Date is: " + orderDate);

            SimpleDateFormat sdf = new SimpleDateFormat("yyyy-MM-dd");
            Calendar c = Calendar.getInstance();
            try {
                c.setTime(sdf.parse(orderDate));
            } catch (ParseException e) {
            }
            c.add(Calendar.DAY_OF_MONTH, -2);
            // // number of days to add
            orderDate = sdf.format(c.getTime());
            System.out.println(orderDate);
            try {
                // 5. Try setting the ship date to an illegal value
                order.setAttribute("DateShipped", orderDate);
                am.getTransaction().commit();
            } catch (JboException ex) {
                System.out.println("ERROR: " + ex.getMessage());
            }
            // 6. Set the ship date to a legal value
            order.setAttribute("DateShipped", orderDate);
            // 7. Show the value of the ship date was updated successfully
            System.out.println("Ship date is: " +
                                                  order.getAttribute("DateShipped"));
                // 8. Show the current value of the customer for this order
                System.out.println("Customer: " + order.getAttribute("CustomerId"));
                // 9. Reassign the order to customer # 210
                order.setAttribute("CustomerId", 210);
                // 10. Show the value of the reference information now
                System.out.println("Customer: " + order.getAttribute("CustomerId"));
                // 11. Rollback the transaction
                am.getTransaction().rollback();
                System.out.println("Transaction canceled");
            }
            Configuration.releaseRootApplicationModule(am, true);
        }

}
```

Running this example produces the output shown in the following example.

```
Order Date is: 2012-08-29
2012-08-27
ERROR: JBO-oracle.summit.model.viewobjects.SOrd_Rule_0:
       You cannot have a shipping date that is before the order date
Ship date is: 2012-08-27
Customer: 204
Customer: 210
Transaction canceled
```

How to Create a New Row for a View Object Instance

To create a new view row instance, follow these basic steps (as illustrated in the following example):

1. Find the view object instance.
2. Create a new row and insert it into the row set.
3. Set the values of the required attributes in the new row.
4. Commit the transaction.

The following example shows the `main()` method finds the `OrdView` view object instance and inserts a new row into the row set. Because the `OrdView` view object is entity-based, the `CreatedBy` attribute derives its value from the mapped entity object attribute. The sample then sets values for the remaining attributes before committing the transaction.

```
package oracle.summit.model.viewobjects;

import java.util.Date;

import oracle.jbo.ApplicationModule;
import oracle.jbo.Row;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;
import oracle.jbo.domain.DBSequence;

public class TestClient4 {

  public static void main(String[] args) {
        String amDef = "oracle.summit.model.viewobjects.AppModule";
        String config = "AppModuleLocal";
        ApplicationModule am =
                         Configuration.createRootApplicationModule(amDef,
config);

        // 1. Find the Orders view object instance.
        ViewObject orders = am.findViewObject("SOrdView1");

        // 2. Create a new row and insert it into the row set
        Row newOrder = orders.createRow();
        orders.insertRow(newOrder);
        // Show the entity object-related defaulting for DateOrdered attribute
        System.out.println("DateOrdered defaults to: " +
                                    newOrder.getAttribute("DateOrdered"));

        // 3. Set values for some of the required attributes
        newOrder.setAttribute("CustomerId", 201);
        newOrder.setAttribute("SalesRepId", 12);
        newOrder.setAttribute("PaymentTypeId", 2);
        newOrder.setAttribute("OrderFilled", "N");

        // 4. Commit the transaction
        am.getTransaction().commit();

        // 5. Retrieve and display the trigger-assigned order id
        DBSequence id = (DBSequence)newOrder.getAttribute("Id");
        System.out.println("Thanks, reference number is " +
                                                  id.getSequenceNumber());
        Configuration.releaseRootApplicationModule(am, true);
  }
}
```

Running this example produces the results shown in the following example.

```
DateOrdered defaults to: 2013-3-11
Thanks, reference number is 6
```

How to Retrieve the Row Key Identifying a Row

To retrieve a row key to identify a row, follow these basic steps (as illustrated in the following example):

1. Find the view object instance.
2. Construct a key using a supplied value.
3. Find the row with this key.
4. Optionally, do something with the key of the row.

The following example shows the `main()` method finds the `OrdView` view object instance and constructs a row key to find an order number. The `findByKey()` method find the `OrdView` rows with the specified key. The sample then displays the key of the row, accesses the row set using the `ItemView` view link accessor, and iterates over the rows to display the key of each `ItemView` row.

```
package oracle.summit.model.viewobjects;

import oracle.jbo.ApplicationModule;
import oracle.jbo.Key;
import oracle.jbo.Row;
import oracle.jbo.RowSet;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;

public class TestClient5 {
    public static void main(String[] args) {
        String amDef = "oracle.summit.model.viewobjects.AppModule";
        String config = "AppModuleLocal";
        ApplicationModule am =
                        Configuration.createRootApplicationModule(amDef,
config);
        // 1. Find the Orders view object instance
        ViewObject vo = am.findViewObject("SOrdView1");
        // 2. Construct a key to find order number 100
        Key orderKey = new Key(new Object[] { 100 });
        // 3. Find the Orders row with the key
        Row[] ordersFound = vo.findByKey(orderKey, 1);
        if (ordersFound != null && ordersFound.length > 0) {
             Row order = ordersFound[0];
             // 4. Displays the key of the Orders row
             showKeyFor(order);
             // 5. Accesses row set of Orders using OrderItems view link accessor
             RowSet items = (RowSet)order.getAttribute("SItemView");
             // 6. Iterates over the Items row
             while (items.hasNext()) {
                 Row itemRow = items.next();
                 // 4. Displays the key of each Items row
                 showKeyFor(itemRow);
             }
        }
        Configuration.releaseRootApplicationModule(am, true);
    }

    private static void showKeyFor(Row r) {
       // get the key for the row passed in
       Key k = r.getKey();
       // format the key as "(val1,val2)"
       String keyAttrs = formatKeyAttributeNamesAndValues(k);
       // get the serialized string format of the key, too
       String keyStringFmt = r.getKey().toStringFormat(false);
       System.out.println("Key " + keyAttrs + " has string format " +
                          keyStringFmt);
    }

    // Build up "(val1,val2)" string for key attributes
    private static String formatKeyAttributeNamesAndValues(Key k) {
       StringBuffer sb = new StringBuffer("(");
       int attrsInKey = k.getAttributeCount();
       for (int i = 0; i < attrsInKey; i++) {
           if (i > 0)
               sb.append(",");
               sb.append(k.getAttributeValues()[i]);
       }
       sb.append(")");
       return sb.toString();
    }
}
```

Running the example produces the results shown in the following example. Notice that the serialized string format of a key is a hexadecimal number that includes information in a single string that represents all the attributes in a key.

```
Key (100) has string format 000100000003313030
Key (100,156) has string format 000200000003C2020200000002C102
Key (100,157) has string format 000200000003C2020200000002C102
...
```

What You May Need to Know About Using Partial Keys with findByKey()

View objects based on multiple entity usages support the ability to find view rows by specifying a partially populated key. A partial key is a multi-attribute `Key` object with some of its attributes set to `null`. However, there are strict rules about what kinds of partial keys can be used to perform the `findByKey()`.

If a view object is based on *n* entity usages, where *n* > 1, then the view row key is by default comprised of all of the primary key attributes from *all* of the participating entity usages. Only the ones from the *first* entity object are *required* to participate in the view row key, but by default all of them do.

If you allow the key attributes from some *secondary* entity usages to remain as key attributes at the view row level, then you should leave *all* of the attributes that form the primary key for that entity object as part of the view row key. Assuming you have left the one or more key attributes in the view row for *m* of the *n* entity usages, where (*m* <= *n*), then you can use `findByKey()` to find rows based on any subset of these *m* entity usages. Each entity usage for which you provide values in the `Key` object, requires that you must provide non-null values for *all* of the attributes in that entity's primary key.

You have to follow this rule because when a view object is based on at least one or more entity usages, its `findByKey()` method finds rows by delegating to the `findByPrimaryKey()` method on the entity definition corresponding to the first entity usage whose attributes in the view row key are non-null. The entity definition's `findByPrimaryKey()` method requires all key attributes for any given entity object to be non-null in order to find the entity row in the cache.

As a concrete example, imagine that you have a `OrderInfoVO` view object with a `OrderEO` entity object as its primary entity usage, and an `AddressEO` entity as secondary reference entity usage. Furthermore, assume that you leave the **Key Attribute** property of *both* of the following view row attributes set to `true`:

- `OrderId` — primary key for the `OrderEO` entity
- `AddressId` — primary key for the `AddressEO` entity

The view row key will therefore be the (`OrderId`, `AddressId`) combination. When you do a `findByKey()`, you can provide a `Key` object that provides:

- A completely specified key for the underlying `OrderEO` entity

  ```
  Key k = new Key(new Object[]{new Number(200), null});
  ```

- A completely specified key for the underlying `AddressEO` entity

  ```
  Key k = new Key(new Object[]{null, new Number(118)});
  ```

- A completely specified key for both entities

  ```
  Key k = new Key(new Object[]{new Number(200), new Number(118)});
  ```

When a valid partial key is specified, the `findByKey()` method can return multiple rows as a result, treating the missing entity usage attributes in the Key object as a wildcard.

How to Authenticate Test Users in the Test Client

If you have enabled ADF Security for your application and provisioned the `jazn-data.xml` file with test users, you will need to include method calls to authenticate a user before you run the test client. To authenticate a user in the test client, follow these basic steps (as illustrated in the following exxample):

1. Create the authentication service.
2. Pass in the login credentials for a test user defined in the `jazn-data.xml` file.
3. If authentication succeeds, then test the application module.
4. Log the user out.

For details about how to run the Configure ADF Security wizard to enable ADF Security and how to create test users in JDeveloper's identity store, see ADF Security Process Overview.

```
package oracle.summit.model.test;
import oracle.jbo.ApplicationModule;
import oracle.jbo.Key;
import oracle.jbo.Row;
import oracle.jbo.RowSet;
import oracle.jbo.ViewObject;
import oracle.jbo.client.Configuration;

import oracle.adf.share.security.AuthenticationService;
import oracle.adf.share.security.authentication.AuthenticationServiceUtil;
import oracle.adf.share.ADFContext;
import oracle.adf.share.security.SecurityContext;
import oracle.adf.share.security.SecurityEnv;

import javax.security.auth.Subject;

public class TestAuthenticationClient {
    public static void main(String[] args) {
        String amDef = "test.TestAuthModule";
        String config = "TestAuthModuleLocal";

        // 1. Create authentication service.
        AuthenticationService authService =
                            AuthenticationServiceUtil.getAuthenticationService();
        try
           {
              // 2. Pass in user id and password defined in local identity store.
              authService.login("tester1", "welcome1");
           }
           catch (Exception e)
           {

           }

        // Uncomment to output authentication status
        // String userName =
                       ADFContext.getCurrent().getSecurityContext().getUserName();

        // System.out.println("*** userName : " + userName);
        // Subject subject =
                       ADFContext.getCurrent().getSecurityContext().getSubject();
        // System.out.println("Subject : " + subject);

        // 3. Test application module if authentication succeeds.
        if (ADFContext.getCurrent().getSecurityContext().isAuthenticated()) {
           ApplicationModule am =
                       Configuration.createRootApplicationModule(amDef,config);
           ViewObject vo = am.findViewObject("TestView");
           // Work with your appmodule and view object here
           Configuration.releaseRootApplicationModule(am,true);

           // 4. Log out test user.
           authService.logout();

           // Uncomment to report logout success
           // boolean isAuthenticated =
                   ADFContext.getCurrent().getSecurityContext().isAuthenticated();
           // System.out.println("*** isAuthenticated : " + isAuthenticated);
        }

    }
}
```

Tuning View Object Performance

This chapter describes advanced techniques you can use while designing and working with your ADF view objects in an Oracle ADF application.
This chapter includes the following sections:

About View Object Tuning

JDeveloper provides you many tools to configure ADF Business Components view objects and improve their performance during transactions.

You can use view objects to read rows of data, create and store rows of transient data, as well as automatically coordinate inserts, updates, and deletes made by end users with your underlying business objects. How you design and use your view objects can definitely affect their performance at runtime. The JDeveloper design time for ADF Business Components provides a number of features that you can use to configure your view objects to get the best possible performance.

Maintaining New Row Consistency Between View Objects Based on the Same Entity

ADF Business Components automatically inserts a new row created in one view object instance into other view object instances based on the same entity object.

When multiple instances of entity-based view objects in an **application module** are based on the same underlying **entity object**, a new row created in one of them can be automatically added (without having to requery) to the row sets of the others to keep your user interface consistent or simply to consistently reflect new rows in different application pages for a pending transaction. Consider an application that displays a customer's list of orders. If the customer goes to create a new order, this task is performed through a different view object and handled by a custom application module method. Using the view object new row consistency feature, the newly created order automatically appears in the customer's list of open orders without having to requery the database.

For historical reasons, this capability is known as the **view link consistency** feature because in prior releases of **Oracle Application Development Framework** (Oracle ADF) the addition of new rows to other relevant row sets only was supported for detail view object instances in a view link based on an association. Now this view link consistency feature works for any view objects for which it is enabled, regardless of whether they are involved in a view link or not.

What Happens at Runtime: When View Link Consistency is Enabled

Consider two entity-based view objects `OrdersViewSummary` and `OrdersView` both based on the same underlying `Orders` entity object. When a new row is created in a row set for one of these view objects (like `OrdersView`) and the row's primary key is set, any of the *other* row sets for view objects based on the same `Orders` entity object (like `OrdersViewSummary`) receive an event indicating a new row has been created. If their view link consistency flag is enabled, then a copy of the new row is inserted into their row set as well.

> **Note:**
>
> By default the view link consistency mechanism adds new rows in an unqualified way. If you want to prevent the new rows from being added to the row sets of all participating view objects, you can write a filter expression on the RowMatch object to qualify the row before it is added to the row set. For more information, see Using RowMatch to Qualify Which New, Unposted Rows Get Added to a Row Set.

What You May Need to Know About Changing the Default View Link Consistency Setting

You can use the overview editor for application module configurations (on the `bc4j.xcfg` file) to control the default setting for the view link consistency feature using the `jbo.viewlink.consistent` configuration parameter.

To display the application module configuration overview editor, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink. In the application module configuration overview editor, select the **Properties** tab and click **Add Property** to select the property from the Add Property dialog and click **OK**.

The default setting for this parameter is the word `DEFAULT`which has the following meaning. If your view object has:

- A single entity usage, view link consistency is enabled
- Multiple entity usages, and:
  - If all secondary entity usages are marked as contributing reference information, then view link consistency is enabled
  - If any secondary entity usage marked as *not* being a reference view link consistency is disabled.

You can globally disable this feature by setting the `jbo.viewlink.consistent` to the value `false` in your configuration. Conversely, you could globally enable this feature by setting `jbo.viewlink.consistent` to the value `true`, but Oracle does *not* recommend doing this. Doing so would force view link consistency to be set on for view objects with secondary entity usages that are not marked as a reference which presently do not support the view link consistency feature well.

To set the feature programmatically, use the `setAssociationConsistent()` API on any `RowSet`. When you call this method on a view object, it affects its default row set.

Using RowMatch to Qualify Which New, Unposted Rows Get Added to a Row Set

If a view object has view link consistency enabled, any new row created by another view object based on the same entity object is added to its row set. By default the mechanism adds new rows in an unqualified way. If your view object has a design-time `WHERE` clause that queries only a certain subset of rows, you can apply a `RowMatch` object to your view object to perform the same filtering in-memory. The filtering expression of the `RowMatch` object you specify prevents new rows from being added that wouldn't make sense to appear in that view object.

For example, an `OrdersByStatus` view object might include a design time `WHERE` clause like this:

```
WHERE /* ... */ AND STATUS LIKE NVL(:StatusCode,'%')
```

Its custom Java class overrides the `create()` method as shown in the following example to force view link consistency to be enabled. It also applies a `RowMatch` object whose filtering expression matches rows whose `Status` attribute matches the value of the `:StatusCode` named bind variable (or matches any row if `:StatusCode` = '%'). This `RowMatch` filter is used by the view link consistency mechanism to qualify the row that is a candidate to add to the row set. If the row qualifies by the `RowMatch`, it is added. Otherwise, it is not.

```
// In OrdersByStatusImpl.java
protected void create() {
  super.create();
  setAssociationConsistent(true);
  setRowMatch(new RowMatch("Status = :StatusCode or :StatusCode = '%'"));
}
```

See Performing In-Memory Filtering with RowMatch for more information on creating and using a `RowMatch` object. For a list of supported SQL operators see Table 11-2. For a list of supported SQL function, see Table 11-3.

> **Note:**
>
> If the `RowMatch` facility does not provide enough control, you can override the view object's `rowQualifies()` method to implement a custom filtering solution. Your code can determine whether a new row qualifies to be added by the view link consistency mechanism or not.

What You May Need to Know About the Dynamic WHERE Clause and View Link Consistency

If you call `setWhereClause()` on a view object to set a dynamic `WHERE` clause, the view link consistency feature is disabled on that view object. If you have provided an appropriate custom `RowMatch` object to qualify new rows for adding to the row set, you can call `setAssociationConsistent(true)` after `setWhereClause()` to reenable view link consistency.

If a row set has view link consistency enabled, then new rows added due to creation by other row sets are added to the bottom of the row set.

If a row set has view link consistency enabled, then when you call the `executeQuery()` method, any qualifying new, unposted rows are added to the top of the row set before the queried rows from the database are added.

Using Bind Variables for Parameterized Queries

Use bind variables when values of the `WHERE` clause can change with every execution.

Whenever the `WHERE` clause of your query includes values that might change from execution to execution, you should use named bind variables. The Create View Criteria dialog that you display from the Query page of the view object overview editor makes this an easy task. Their use also protects your application against abuse through SQL injection attacks by malicious end-users. For information about defining **view criteria** with bind variables, see How to Create Named View Criteria Declaratively.

Use Bind Variables to Avoid Reparsing of Queries

Bind variables are place holders in the SQL string whose value you can easily change at runtime without altering the text of the SQL string itself. Since the query text doesn't change from execution to execution, the database can efficiently reuse the same parsed statement each time. Avoiding reparsing of your statement alleviates the database from having to continually re-determine its query optimization plan and eliminates contention by multiple end-users on other costly database resources used during this parsing operation. This savings leads to higher runtime performance of your application. See How to Add WHERE Clause Bind Variables to a View Object Definition for details on how to use named bind variables.

Use Bind Variables to Prevent SQL-Injection Attacks

Using bind variables for parameterized WHERE clause values is especially important if their values will be supplied by *end-users* of your application. Consider the following example. It adds a dynamic WHERE clause formed by concatenating a user-supplied parameter value into the statement.

```
// EXAMPLE OF BAD PRACTICE, Do not follow this approach!
String userSuppliedValue = ... ;
yourViewObject.setWhereClause("BANK_ACCOUNT_ID = "+userSuppliedValue);
```

A user with malicious intentions — if able to learn any details about your application's underlying database schema — could supply a carefully constructed "bank account number" as a field value or URL parameter like:

```
BANK_ACCOUNT_ID
```

When the code in the above example concatenates this value into the dynamically applied where clause, what the database sees is a query predicate like this:

```
WHERE (BANK_ACCOUNT_ID = BANK_ACCOUNT_ID)
```

This WHERE clause retrieves *all* bank accounts instead of just the current user's, perhaps allowing the hacker to view private information of another person's account. This technique of short-circuiting an application's WHERE clause by trying to supply a maliciously constructed parameter value into a SQL statement is called a SQL injection attack. Using named bind variables instead for these situations as shown in the followign example prevents the vulnerability.

```
// Best practice using named bind variables
String userSuppliedValue = ... ;
yourViewObject.setWhereClause("BANK_ACCOUNT_ID = :BankAcccountId");
yourViewObject.defineNamedWhereClauseParam("BankAcccountId", null, null);
yourViewObject.setNamedWhereClauseParam("BankAcccountId",userSuppliedValue);
```

If a malicious user supplies an illegal value in this case, they receive an error your application can handle instead of obtaining data they are not suppose to see.

Log Bind Parameter Values

When you want to be able to determine the bind parameter values that are used to execute the queries of your view objects, you can configure the log level before a test run or during a debug session. The log level you specify will determine the type and quantity of log messages. To view bind parameter information, you must set a minimum Java log level of CONFIG. For details about using and configuring the Log Analyzer, see How to Use the Log Analyzer to View Log Messages.

Alternatively, you can log bind parameter values programmatically, by overriding the bindParametersForCollection() method on the view object's ViewObjectImpl class. This method is used to log bind parameter names and values used in the query. Your implementation may log the bind parameter values, which is especially useful in those scenarios where the bind parameter is generated by the runtime. For example, when an ADF Faces Tree component is built using view link association, the nodes will be populated by bind parameters that you may log. The following example shows how to define the bindParametersForCollection() method for this purpose.

```
@Override protected void bindParametersForCollection(QueryCollection qc,
                                               Object[] params,
                                               PreparedStatement stmt) throws
SQLException {        String vrsiName = null;
        if (qc != null) {
            ViewRowSetImpl vrsi = qc.getRowSetImpl();
            vrsiName = vrsi.isDefaultRS() ? "<Default>" : vrsi.getName();
        }
        String voName = getName();
        String voDefName = getDefFullName();
        if (qc != null) {
            System.out.println("----[Exec query for VO=" + voName + ", RS=" +
                               vrsiName + "]----");
        } else {
            System.out.println("----[Exec COUNT query for VO=" + voName +
                               "]----");
        }
        System.out.println("VODef =" + voDefName);
        System.out.println(getQuery());
        if (params != null) {
            if (getBindingStyle() == SQLBuilder.BINDING_STYLE_ORACLE_NAME) {
                StringBuilder binds = new StringBuilder("BindVars:(");
                int paramNum = 0;
                for (Object param : params) {
                    paramNum++;
                    Object[] nameValue = (Object[])param;
                    String name = (String)nameValue[0];
                    Object value = nameValue[1];
                    if (paramNum > 1) {
                        binds.append(",");
                    }
                    binds.append(name).append("=").append(value);
                }
                binds.append(")");
                System.out.println(binds);
            }
        }
        super.bindParametersForCollection(qc, params, stmt);
```

Working with Multiple Row Sets and Row Set Iterators

JDeveloper allows you to create secondary, named rowsets and secondary, named rows set iterators.

While you typically work with a view object's *default* row set, you can call the `createRowSet()` method on the `ViewObject` interface to create secondary, named row sets based on the same view object's query. One situation where this could make sense is when your view object's SQL query contains named bind variables. Since each `RowSet` object stores its own copy of bind variable values, you could use a single view object to produce and process multiple row sets based on different combinations of bind variable values. You can find a named row set you've created using the `findRowSet()` method. When you're done using a secondary row set, call its `closeRowSet()` method.

For any `RowSet`, while you typically work with its *default* row set iterator, you can call the `createRowSetIterator()` method of the `RowSet` interface to create secondary, named row set iterators. You can find a named row set iterator you've created using the `findRowSetIterator()` method. When you're done using a secondary row set iterator, call its `closeRowSetIterator()` method.

> **Performance Tip:**
>
> When you need to perform programmatic iteration over a result set, create a secondary iterator to avoid disturbing the current row of the *default* row set iterator. For example, through the ADF Model declarative data binding layer, user interface pages in your application work with the default row set iterator of the default row set of view objects in the application module's data model. In this scenario, if you did not create a secondary row set iterator for the business logic you write to iterate over a view object's default row set, you would consequently change the current row of the *default* row set iterator used by the user interface layer.

Using Entity-Based View Objects for Read-Only Data

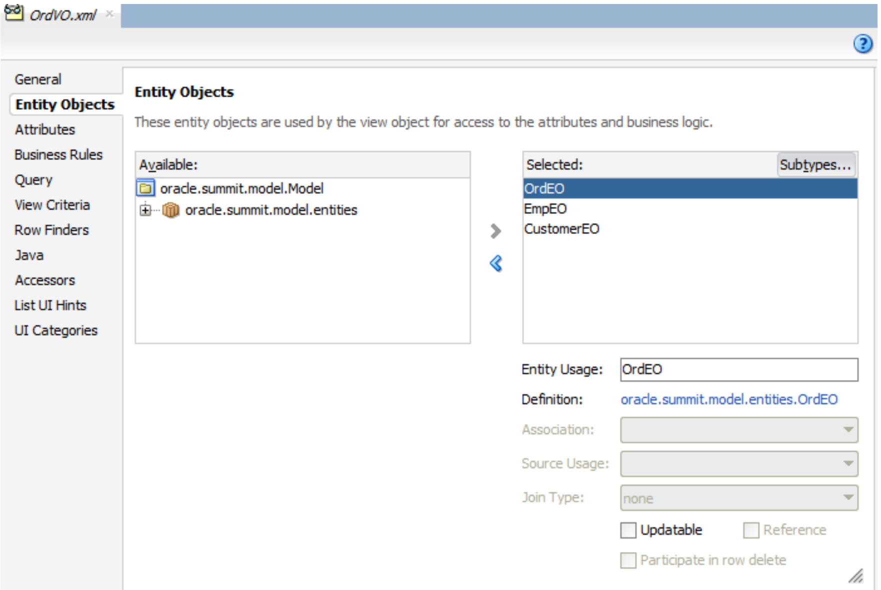
Depending on functional requirements, JDeveloper allows you to design read-only view objects. You use such view objects for SQL-validation and displaying list of values in a selection component to name a few.

Typically view objects used for SQL-based validation purposes, as well as for displaying the list of valid selections in a dropdown list, can be read-only. You need to decide what kind of functionality your application requires and design the view object accordingly.

> **Best Practice:**
>
> In previous releases, an Oracle best practice recommendation for read-only data had been to create read-only, custom SQL view objects. The purpose of this recommendation had been to avoid the overhead of storing the relating rows in an entity object cache. Oracle has now optimized a solution such that this best practice is no longer relevant.
>
> In the current release, when you need to create a read-only view object for data lookup, use the entity-based view object and deselect the **Updatable** option in the Entity Objects page of the view object overview editor. This approach has two benefits: First, it benefits from the design time editors which aid in generating the SQL query, and second, if you ever decide to make the view object updatable, it is already backed by an updatable entity object.
>
> The alternative of creating a read-only, custom SQL view object still has merit when you can specify a fully fledged SQL query, and will be especially useful for cases where Unions and Group By Queries cannot be expressed using entity objects.

View objects can either be related to underlying entity objects or not. When a view object is related to one or more underlying entity objects the default behavior supports creating new rows and modifying or removing queried rows. However, the update feature can be disabled by deselecting **Updatable** in the overview editor for the entity-based view object, as shown in Figure 9-1.

Figure 9-1 Deselecting the Updatable Option for an Entity-based View Object



Entity Objects

These entity objects are used by the view object for access to the attributes and business logic.

Available:
- oracle.summit.model.Model
- oracle.summit.model.entities

Selected:
- OrdEO
- EmpEO
- CustomerEO

Entity Usage: OrdEO

Definition: oracle.summit.model.entities.OrdEO

Association:

Source Usage:

Join Type: none

☐ Updatable ☐ Reference

☐ Participate in row delete

The alternative is to create a read-only view object and define the SQL query by selecting **Write Custom SQL** in the Query page of the overview editor. For the Business Components developer not comfortable with constructing a complex SQL statement, it will always be more convenient to create a nonupdatable view object based on an entity object since the editor simplifies the task of creating the query. Entity-based view objects that you set to nonupdatable compare favorably to read-only, custom SQL view objects:

- There is the ability to optimize the select list at runtime to include only those attributes that are required by the user interface
- There is no significant performance degradation incurred by using the entity object to create the local cache
- The data in the view object will reflect the state of the local cache rather than need to return to the database for each read operation
- The data in the local cache will stay consistent should another view object you define need to perform an update on the nonupdatable view object's base entity object.

So, while there is a small amount of runtime overhead associated with the coordination between view object rows and entity object rows (estimates show less than 5% overhead), weigh this against the ability to keep the view object definition entirely declarative and maintain a customizable view object. Custom SQL view objects are not customizable but they can be used to perform Unions and Group By queries that cannot be expressed in entity objects. Custom SQL view objects are also useful in SQL-based validation queries used by the view object-based Key Exists validator.

When data is not read-only, the best (and only) choice is to create entity-based view objects. Entity-based view objects that are updatable (default behavior) are the only way to pickup entity-derived attribute default values, reflect pending changes made to relevant entity object attributes through other view objects in the same transaction, and reflect updated reference information when foreign key attribute values are changed is to use an entity-based view object.

Using SQL Tracing to Identify Ill-Performing Queries

JDeveloper allows you to tune queries so that the query plan that is used by the database query optimizer is not doing a full table scan and creating performance overheads.

After deciding whether your view object should be mapped to entities or not, your attention should turn to the query itself. On the Query page of the view object overview editor, click the **Test and Explain** button to see the query plan that the database query optimizer will use. If you see that it is doing a full table scan, you should consider adding indexes or providing a value for the **Query Optimizer Hint** field on the **Tuning** section of the overview editor's General page. This will let you explicitly control which query plan will be used. These facilities provide some useful tools to the developer to evaluate the query plans for individual view object SQL statements. However, their use is not a substitute for tracing the SQL of the entire application to identify poorly performing queries in the presence of a production environment's amount of data and number of end users.

You can use the Oracle database's SQL Tracing facilities to produce a complete log of all SQL statements your application performs. The approach that works in all versions of the Oracle database is to issue the command:

```
ALTER SESSION SET SQL_TRACE TRUE
```

Specifically in version 10g of Oracle, the DBA would need to grant `ALTER SESSION` privilege in order to execute this command.

This command enables tracing of the current database session and logs all SQL statements to a server-side trace file until you either enter `ALTER SESSION SET SQL_TRACE FALSE` or close the connection. To simplify enabling this option to trace your Fusion web applications, override the `afterConnect()` method of your application module (or custom application module framework extension class) to conditionally perform the `ALTER SESSION` command to enable SQL tracing based on the presence of a Java system property as shown in the following example.

```
// In YourCustomApplicationModuleImpl.java
protected void afterConnect() {
  super.afterConnect();
  if (System.getProperty("enableTrace") != null) {
    getDBTransaction().executeCommand("ALTER SESSION SET SQL_TRACE TRUE");
  }
}
```

After producing a trace file, you use the `TKPROF` utility supplied with the database to format the information and to better understand information about each query executed like:

- The number of times it was (re)parsed
- The number of times it was executed
- How many round-trips were made between application server and the database
- Various quantitative measurements of query execution time

Using these techniques, you can decide which additional indexes might be required to speed up particular queries your application performs, or which queries could be changed to improve their query optimization plan. For details about working with the `TKPROF` utility, see sections "Understanding SQL Trace and TKPROF" and "Using the SQL Trace Facility and TKPROF" in the "Performing Application Tracing" chapter of the *Oracle Database SQL Tuning Guide*.

Note:

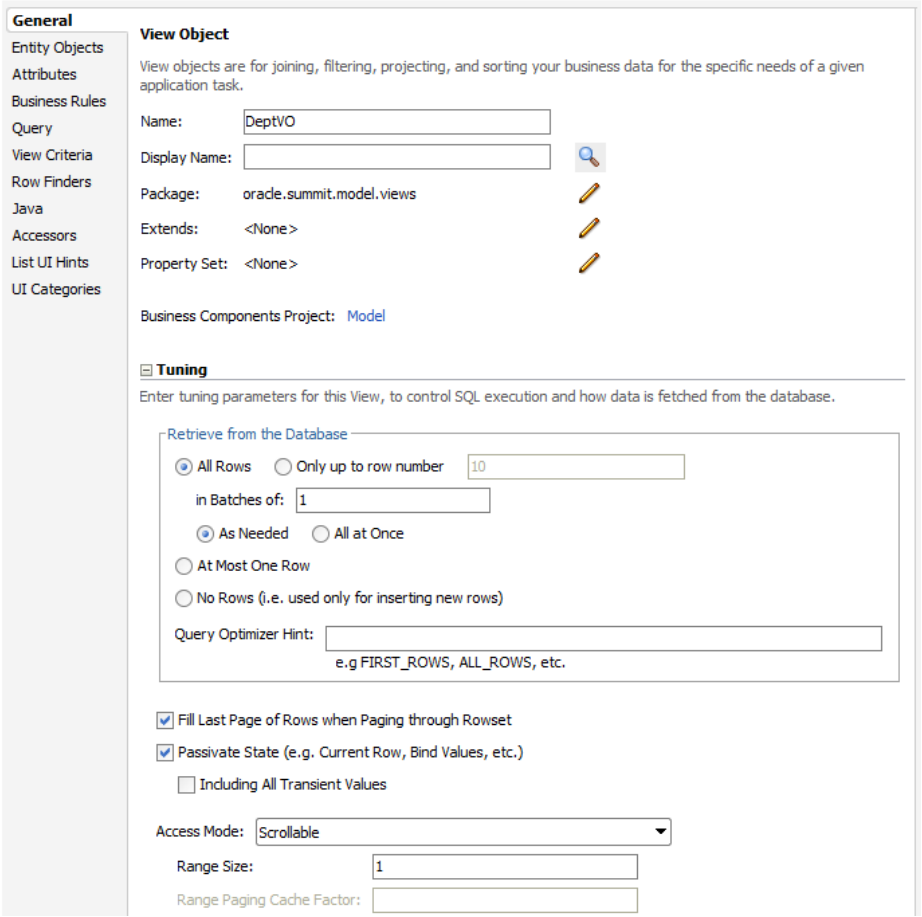
The Oracle database provides the `DBMS_MONITOR` package that further simplifies SQL tracing and integrates it with Oracle Enterprise Manager for visually monitoring the most frequently performed query statements your applications perform.

Using the Appropriate View Object Tuning Settings

The view object overview editor’s Tuning section provides various options to tune the query’s performance.

The Tuning section on the General page of the view object overview editor lets you set various options that can dramatically effect your query's performance. Figure 9-2 shows the default options that the new view object defines.

Figure 9-2 View Object Default Tuning Options



View Object

View objects are for joining, filtering, projecting, and sorting your business data for the specific needs of a given application task.

Name: DeptVO

Display Name:

⊟ **Tuning**

Enter tuning parameters for this View, to control SQL execution and how data is fetched from the database.

Retrieve from the Database

● All Rows ○ Only up to row number 10

in Batches of: 1

● As Needed ○ All at Once

○ At Most One Row

○ No Rows (i.e. used only for inserting new rows)

Query Optimizer Hint:

e.g FIRST_ROWS, ALL_ROWS, etc.

☑ Fill Last Page of Rows when Paging through Rowset

☑ Passivate State (e.g. Current Row, Bind Values, etc.)

☐ Including All Transient Values

Access Mode: Scrollable

Range Size: 1

Range Paging Cache Factor:

What You May Need to Know About the Retrieve from Database Options

In the Tuning section of the view object overview editor General page, the **Retrieve from the Database** group box controls how the view object retrieves rows from the database server. The options for the fetch mode are **All Rows**, **Only Up To Row Number, At Most One Row**, and **No Rows**. Most view objects will use the default **All Rows** option, which will be retrieved **As Needed** (default) or **All at Once** depending on which option you choose.

> **Note:**
>
> The **All at Once** option does not enforce a single database round trip to fetch the rows specified by the view object query. The **As Needed** and **All at Once** options work in conjunction with the value of **in Batches of** (also known as fetch size) to determine the number of round trips. For best database access performance, you should consider changing the fetch size as described in Consider Whether Fetching One Row at a Time is Appropriate.

The **As Needed** option ensures that an `executeQuery()` operation on the view object initially retrieves only as many rows as necessary to fill the first page of a display, whose number of rows is set based on the view object's range size. If you use **As Needed**, then you will require only as many database round trips as necessary to deliver the number of rows specified by the initial range size, as defined by the **Range Size** option. Whereas, if you use **All at Once**, then the application will perform as many round trips as necessary to deliver all the rows based on the value of **in Batches of** (fetch size) and the number of rows identified by the query.

For view objects whose `WHERE` clause expects to retrieve a *single* row, set the option to **At Most One Row** for best performance. This way, the view object knows you don't expect any more rows and will skip its normal test for that situation. Finally, if you use the view object only for creating new rows, for optimal performance set the option to **No Rows** so no query will ever be performed.

Before you begin:

It may be helpful to have an understanding of view objects. For more information, see About View Objects.

To set view object row fetch options:

1. In the Applications window, double-click the view object that you want to edit.
2. In the overview editor, click the **General** navigation tab and expand the **Tuning** section.
3. In the **Retrieve from the Database** group box, select the option to control how many rows should be fetched from the database.
4. Enter a **Query Optimizer Hint** hat the database will use to optimize the query for this view object.

   At runtime, the hint is added immediately after the SELECT keyword in the query. For example, you would enter `ALL_ROWS` when you want to retrieve all rows as quickly as possible or `FIRST_ROWS` when you want to retrieve the first rows as quickly as possible (rather than optimize the retrieval of all rows).

Consider Whether Fetching One Row at a Time is Appropriate

The fetch size controls how many rows will be returned in each round trip to the database. By default, the framework will fetch rows in batches of one row at a time. If you are fetching any more than one row, you will gain efficiency by setting this **in Batches of** value on the Tuning section of the General page of the view object overview editor.

Unless your query *actually* fetches just one row, leaving the *default* fetch size of one (1) in the **in Batches of** field is not recommended due to many unnecessary round trips between the application server and the database. Oracle strongly recommends considering the appropriate value for each view object's fetch size.

If you are displaying results *n* rows at a time in the user interface, for simple web pages, it is good to set the fetch size to at least *n*+3 so that each page of results can be retrieved in a single round trip to the database. However the higher the number, the larger the client-side buffer required, so avoid setting this number to values the exceed Oracle JDBC fetch size recommendations.

In general, fetch size should be consistent with Oracle database 12*c* recommendations, which state fetch size should be no more than 100, although in some cases larger size may be appropriate. For more information, see *Oracle JDBC Memory Management* for Oracle Database 12*c* located at `http://www.oracle.com/technetwork/database/application-development/jdbc-memory-management-12c-1964666.pdf`.

Before you begin:

It may be helpful to have an understanding of view objects. For more information, see About View Objects.

To limit the number of database roundtrips for a view object:

1. In the Applications window, double-click the view object that you want to edit.
2. In the overview editor, click the **General** navigation tab and expand the **Tuning** section.
3. In the **Retrieve from the Database** group box, select **All Rows** or **Only up to Row Number**.
4. In the **In Batches of** field, enter the number of rows to return from each database roundtrip.
5. Select the option **All at Once** when you want to fetch all rows whether or not the number of rows fetched fits within the web page displaying the row set. Otherwise, to fetch only the number of rows necessary to fill the first page of the web page displaying the row se, leave the default setting **As Needed** selected.

   If you select **All at Once**, then the application will perform as many roundtrips as necessary to deliver all the rows based on the value of **In Batches of** (fetch size) and the number of rows identified by the query.

Specify a Query Optimizer Hint if Necessary

The **Query Optimizer Hint** field allows you to specify an optional hint to the Oracle query optimizer to influence what execution plan it will use. You can set this hint in the Tuning page of the overview editor for the view object, as shown in Figure 9-2.

At runtime, the hint you provide is added immediately after the `SELECT` keyword in the query, wrapped by the special comment syntax `/*+` *`YOUR_HINT`* `*/`. Two common optimizer hints are:

- `FIRST_ROWS` — to hint that you want the first rows as quickly as possible
- `ALL_ROWS` — to hint that you want all rows as quickly as possible

There are many other optimizer hints that are beyond the scope of this manual to document. Reference the Oracle database reference manuals for more information on available hints.

Before you begin:

It may be helpful to have an understanding of view objects. For more information, see About View Objects.

To edit a view object definition:

1. In the Applications window, double-click the view object that you want to edit.
2. In the overview editor, click the **General** navigation tab and expand the **Tuning** section.

3. In the **Retrieve from the Database** group box, select the option to control how many rows should be fetched from the database.
4. Enter a **Query Optimizer Hint** hat the database will use to optimize the query for this view object.

   At runtime, the hint is added immediately after the SELECT keyword in the query. For example, you would enter `ALL_ROWS` when you want to retrieve all rows as quickly as possible or `FIRST_ROWS` when you want to retrieve the first rows as quickly as possible (rather than optimize the retrieval of all rows).

Using Fetch Size to Limit the Maximum Number of Records Fetched for a View Object

You can set an upper bound on the number of rows a view object retrieves. You can configure a global threshold for all view object queries or a threshold for a specific ADF view object query.

When your application needs to iterate over the rows of the view object query result, you may want to specify a maximum number of records to fetch. The default maximum fetch size of a view object is minus one (-1), which indicates there should be no limit to the number of rows that can be fetched. By default, rows are fetched as needed, so -1 does not imply a view object will necessarily fetch all the rows. It does means that if you attempt to iterate through all the rows in the query result, you will get them all.

To put an upper bound on the maximum number of rows that a view object will retrieve, use the following settings:

- You can configure a global threshold for all view objects queries using the **Row Fetch Limit** property on the Business Components page of the overview editor for the `adf-config.xml` file. You can locate the file in the Application Resources panel by expanding the **Descriptors** and **ADF META-INF** nodes.

  Note: Since **Row Fetch Limit** specifies a global threshold for all query operations in the application (including iterator binding property **RowCountThreshold** used to determine an estimated row count for the iterator result set), using this property means you can avoid changing settings for individual query operations where that operation's default behavior allows all rows to be fetched. If you do specify a fetch limit for individual view objects using the **Max Fetch Size**, then the **Row Fetch Limit** setting will be ignored in those cases. Note that the **Row Fetch Limit** setting is also ignored if the view object implementation class overrides `getRowLimit()` to return an appropriate value for a view object.
- You can configure a threshold for a specific view object query using the **Only up to row number** field selected in the Tuning section of the General page of the overview editor for the view object. Note that the Property Inspector displays this setting in the **Max Fetch Size** property.

> **Tip:**
>
> If you want to set the global threshold for query operations using **Row Fetch Limit** and you still need to allow specific view object queries to return all available rows, then you can set the **Max Fetch Size** with the **Only up to row number** field for those view objects to a very large number.

For example, if you write a query containing an `ORDER BY` clause and only want to return the first *n* rows to display the "Top-N" entries in a page, you can use the overview editor for the view object to specify a value for the **Only up to row number** field in the Tuning section of the General page. For example, to fetch only the first five rows, you would enter "5" in this field. This is equivalent to calling the `setMaxFetchSize()` method on your view object to set the maximum fetch size to `5`. The view object will stop fetching rows when it hits the maximum fetch size. Often you will combine this technique with specifying a **Query Optimizer Hint** of `FIRST_ROWS` also on the Tuning section of the General page of the overview editor. This gives a hint to the database that you want to retrieve the first rows as quickly as possible, rather than trying to optimize the retrieval of all rows.

Using Range Size to Present and Scroll Data a Page at a Time

You can configure an ADF view object to retrieve and manage a predetermined number of data-rows on each page.

To present and scroll through data a page at a time, you can configure a view object to manage for you an appropriately sized range of rows. The range facility allows a client to easily display and update a subset of the rows in a row set, as well as easily scroll to subsequent pages, *n* rows as a time. You call `setRangeSize()` to define how many rows of data should appear on each page. The default range size is one (`1`) row. A range size of minus one (`-1`) indicates the range should include all rows in the row set.

> **Note:**
>
> When using the declarative bindings in the **ADF Model** layer, the **iterator binding** in the **page definition file** has a `RangeSize` attribute. At runtime, the iterator binding invokes the `setRangeSize()` method on its corresponding **row set iterator**, passing the value of this `RangeSize` attribute. The ADF design time by default sets this `RangeSize` attribute to `10` rows for most iterator bindings. An exception is the range size specified for a List binding to supply the set of valid values for a UI component like a dropdown list. In this case, the default range size is minus one (`-1`) to allow the range to include all rows in the row set.

When you set a range size greater than one, you control the row set paging behavior using the iterator mode. The two iterator mode flags you can pass to the `setIterMode()` method are:

- `RowIterator.ITER_MODE_LAST_PAGE_PARTIAL`

  In this mode, the last page of rows may contain fewer rows than the range size. For example, if you set the range size to 10 and your row set contains 23 rows, the third page of rows will contain only three rows. This is the style that works best for Fusion web applications.

- `RowIterator.ITER_MODE_LAST_PAGE_FULL`

  In this mode, the last page of rows is kept full, possibly including rows at the top of the page that had appeared at the bottom of the previous page. For example, if you set the range size to 10 and your row set contains 23 rows, the third page of rows will contain 10 rows, the first seven of which appeared as the last seven rows of page two. This is the style that works best for desktop-fidelity applications using Swing.

Using Range Paging to Efficiently Scroll Through Large Result Sets

The Fusion web application allows you to limit very large query results by pre-determining how many ADF Business Components rows the query fetches. If it is very large, the end-user can be prompted to provide more filter criteria.

As a general rule, for highest performance, Oracle recommends building your application in a way that avoids giving the end user the opportunity to scroll through very large query results. To enforce this recommendation, call the `getEstimatedRowCount()` method on a view object to determine how many rows would be returned by the user's query *before* actually executing the query and allowing the user to proceed. If the estimated row count is unreasonably large, your application can demand that the end-user provide additional search criteria.

However, when you *must* work with very large result sets, typically over 100 rows, you can use the view object's access mode called "range paging" to improve performance. The feature allows your applications to page back and forth through data, a range of rows at a time, in a way that is more efficient for large data sets than the default "scrollable" access mode.

The range paging access mode is typically used for paging through read-only row sets, and often is used with read-only view objects. You allow the user to find the row they are looking for by paging through a large row set with range paging access mode, then you use the `Key` of that row to find the selected row in a different view object for editing.

Range paging for view objects supports a standard access mode and a variation of the standard access mode that combines the benefits of range paging and result set scrolling with a minimum number of visits to the database. These modes for the view object range paging feature include:

- `RANGE_PAGING`, standard access mode fetches the number of rows specified by a range size. In this mode, the number of rows that may be scrolled without requerying the database is determined by a range size that you set. The default is to fetch a single row, but it is expected that you will set a range size equal to the number of rows you want to be able to display to the user before they scroll to the next result set. The application requeries the database each time a row outside of the range is accessed by the end user. Thus, scrolling backward and forward through the row set will requery the database. For clarification about this database-centric paging strategy, see Understanding How Oracle Supports "TOP-N" Queries.
- `RANGE_PAGING_INCR`, incremental access mode gives the UI designer more flexibility for the number of rows to display at a time while keeping database queries to a minimum. In this mode, the UI incrementally displays the result set from the memory cache and thus supports scrolling within a single database query. The number of rows that the end user can scroll though in a single query is determined by the range size and a range paging cache factor that you set. For example, suppose that you set the range size to 4 and the cache factor to

5. Then, the maximum number of rows to cache in memory will be 4*5 = 20. For further explanation of the caching behavior, see What Happens When View Rows are Cached When Using Range Paging.

> **Note:**
>
> Additionally, the view object supports a `RANGE_PAGING_AUTO_POST` access mode to accommodate the inserting and deleting of rows from the row set. This mode behaves like the `RANGE_PAGING` mode, except that it eagerly calls `postChanges()` on the database transaction whenever any changes are made to the row set. However, this mode is typically not appropriate for use in Fusion web applications unless you can guarantee that the transaction will definitely be committed or rolled-back during the same HTTP request. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

Understanding How Oracle Supports "TOP-N" Queries

The Oracle database supports a feature called a "Top-N" query to efficiently return the first *n* ordered rows in a query. For example, if you have a query like:

```
SELECT EMPNO, ENAME,SAL FROM EMP ORDER BY SAL DESC
```

If you want to retrieve the top 5 employees by salary, you can write a query like:

```
SELECT * FROM (
   SELECT X.*,ROWNUM AS RN FROM (
      SELECT EMPNO,ENAME,SAL FROM EMP ORDER BY SAL DESC
   ) X
) WHERE RN <= 5
```

which gives you results like:

```
     EMPNO ENAME       SAL    RN
---------- -------- ------ ----
      7839 KING       5000     1
      7788 SCOTT      3000     2
      7902 FORD       3000     3
      7566 JONES      2975     4
      7698 BLAKE      2850     5
```

The feature is not only limited to retrieving the first *n* rows in order. By adjusting the criteria in the outermost `WHERE` clause you can efficiently retrieve any range of rows in the query's sorted order. For example, to retrieve rows `6` through `10` you could alter the query this way:

```
SELECT * FROM (
  SELECT X.*,ROWNUM AS RN FROM  (
     SELECT EMPNO,ENAME,SAL FROM EMP ORDER BY SAL DESC
  ) X
) WHERE RN BETWEEN 6 AND 10
```

Generalizing this idea, if you want to see page number *P* of the query results, where each page contains *R* rows, then you would write a query like:

```
SELECT * FROM (
  SELECT X.*,ROWNUM AS RN FROM (
    SELECT EMPNO,ENAME,SAL FROM EMP ORDER BY SAL DESC
  ) X
) WHERE RN BETWEEN ((:P - 1) * :R) + 1 AND (:P) * :R
```

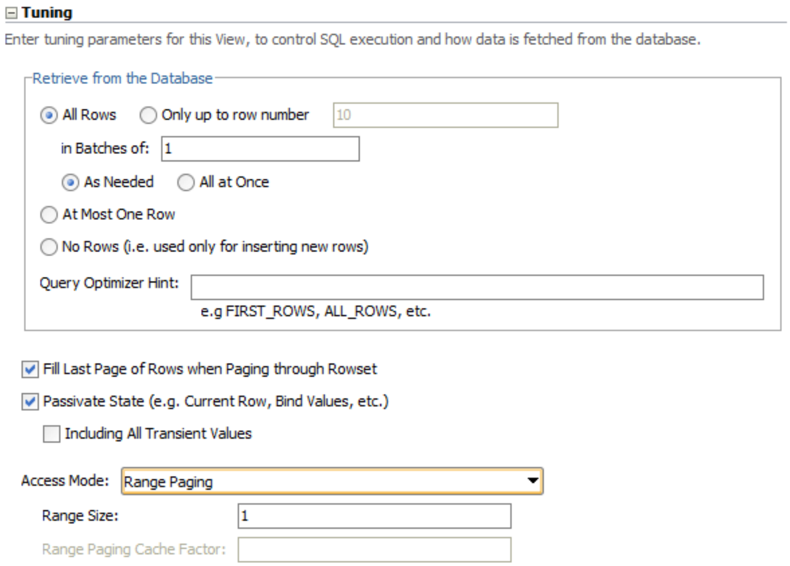
As the result set you consider grows larger and larger, it becomes more and more efficient to use this technique to page through the rows. Rather than retrieving hundreds or thousands of rows over the network from the database, only to display ten of them on the page, instead you can produce a clever query to retrieve only the `R` rows on page number `P` from the database. No more than a handful of rows at a time needs to be returned over the network when you adopt this strategy.

To implement this database-centric paging strategy in your application, you could handcraft the clever query yourself and write code to manage the appropriate values of the `:R` and `:P` bind variables. Alternatively, you can use the view object's range paging access mode, which implements it automatically for you.

How to Enable Range Paging for a View Object

You can use the Tuning panel of the overview editor for the view object to set the access mode to either standard range paging or incremental range paging. The **Range Paging Cache Factor** field is only editable when you select **Range Paging Incremental**. Figure 9-3 shows the view object's **Access Mode** set to **Range Paging** (standard mode) with the default range size of 1. To understand the row set caching behavior of both access modes, see What Happens When View Rows are Cached When Using Range Paging.

Figure 9-3 Access Mode in the Overview Editor for the View Object



⊟ Tuning

Enter tuning parameters for this View, to control SQL execution and how data is fetched from the database.

Retrieve from the Database

● All Rows ○ Only up to row number 10

in Batches of: 1

● As Needed ○ All at Once

○ At Most One Row

○ No Rows (i.e. used only for inserting new rows)

Query Optimizer Hint:

e.g FIRST_ROWS, ALL_ROWS, etc.

☑ Fill Last Page of Rows when Paging through Rowset

☑ Passivate State (e.g. Current Row, Bind Values, etc.)

□ Including All Transient Values

Access Mode: Range Paging

Range Size: 1

Range Paging Cache Factor:

To programmatically enable standard range paging for your view object, first call `setRangeSize()` to define the number of rows per page, then call the following method with the desired mode:

```
yourViewObject.setAccessMode(RowSet.RANGE_PAGING | RANGE_PAGING_INCR);
```

If you set RANGE_PAGING_INCR, then you must also call the following method to set the cache factor for your defined range size:

```
yourViewObject.setRangePagingCacheFactor(int f);
```

What Happens When You Enable Range Paging

When a view object's access mode is set to RANGE_PAGING, the view object takes its default query like:

```
SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
```

and automatically "wraps" it to produce a Top-N query.

For best performance, the statement uses a combination of greater than and less than conditions instead of the BETWEEN operator, but the logical outcome is the same as the Top-N wrapping query you saw above. The actual query produced to wrap a base query of:

```
SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
```

looks like this:

```
SELECT * FROM (
  SELECT /*+ FIRST_ROWS */ IQ.*, ROWNUM AS Z_R_N FROM (
    SELECT EMPNO, ENAME, SAL FROM EMP ORDER BY SAL DESC
  ) IQ  WHERE ROWNUM < :0)
WHERE Z_R_N > :1
```

The two bind variables are bound as follows:

- :1 index of the first row in the current page
- :0 is bound to the last row in the current page

What Happens When View Rows are Cached When Using Range Paging

When a view object operates in RANGE_PAGING access mode, it only keeps the current range (or "page") of rows in memory in the view row cache at a time. That is, if you are paging through results ten at a time, then on the first page, you'll have rows 1 through 10 in the view row cache. When you navigate to page two, you'll have rows 11 through 20 in the cache. This also can help make sure for large row sets that you don't end up with tons of rows cached just because you want to preserve the ability to scroll backwards and forwards.

When a view object operates in RANGE_PAGING_INCR access mode, the cache factor determines the number of rows to cache in memory for a specific range size. For example, suppose the range size is set to 4 and cache factor to 5. Then, the memory will keep at most 4*5 = 20 rows in its collection. In this example, when the range is refreshed for the first time, the memory will have just four rows even though the range paging query is bound to retrieve rows 0 to 19 (for a total of twenty rows). When the range is scrolled past the forth row, more rows will be read in from the current result set. This will continue until all twenty rows from the query result are read. If the user's action causes the next set of rows to be retrieve, the query will be reexecuted with the new row number bind values. The exact row number bind values are determined by the new range-start and the number of rows that can be retained from the cache. For example, suppose all twenty rows have been filled up and the user asks to move the range-start to 18 (0-based). This means that memory can retain row 18 and row 19 and will need two more rows to fill the range. The query is reexecuted for rows 20 and 21.

How to Scroll to a Given Page Number Using Range Paging

When a view object operates in `RANGE_PAGING` access mode, to scroll to page number *n* call its `scrollToRangePage()` method, passing *n* as the parameter value.

How to Estimate the Number of Pages in the Row Set Using Range Paging

When a view object operates in `RANGE_PAGING` access mode, you can access an estimate of the total number of pages the entire query result would produce using the `getEstimatedRangePageCount()` method.

Understanding the Tradeoffs of Using a Range Paging Mode

You might ask yourself, "Why wouldn't I *always* want to use `RANGE_PAGING` or `RANGE_PAGING_INCR` mode?" The answer is that using range paging potentially causes more overall queries to be executed as you are navigating forward and backward through your view object rows. You would want to avoid using `RANGE_PAGING` mode in these situations:

- You plan to read all the rows in the row set immediately (for example, to populate a dropdown list).

  In this case your range size would be set to `-1` and there really is only a single "page" of all rows, so range paging does not add value.

- You need to page back and forth through a small-sized row set.

  If you have 100 rows or fewer, and are paging through them 10 at a time, with `RANGE_PAGING` mode you will execute a query each time you go forward and backward to a new page. Otherwise, in the default scrollable mode, you will cache the view object rows as you read them in, and paging backwards through the previous pages will not reexecute queries to show those already-seen rows. Alternatively, you can use `RANGE_PAGING_INCR` mode to allow scrolling through in-memory results based on a row set cache factor that you determine.

In the case of a very large (or unpredictably large) row set, the trade off of potentially doing a few more queries — each of which only returns up to the `RangeSize` number of rows from the database — is more efficient then trying to cache all of the previously viewed rows. This is especially true if you allow the user to jump to an arbitrary page in the list of results. Doing so in default, scrollable mode requires fetching and caching all of the rows between the current page and the page the users jumps to. In `RANGE_PAGING` mode, it will ask the database just for the rows on that page. Then, if the user jumps back to a page of rows that they have already visited, in `RANGE_PAGING` mode, those rows get requeried again since only the current page of rows is held in memory in this mode. The incremental range paging access mode `RANGE_PAGING_INCR` combines aspects of both standard range paging and scrollable access mode since it allows the application to cache more rows in memory and permits the user to jump to any combination of those rows without needing to requery.

Using Forward Only Mode to Avoid Caching View Rows

You can set the `forward only` mode on the ADF view object if each row in the row set needs to be read only once and does not require reiteration. This technique avoids caching of retrieved rows.

Often you will write code that programmatically iterates through the results of a view object. A typical situation will be custom validation code that must process multiple rows of query results to determine whether an attribute or an entity is valid or not. In these cases, if you intend to read each row in the row set a single time and never require scrolling backward or reiterating the row set a subsequent time, then you can use "forward only" mode to avoid caching the retrieved rows. To enable forward only mode, call `setForwardOnly(true)` on the view object.

> **Note:**
>
> Using a read-only view object (with no entity usages) in forward-only mode with an appropriately tuned fetch size is the most efficient way to programmatically read data.

You can also use forward-only mode to avoid caching rows when inserting, updating, or deleting data as long as you never scroll backward through the row set and never call `reset()` to set the iterator back to the first row. Forward only mode only works with a range size of one (`1`).

Using Retain Row Set to Optimize View Link Accessor Access

You can force an ADF view link accessor row set to refresh its rows from the database. This is because each time you access a view link accessor row set, you access an object of this rowset without a database roundtrip.

Each time you retrieve a view link accessor row set, by default the view object creates a new `RowSet` object to allow you to work with the rows. This does *not* imply *re-executing* the query to produce the results each time, only creating a new instance of a `RowSet` object with its default iterator reset to the "slot" before the first row. To force the row set to refresh its rows from the database, you can call its `executeQuery()` method.

You can enable caching of the view link accessor row set when you do not want the application to incur the small amount of overhead associated with creating new detail row sets. For example, because **view accessor** row sets remain stable as long as the master row view accessor attribute remains unchanged, it would not be necessary to re-create a new row set for UI components, like the tree control, where data for each master node in a tree needs to retain its distinct set of detail rows. The view link accessor's detail row set can also be accessed programmatically. In this case, if your application makes numerous calls to the same view link accessor attributes, you can consider caching the view link accessor row set. This style of managing master-detail coordination differs from creating view link instances in the data model, as explained in What You May Need to Know About View Link Accessors Versus Data Model View Link Instances.

You can enable retention of the view link accessor row set using the overview editor for the view object that is the source for the view link accessor. Select **Retain Row Set** in the View Accessors page of the overview editor for the view object.

Alternatively, you can enable a custom Java class for your view object, override the `create()` method, and add a line after `super.create()` that calls the `setViewLinkAccessorRetained()` method passing `true` as the parameter. It affects all view link accessor attributes for that view object.

When this feature is enabled for a view object, since the view link accessor row set is not re-created each time, the current row of its default row set iterator is also retained as a side-effect. This means that your code will need to explicitly call the `reset()` method on the row set you retrieve from the view link accessor to reset the current row in its default row set iterator back to the "slot" before the first row.

Note, however, that with accessor retention enabled, your failure to call `reset()` each time before you iterate through the rows in the accessor row set can result in a subtle, hard-to-detect error in your application. For example, if you iterate over the rows in a view link accessor row set like this, for example to calculate some aggregate total:

```
RowSet rs = (RowSet)row.getAttribute("OrdersShippedToPurchaser");
while (rs.hasNext()) {
  Row r = rs.next();
  // Do something important with attributes in each row
}
```

The first time you work with the accessor row set the code will work. However, since the row set (and its default row set iterator) are retained, the second and subsequent times you access the row set the current row will already be at the end of the row set and the while loop will be skipped since `rs.hasNext()` will be `false`. Instead, with this feature enabled, write your accessor iteration code like this:

```
RowSet rs = (RowSet)row.getAttribute("OrdersShippedToPurchaser");
rs.reset(); // Reset default row set iterator to slot before first row!
while (rs.hasNext()) {
  Row r = rs.next();
  // Do something important with attributes in each row
}
```

Recall that if view link consistency is on, when the accessor is retained the new unposted rows will show up at the end of the row set. This is slightly different from when the accessor is not retained (the default), where new unposted rows will appear at the beginning of the accessor row set.

Using Dynamic Attributes On View Objects to Store UI State

You can add dynamic attributes which hold serializable objects as values to an ADF view object.

You can add one or more dynamic attributes to a view object at runtime using the `addDynamicAttribute()` method. Dynamic attributes can hold any serializable object as their value. Typically, you will consider using dynamic attributes when writing generic framework extension code that requires storing some additional per-row transient state to implement a feature you want to add to the framework in a global, generic way.

10

Defining Validation and Business Rules Declaratively

This chapter describes how to use ADF entity objects to write business rules that implement declarative validation in an Oracle ADF application.
This chapter includes the following sections:

About Declarative Validation

Use the overview editor of the ADF entity object to define declarative validation rules. These rules are stored in the entity object XML file. In addition to built-in declarative validation, you can write custom rules.

The easiest way to create and manage validation rules is through **declarative validation rules**. Declarative validation rules are defined using the overview editor, and once created, are stored in the **entity object** XML file. Declarative validation is different from programmatic validation (covered in Implementing Validation and Business Rules Programmatically), which is stored in an entity object's Java file.

Oracle ADF provides built-in declarative validation rules that satisfy many of your business needs. If you have custom validation rules you want to reuse, you can code them and add them to the IDE, so that the rules are available directly from JDeveloper. Custom validation rules are an advanced topic and covered in Implementing Custom Validation Rules. You can also base validation on a Groovy expression, as described in Using Groovy Expressions For Business Rules and Triggers.

When you add a validation rule, you supply an appropriate error message and can later translate it easily into other languages if needed. You can also define how validation is triggered and set the severity level.

Declarative Validation Use Cases and Examples

In a Fusion web application containing **ADF Business Components**, most of your validation code is defined in your entity objects. Encapsulating the business logic in these shared, reusable components ensures that your business information is validated consistently in every **view object** or client that accesses it, and it simplifies maintenance by centralizing where the validation is stored.

Another benefit of using declarative validation (versus writing your own validation) is that the validation framework takes care of the complexities of batching validation exceptions, which frees you to concentrate on your application's specific validation rule logic.

In the model layer, ADF Model validation rules can be set for the attributes of a collection. Many of the declarative validation features available for entity objects are also available at the model layer, should your application warrant the use of model-layer validation in addition to business-layer validation. For more information, see Using Validation in the ADF Model Layer .

When you use the ADF Business Components **application module data control**, you do not need to use model-layer validation. Consider defining all or most of your validation rules in the centralized, reusable, and easier to maintain entity objects of your business layer. With other types of **data controls**, **ADF Model** layer validation can be more useful.

Additional Functionality for Declarative Validation

You may find it helpful to understand other Oracle ADF features before you start using declarative validation. It is possible to go beyond the declarative behavior to implement more complex validation rules for your business domain layer when needed. Following are links to other functionality that may be of interest.

- Using Method Validators explains how to use the Method validator to invoke custom validation code.
- Implementing Custom Validation Rules details how to extend the basic set of declarative rules with custom rules of your own.

Determining Where to Implement Validation

Oracle ADF follows the Model View Controller (MVC) architectural design pattern that allows validation implementation at each layer. Depending on business needs, implement validations at particular layers.

As explained in Oracle ADF Architecture, the model-view-controller (MVC) architecture of a Fusion web application has multiple layers that provide a clean separation of business logic, page navigation, and user interface. These layers also provide multiple options for implementing validation, and there are benefits and disadvantages to using validation at each layer. The place where you choose to implement validation is dependent on the given business need or use case. Generally, the validations that occur closer to the data source are more centralized and therefore easier to maintain, while those that occur closer to the user interface provide more immediate feedback at runtime.

Data services layer -- Whether it be a database or a web service or some other source of data, the data services layer typically resides outside the context of the application itself and employs constraints that define the nature of each field of data. Data services constraints are typically defined for every piece of data that is stored, and are very important to maintaining the integrity of that data. However, it is neither effective nor efficient to rely solely on these constraints, because they are not enforced until the data reaches the data source, typically when the application attempts to commit a transaction. This requires a round trip from the client UI to the data source and back, and a single error on a single record can cause the rollback of entire transaction.

Business services layer -- Business rules that you implement at the business service layer in ADF Business Components (such as entity objects and view objects) provide more efficiency than data services constraints because they don't require a round trip to the data source. They are also easier to maintain than validators implemented at the view layer because a business rule defined on an attribute for a given entity object is enforced on every page that uses that entity object. In addition to attribute-level validators, you can also implement entity-level validators when the validity of the value of one attribute is dependent on the value of another. For example, `DateShipped` must be greater than `DateOrdered`. This kind of business rule is explained in this chapter.

Model layer -- Although not used as commonly as the other kinds of business rules, model layer validation can also be useful. You can define business rules on a binding to a business service. This feature can be useful, for example, if you can't implement validation on the business service itself because your application consumes an external web service. See Using Validation in the ADF Model Layer .

View layer -- From the user's perspective, view layer validations are the most efficient. They provide immediate feedback when the user enters data and subsequently leaves (tabs out of) a given field, without requiring even a trip to the application server. However, view layer validations are implemented on the page, so every page that provides access to a given data field must define the validation for that field. See the "Validating and Converting Input" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

Understanding the Validation Cycle

You can enforce validation on an ADF entity row, either when a persistent entity row attribute is modified, or an entity row is created.

Each entity row tracks whether or not its data is valid. When an existing entity row is retrieved from the database, the entity is assumed to be valid. When the first persistent attribute of an existing entity row is modified, or when a new entity row is created, the entity is marked invalid.

When an entity is in an invalid state, the declarative validation you have configured and the programmatic validation rules you have implemented are evaluated again before the entity can be considered valid again. You can determine whether a given entity row is valid at runtime by calling the `isValid()` method on it.

> **Note:**
>
> Because attributes can (by default) be left blank, validations are not triggered if the attribute contains no value. For example, if a user creates a new entity row and does not enter a value for a given attribute, the validation on that attribute is not run. To force the validation to execute in this situation, set the Mandatory flag on the attribute.

Types of Entity Object Validation Rules

Entity object validation rules fall into two basic categories: *attribute-level* and *entity-level*.

Attribute-Level Validation Rules

Attribute-level validation rules are triggered for a particular entity object attribute when either the end user or the program code attempts to modify the attribute's value. Since you cannot determine the order in which attributes will be set, attribute-level validation rules should be used only when the success or failure of the rule depends exclusively on the candidate value of that single attribute.

The following represent attribute-level validations:

- The value of the `OrderDate` of an order should not be a date in the past.
- The `ProductId` attribute of a product should represent an existing product.

Entity-Level Validation Rules

All other kinds of validation rules are entity-level validation rules. These are rules whose implementation requires considering two or more entity attributes, or possibly composed children entity rows, in order to determine the success or failure of the rule.

The following represent entity-level validations:

- The value of the `OrderShippedDate` should be a date that comes after the `OrderDate`.
- The `ProductId` attribute of an order should represent an existing product.

Entity-level validation rules are triggered by calling the `validate()` method on a `Row`. This occurs when:

- You call the method explicitly on the entity object
- You call the method explicitly on a view row with an entity row part that is invalid
- A view object's iterator calls the method on the current row in the view object before allowing the current row to change
- During transaction commit, processing validates an invalid entity (in the list of pending changes) before proceeding with posting the changes to the database

As part of transaction commit processing, entity-level validation rules can fire multiple times (up to a specified limit). For more information, see Avoiding Infinite Validation Cycles.

Understanding Commit Processing and Validation

Transaction commit processing happens in three basic phases:

1. Ensure that any invalid entity rows on the pending changes list are valid.
2. Post the pending changes to the database by performing appropriate DML operations.
3. Commit the transaction.

If you have business validation logic in your entity objects that executes queries or stored procedures that depend on seeing the posted changes in the `SELECT` statements they execute, they should be coded in the `beforeCommit()` method described in What You May Need to Know About Row Set Access with View Accessors. This method fires after all DML statements have been applied so queries or stored procedures invoked from that method can "see" all of the pending changes that have been saved, but not yet committed.

> **Caution:**
>
> Don't use the transaction-level `postChanges()` method in web applications unless you can guarantee that the transaction will definitely be committed or rolled-back during the same HTTP request. This method exists to force the transaction to post unvalidated changes without committing them. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

Understanding the Impact of Composition on Validation Order

Because a composed child entity row is considered an integral part of its composing parent entity object, any change to composed child entity rows causes the parent entity to be marked invalid. For example, if a line item on an order were to change, the entire order would now be considered to be changed, or invalid.

Therefore, when the composing entity is validated, it causes any currently invalid composed children entities to be validated first. This behavior is recursive, drilling into deeper levels of invalid composed children if they exist.

Avoiding Infinite Validation Cycles

If your validation rules contain code that updates attributes of the current entity or other entities, then the act of validating the entity can cause that or other entities to become invalid. As part of the transaction commit processing phase that attempts to validate all invalid entities in the pending changes list, the transaction performs multiple passes (up to a specified limit) on the pending changes list in an attempt to reach a state where all pending entity rows are valid.

The maximum number of validation passes is specified by the transaction-level validation threshold setting. The default value of this setting is 10. You can increase the threshold count if the entities involved contain the appropriate logic to validate themselves in the subsequent passes.

If after 10 passes, there are still invalid entities in the list, you will see the following exception:

```
JBO-28200: Validation threshold limit reached. Invalid Entities still in cache
```

This is a sign that you need to debug your validation rule code to avoid inadvertently invalidating entities in a cyclic fashion.

To change the validation threshold:

1. In the Applications window, double-click the desired application module.
2. In the overview editor, click the **Configurations** navigation tab, select the configuration hyperlink for which you want to adjust the validation threshold.
3. In the overview editor for application module configurations (on the `bc4j.xcfg` file), click the **Properties** tab, and click **Add Property**.
4. In the Add Property dialog, select the `jbo.validation.threshold` property and click **OK**.
5. In the overview editor, in the Properties list, enter a new value for the `jbo.validation.threshold` property and save your changes.

You can also change the validation threshold programmatically by using the `SetValidationThreshold()` method as shown below. In this example, the new threshold is 12.

```
oracle.jbo.server.DBTransaction::setValidationThreshold(12)
```

What Happens When Validations Fail

When an entity object's validation rules throw exceptions, the exceptions are bundled and returned to the client. If the validation failures are thrown by methods you've overridden to handle events during the transaction `postChanges` processing, then the validation failures cause the transaction to roll back any database `INSERT`, `UPDATE`, or `DELETE` statements that might have been performed already during the current `postChanges` cycle.

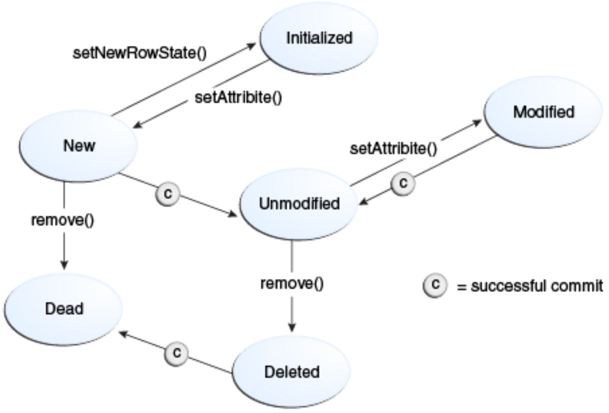
> **Note:**
>
> The bundling of exceptions is the default behavior for ADF Model-based web applications, but not for Oracle ADF Model Tester or Swing bindings. Additional configuration is required to bundle exceptions for the Oracle ADF Model Tester or Swing clients.

Understanding Entity Objects Row States

When an entity row is in memory, it has an entity state that reflects the logical state of the row. Figure 10-1 illustrates the different entity row states and how an entity row can transition from one state to another. When an entity row is first created, its status is `New`. You can use the `setNewRowState()` method to mark the entity as being `Initialized`, which removes it from the transaction's list of pending changes until the user sets at least one of its attributes, at which time it returns to the New state. This allows you to create more than one initialized row and post only those that the user modifies.

The Unmodified state reflects an entity that has been retrieved from the database and has not yet been modified. It is also the state that a New or Modified entity transitions to after the transaction successfully commits. During the transaction in which it is pending to be deleted, an Unmodified entity row transitions to the Deleted state. Finally, if a row that was New and then was removed before the transaction commits, or Unmodified and then successfully deleted, the row transitions to the Dead state.

Figure 10-1 Diagram of Entity Row States and Transitions



You can use the getEntityState() and getPostState() methods to access the current state of an entity row in your business logic code. The getEntityState() method returns the current state of an entity row with regard to the transaction, while the getPostState() method returns the current state of an entity row with regard to the database after using the postChanges() method to post pending changes without committing the transaction.

For example, if you start with a new row, both getEntityState() and getPostState() return STATUS_NEW. Then when you post the row (before commit or rollback), the row will have an entity state of STATUS_NEW and a post state of STATUS_UNMODIFIED. If you subsequently remove that row, the entity state will remain STATUS_NEW because for the transaction the row is still new. But the post state will be STATUS_DEAD.

Understanding Bundled Exception Mode

An **application module** provides a feature called bundled exception mode which allows web applications to easily present a maximal set of failed validation exceptions to the end user, instead of presenting only the *first* error that gets raised. By default, the ADF Business Components **application module pool** enables bundled exception mode for web applications.

You typically will not need to change this default setting. However it is important to understand that it is enabled by default since it effects how validation exceptions are thrown. Since the Java language and runtime only support throwing a single exception object, the way that bundled validation exceptions are implemented is by wrapping a set of exceptions as details of a new "parent" exception that contains them. For example, if multiple attributes in a single entity object fail attribute-level validation, then these multiple `ValidationException` objects will be wrapped in a `RowValException`. This wrapping exception contains the row key of the row that has failed validation. At transaction commit time, if multiple rows do not successfully pass the validation performed during commit, then all of the `RowValException` objects will get wrapped in an enclosing `TxnValException` object.

When writing custom error processing code, you can use the `getDetails()` method of the `JboException` base exception class to recursively process the bundled exceptions contained inside it.

> **Note:**
>
> All the exception classes mentioned here are in the `oracle.jbo` package.

Adding Validation Rules to Entity Objects and Attributes

ADF Business Components allows you to declaratively add validations rules to an entity object.

The process for adding a validation rule to an entity object is similar for most of the validation rules, and is done using the Add Validation Rule dialog. You can open this dialog from the overview editor by clicking the **Add** icon on the Business Rules page.

It is important to note that when you define a rule declaratively using the Add Validation Rule dialog, the rule definition you provide specifies the *valid* condition for the attribute or entity object. At runtime, the entry provided by the user is evaluated against the rule definition and an error or warning is raised if the entry fails to satisfy the specified criteria. For example, if you specify a Length validator on an attribute that requires it to be `Less Than or Equal To 12`, the validation fails if the entry is more than 12 characters, and the error or warning is raised.

How to Add a Validation Rule to an Entity or Attribute

To add a declarative validation rule to an entity object, use the Business Rules page of the overview editor.

Before you begin:

It may be helpful to have an understanding of the use of validation rules in entity objects and attributes. For more information, see Adding Validation Rules to Entity Objects and Attributes.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To add a validation rule:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select the object for which you want to add a validation rule, and then click the **Add** icon.
   - To add a validation rule at the entity object level, select **Entity**.

- To add a validation rule for an attribute, expand **Attributes** and select the desired attribute.

When you add a new validation rule, the Add Validation Rule dialog appears.

3. In the Add Validation Rule dialog, select the desired type of validation rule from the **Rule Type** dropdown list.
4. Use the dialog settings to configure the new rule.

   The controls will change depending on the kind of validation rule you select.

   For more information about the different validation rules, see Using the Built-in Declarative Validation Rules.
5. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression.

   For more information, see Triggering Validation Execution.

   > **Note:**
   >
   > For Key Exists and Method entity validators, you can also use the **Validation Execution** tab to specify the validation level.
6. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails.

   For more information, see Creating Validation Error Messages.
7. Click **OK**.

How to View and Edit a Validation Rule on an Entity Object or Attribute

The Business Rules page of the overview editor for entity objects displays the validation rules for an entity and its attributes in a tree control. To see the validation rules that apply to the entity as a whole, expand in the **Entity** node. To see the validation rules that apply to an attribute, expand the **Attributes** node and then expand the attribute.

The validation rules that are shown on the Business Rules page of the overview editor include those that you have defined as well as database constraints, such as mandatory or precision. To open a validation rule for editing, double-click the rule or select the rule and click the **Edit** icon.

What Happens When You Add a Validation Rule

When you add a validation rule to an entity object, JDeveloper updates the entity object's XML document to include an entry describing what rule you've used and what rule properties you've entered. For example, if you add a range validation rule to the `DiscountAmount` attribute, this results in a `RangeValidationBean` entry in the XML file, as shown in the following example.

```
<Attribute
  Name="DiscountAmount"
  IsNotNull="true"
  ColumnName="DISCOUNT_AMOUNT"
  . . .
```

```
    <validation:RangeValidationBean
      xmlns="http://xmlns.oracle.com/adfm/validation"
      Name="DiscountAmount_Rule_0"
      ResId="DiscountAmount_RangeError_0"
      OnAttribute="DiscountAmount"
      OperandType="LITERAL"
      Inverse="false"
      MinValue="0"
      MaxValue="40"/>
    . . .
  </Attribute>
```

At runtime, the rule is enforced by the entity object based on this declarative information.

What You May Need to Know About Entity and Attribute Validation Rules

Declarative validation enforces both entity-level and attribute-level validation, depending on where you place the rules. Entity-level validation rules are enforced when a user tries to commit pending changes or navigates between rows. Attribute-level validation rules are enforced when the user changes the value of the related attribute.

The Unique Key validator (described in How to Ensure That Key Values Are Unique) can be used only at the entity level. Internally the Unique Key validator behaves like an attribute-level validator. This means that users see the validation error when they tab out of the key attribute for the key that the validator is validating. This is done because the internal cache of entities can never contain a duplicate, so it is not allowed for an attribute value to be set that would violate that. This check needs to be performed when the attribute value is being set because the cache consistency check is done during the setting of the attribute value.

> **Best Practice:**
>
> If the validity of one attribute is dependent on one or more other attributes, enforce this rule using entity validation, not attribute validation. Examples of when you would want to do this include the following:
>
> - You have a Compare validator that compares one attribute to another.
> - You have an attribute with an expression validator that examines the value in another attribute to control branching in the expression to validate the attribute differently depending on the value in this other attribute.
> - You make use of conditional execution, and your precondition expression involves an attribute other than the one that you are validating.

Entity object validators are triggered whenever the entity, as a whole, is dirty. To improve performance, you can indicate which attributes play a role in your rule and thus the rule should be triggered only if one or more of these attributes are dirty. For more information on triggering attributes, see, Triggering Validation Execution.

What You May Need to Know About List of Values and Attribute Validation Rules

Developers may define a **List of Values (LOV)** attribute on a view object to support displaying choice lists in the user interface. The view object's LOV attribute in turn relies on a data source view object to provide the values for display. Because the LOV feature assumes that the queried data source contains only valid values, any validation rules defined on data source view object attributes will be suppressed before the choice list displays in the user interface. Therefore, the developer who defines the LOV must ensure that the list of values returned by the data source view object contains only valid values, as describe in Working with List of Values (LOV) in View Object Attributes.

Using the Built-in Declarative Validation Rules

ADF Business Components provides numerous built-in declarative validation rules to achieve numerous validation use cases.

The built-in declarative validation rules can satisfy many, if not all, of your business needs. These rules are easy to implement because you don't write any code. You use the user-interface tools to choose the type of validation and how it is used.

Built-in declarative validation rules can be used to:

- Ensure that key values are unique (primary key or other unique keys)
- Determine the existence of a key value
- Make a comparison between an attribute and anything from a literal value to a SQL query
- Validate against a list of values that might be a literal list, a SQL query, or a view attribute
- Make sure that a value falls within a certain range, or that it is limited by a certain number of bytes or characters
- Validate using a regular expression or evaluate a Groovy expression
- Make sure that a value satisfies a relationship defined by an aggregate on a child entity available through an accessor
- Validate using a validation condition defined in a Java method on the entity

How to Ensure That Key Values Are Unique

The Unique Key validator ensures that primary key values for an entity object are always unique. The Unique Key validator can also be used for a non-primary-key attribute, as long as the attribute is defined as an alternate key. For information on how to define alternate keys, see How to Define Alternate Key Values.

Whenever any of the key attribute values change, this rule validates that the new key does not belong to any other entity object instance of this entity object class. (It is the business-logic tier equivalent of a unique constraint in the database.) If the key is found in one of the entity objects, a `TooManyObjectsException` is thrown. The validation check is done both in the entity cache and in the database.

There is a slight possibility that unique key validation might not be sufficient to prevent duplicate rows in the database. It is possible for two application module sessions to simultaneously attempt to create records with the same key. To prevent this from happening, create a unique index in the database for any unique constraint that you want to enforce.

Before you begin:

It may be helpful to have a general understanding of the built-in validation rules. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To ensure that a key value is unique:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select the **Entity** node, and click the **Add** icon.
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **UniqueKey**.
4. In the **Keys** box, select the primary or alternate key.
5. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression.

   For more information, see Triggering Validation Execution.

   > **Best Practice:**
   >
   > While it is possible to add a precondition for a Unique Key validator, it is not a best practice. If a Unique Key validator fails to fire, for whatever reason, the cache consistency check is still performed and an error will be returned. It is generally better to add the validator and a meaningful error message.

6. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails.

   For more information, see Creating Validation Error Messages.
7. Click **OK**.

What Happens When You Use a Unique Key Validator

When you use a Unique Key validator, a `<UniqueKeyValidationBean>` tag is added to the entity object's XML file. The following example shows the XML for a Unique Key validator.

```
<validation:UniqueKeyValidationBean
  Name="CustomerEORule0"
  KeyName="SCustomerIdPk">
  <validation:OnAttributes>
    <validation:Item
      Value="Id"/>
  </validation:OnAttributes>
</validation:UniqueKeyValidationBean>
```

How to Validate Based on a Comparison

The Compare validator performs a logical comparison between an entity attribute and a value. When you add a Compare validator, you specify an operator and something to compare with. You can compare the following:

- Literal value

  When you use a Compare validator with a literal value, the value in the attribute is compared against the specified literal value. When using this kind of comparison, it is important to consider data types and formats. The literal value must conform to the format specified by the data type of the entity attribute to which you are applying the rule. In all cases, the type corresponds to the type mapping for the entity attribute.

  For example, an attribute of column type DATE maps to the `oracle.jbo.domain.Date` class, which accepts dates and times in the same format accepted by `java.sql.TimeStamp` and `java.sql.Date`. You can use format masks to ensure that the format of the value in the attribute matches that of the specified literal. For information about entity object attribute type mappings, see How to Set Database and Java Data Types for an Entity Object Attribute. For information about the expected format for a particular type, refer to the Javadoc for the type class.

- Query result

  When you use this type of validator, the SQL query is executed each time the validator is executed. The validator retrieves the first row from the query result, and it uses the value of the first column in the query (of that first row) as the value to compare. Because this query cannot have any bind variables in it, this feature should be used only when selecting one column of one row of data that does not depend on the values in the current row.

- View object attribute

  When you use this type of validator, the view object's SQL query is executed each time the validator is executed. The validator retrieves the first row from the query result, and it uses the value of the selected view object attribute from that row as the value to compare. Because you cannot associate values with the view object's named bind variables, those variables can only take on their default values. Therefore this feature should be used only for selecting an attribute of one row of data that does not depend on the values in the current row.

- **View accessor** attribute

  When defining the view accessor, you can assign row-specific values to the validation view object's bind variables.

- Expression

  For information on the expression option, see Using Groovy Expressions For Business Rules and Triggers.

- Entity attribute

  The entity attribute option is available only for entity-level Compare validators.

Before you begin:

It may be helpful to have a general understanding of the built-in validation rules. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To validate based on a comparison:

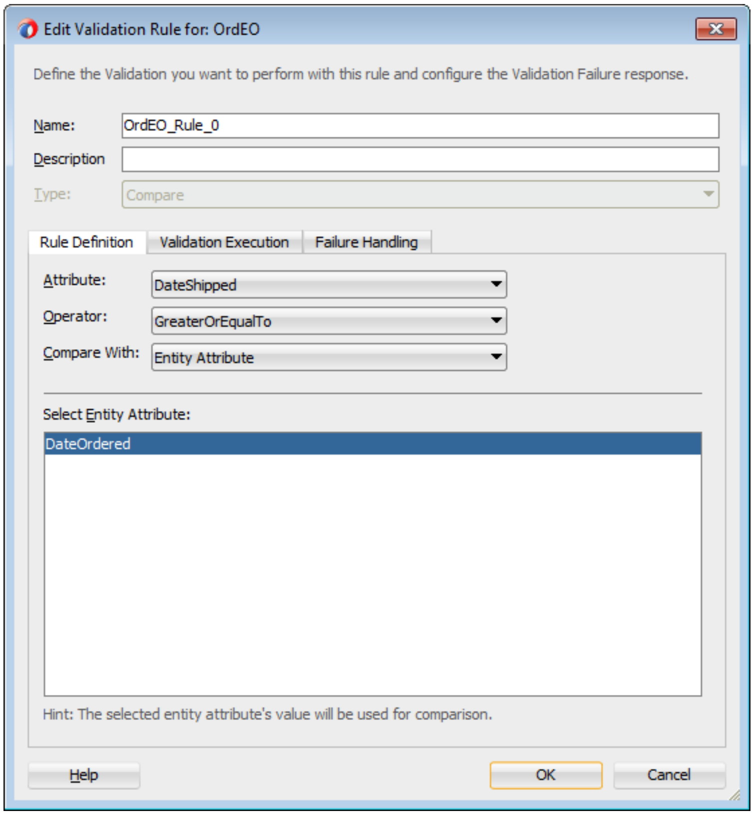
1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select where you want to add the validator, and click the **Add** icon.
   - To add an entity-level validator, select the **Entity** node.
   - To add an attribute-level validator, expand the **Attributes** node and select the appropriate attribute.
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **Compare**. Note that the subordinate fields change depending on your choices.
4. Select the appropriate operator.
5. Select an item in the **Compare With** list, and based on your selection provide the appropriate comparison value.
6. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression.

   For more information, see Triggering Validation Execution.
7. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails.

   For more information, see Creating Validation Error Messages.
8. Click **OK**.

Figure 10-2 shows what the dialog looks like when you use an entity-level Compare validator with an entity object attribute.

Figure 10-2 Compare Validator Using an Entity Object Attribute



Edit Validation Rule for: OrdEO

Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: OrdEO_Rule_0

Description:

Type: Compare

Attribute: DateShipped

Operator: GreaterOrEqualTo

Compare With: Entity Attribute

Select Entity Attribute: DateOrdered

Hint: The selected entity attribute's value will be used for comparison.

What Happens When You Validate Based on a Comparison

When you create a Compare validator, a `<CompareValidationBean>` tag is added to an entity object's XML file. The following example shows the XML code for an entity level validator in the `OrdEO` entity object.

```
<validation:CompareValidationBean
    Name="OrdEO_Rule_0"
    ResId="oracle.summit.model.entities.OrdEO_Rule_0"
    OnAttribute="DateShipped"
    OperandType="ATTR"
    Inverse="false"
    CompareType="GREATERTHANEQUALTO"
    CompareValue="DateOrdered">
    <validation:OnAttributes>
      <validation:Item
        Value="DateShipped"/>
      <validation:Item
        Value="DateOrdered"/>
    </validation:OnAttributes>
  </validation:CompareValidationBean>
```

How to Validate Using a List of Values

The List validator compares an attribute against a list of values (LOV). When you add a List validator, you specify the type of list to choose from:

- Literal values - The validator ensures that the entity attribute is in (or not in, if specified) the list of values.
- Query result - The validator ensures that the entity attribute is in (or not in, if specified) the first column of the query's result set. The SQL query validator cannot use a bind variable, so it should be used only on a fixed, small list that you have to query from a table. All rows of the query are retrieved into memory.
- View object attribute - The validator ensures that the entity attribute is in (or not in, if specified) the view attribute. The View attribute validator cannot use a bind variable, so it should be used only on a fixed, small list that you have to query from a table. All rows of the query are retrieved into memory.
- View accessor attribute - The validator ensures that the entity attribute is in (or not in) the view accessor attribute. The view accessor is probably the most useful option, because it can take bind variables and after you've created the LOV on the user interface, a view accessor is required.

> **Best Practice:**
>
> When using a List validator, the view accessor is typically the most useful choice because you can define a **view criteria** on the view accessor to filter the view data when applicable; and when defining an LOV on a view attribute, you typically use a view accessor with a view criteria.

Before you begin:

It may be helpful to have a general understanding of the built-in validation rules. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To validate using a list of values:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select where you want to add the validator, and click the **Add** icon.
   - To add an entity-level validator, select the **Entity** node.
   - To add an attribute-level validator, expand the **Attributes** node and select the appropriate attribute.
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **List**.
4. In the **Attribute** list, choose the appropriate attribute.
5. In the **Operator** field, select **In** or **NotIn**, depending on whether you want an inclusive or exclusive list.
6. In the **List Type** field, select the appropriate type of list.
7. Depending on the type of list you selected, you can either enter a list of values (each value on a new line) or an SQL query, or select a view object attribute or view accessor attribute.

8. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression.

   For more information, see Triggering Validation Execution.

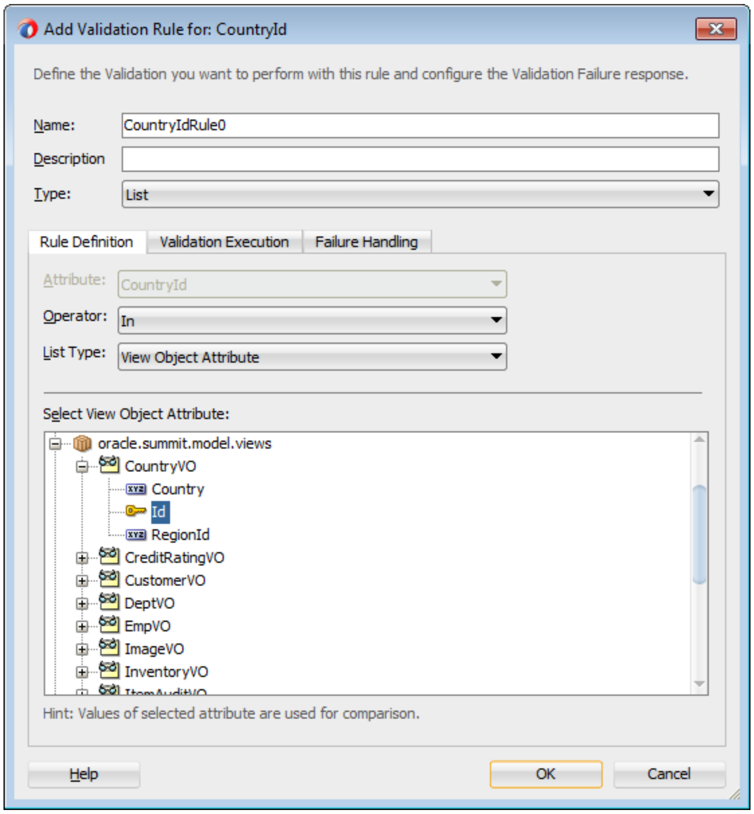
9. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails.

   For more information, see Creating Validation Error Messages.

10. Click **OK**.

Figure 10-3 shows what the dialog looks like when you use a List validator with a view object attribute.

Figure 10-3 List Validator Using a View Object Attribute



Add Validation Rule for: CountryId

Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: CountryIdRule0

Description:

Type: List

Attribute: CountryId

Operator: In

List Type: View Object Attribute

Select View Object Attribute:

```
oracle.summit.model.views
    CountryVO
        Country
        Id
        RegionId
    CreditRatingVO
    CustomerVO
    DeptVO
    EmpVO
    ImageVO
    InventoryVO
    ItemAuditVO
```

Hint: Values of selected attribute are used for comparison.

What Happens When You Validate Using a List of Values

When you validate using a list of values, a `<ListValidationBean>` tag is added to an entity object's XML file. The following example shows the `CustomerEO.CountryId` attribute, which uses a view object attribute for the List validator.

```
<validation:ListValidationBean
      Name="CountryIdRule0"
      OnAttribute="CountryId"
      OperandType="JBO"
      Inverse="false"
      ListValue="oracle.summit.model.views.CountryVO.Id"/>
```

What You May Need to Know About the List Validator

The List validator is designed for validating an attribute against a relatively small set of values. If you select the **Query Result** or **View Object Attribute** type of list validation, keep in mind that the validator retrieves all of the rows from the query before performing an in-memory scan to validate whether the attribute value in question matches an attribute in the list. The query performed by the validator's SQL or view object query does not reference the value being validated in the `WHERE` clause of the query.

It is inefficient to use a validation rule when you need to determine whether a user-entered product code exists in a table of a large number of products. Instead, Using View Objects for Validation explains the technique you can use to efficiently perform SQL-based validations by using a view object to perform a targeted validation query against the database. See also Using Validators to Validate Attribute Values.

Also, if the attribute you're comparing to is a key, the Key Exists validator is more efficient than validating a list of values; and if these choices need to be translatable, you should use a static view object instead of the literal choice.

How to Make Sure a Value Falls Within a Certain Range

The Range validator performs a logical comparison between an entity attribute and a range of values. When you add a Range validator, you specify minimum and maximum literal values. The Range validator verifies that the value of the entity attribute falls within the range (or outside the range, if specified).

If you need to dynamically calculate the minimum and maximum values, or need to reference other attributes on the entity, use the Script Expression validator and provide a Groovy expression. For more information, see What You May Need to Know About Referencing Business Components in Groovy Expressions and What You May Need to Know About Manipulating Business Component Attribute Values in Groovy Expressions.

Before you begin:

It may be helpful to have a general understanding of the built-in validation rules. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it useful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To validate within a certain range:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select where you want to add the validator, and click the **Add** icon.
   - To add an entity-level validator, select the **Entity** node.
   - To add an attribute-level validator, expand the **Attributes** node and select the appropriate attribute.
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **Range**.
4. In the **Attribute** list, select the appropriate attribute.

5. In the **Operator** field, select **Between** or **NotBetween**.
6. In the **Minimum** and **Maximum** fields, enter appropriate values.
7. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression.

   For more information, see Triggering Validation Execution.
8. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails.

   For more information, see Creating Validation Error Messages.
9. Click **OK**.

What Happens When You Use a Range Validator

When you validate against a range, a `<RangeValidationBean>` tag is added to the entity object's XML file. The following example shows the `ItemEO.Quantity` attribute with a minimum quantity of one and a maximum of 99.

```
<validation:RangeValidationBean
      Name="QuantityRule0"
      OnAttribute="Quantity"
      OperandType="LITERAL"
      Inverse="false"
      MinValue="1"
      MaxValue="99"/>
```

How to Validate Against a Number of Bytes or Characters

The Length validator validates whether the string length (in characters or bytes) of an attribute's value is less than, equal to, or greater than a specified number, or whether it lies between a pair of numbers.

Before you begin:

It may be helpful to have a general understanding of the built-in validation rules. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To validate against a number of bytes or characters:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select where you want to add the validator, and click the **Add** icon.
   - To add an entity-level validator, select the **Entity** node.
   - To add an attribute-level validator, expand the **Attributes** node and select the appropriate attribute.
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **Length**.
4. In the **Attribute** list, select the appropriate attribute.
5. In the **Operator** field, select how to evaluate the value.

6. In the **Comparison Type** field, select **Byte** or **Character** and enter a length.
7. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression. For more information, see Triggering Validation Execution.
8. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails. For more information, see Creating Validation Error Messages.
9. Click **OK**.

What Happens When You Validate Against a Number of Bytes or Characters

When you validate using length, a `<LengthValidationBean>` tag is added to the entity object's XML file, as shown in the following example. For example, you might have a field where the user enters a password or PIN and the application wants to validate that it is at least 6 characters long, but not longer than 10. You would use the Length validator with the Between operator and set the minimum and maximum values accordingly.

```
<validation:LengthValidationBean
  OnAttribute="pin"
  CompareType="BETWEEN"
  DataType="CHARACTER"
  MinValue="6"
  MaxValue="10"
  Inverse="false"/>
```

How to Validate Using a Regular Expression

The Regular Expression validator compares attribute values against a mask specified by a Java regular expression.

If you want to create expressions that can be personalized in metadata, you can use the Script Expression validator. For more information, see Using Groovy Expressions For Business Rules and Triggers.

Before you begin:

It may be helpful to have a general understanding of the built-in validation rules. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it useful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To validate using a regular expression

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select where you want to add the validator, and click the **Add** icon.
   - To add an entity-level validator, select the **Entity** node.
   - To add an attribute-level validator, expand the **Attributes** node and select the appropriate attribute.

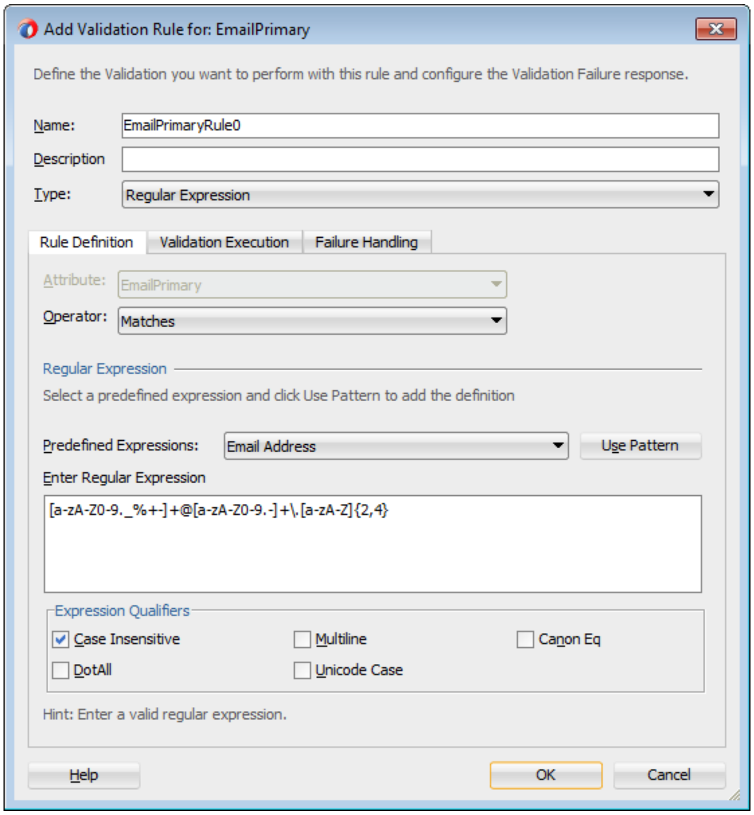
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **Regular Expression**.
4. In the **Operator** field, select **Matches** or **Not Matches**.
5. To use a predefined expression (if available), you can select one from the dropdown list and click **Use Pattern**. Otherwise, write your own regular expression in the field provided.

> **Note:**
>
> You can add your own expressions to the list of predefined expressions. To add a predefined expression, add an entry in the `PredefinedRegExp.properties` file in the BC4J subdirectory of the JDeveloper system directory (for example, `C:\Documents and Settings\`*`username`*`\Application Data\JDeveloper\`*`system##`*`\o.BC4J\PredefinedRegExp.properties`).

6. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression. For more information, see Triggering Validation Execution.
7. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails. For more information, see Creating Validation Error Messages.
8. Click **OK**.

Figure 10-4 shows what the dialog looks like when you select a Regular Expression validator and validate that the `Email` attribute matches a predefined **Email Address** expression.

Figure 10-4   Regular Expression Validator Matching Email Address



Add Validation Rule for: EmailPrimary
Define the Validation you want to perform with this rule and configure the Validation Failure response.
Description
Rule Definition
Validation Execution
Failure Handling
Regular Expression
Select a predefined expression and click Use Pattern to add the definition
Use Pattern
Enter Regular Expression
Expression Qualifiers
Hint: Enter a valid regular expression.
Help
OK
Cancel

Name: EmailPrimaryRule0

Type: Regular Expression

Attribute: EmailPrimary

Operator: Matches

Predefined Expressions: Email Address

```
[a-zA-Z0-9._%+-]+@[a-zA-Z0-9.-]+\.[a-zA-Z]{2,4}
```

☑ Case Insensitive　☐ Multiline　☐ Canon Eq
☐ DotAll　☐ Unicode Case

What Happens When You Validate Using a Regular Expression

When you validate using a regular expression, a `<RegExpValidationBean>` tag is added to the entity object's XML file. The following example shows an `Email` attribute that must match a regular expression.

```
<validation:RegExpValidationBean
    Name="EmailPrimaryRule0"
    OnAttribute="EmailPrimary"
    Pattern="[a-zA-Z0-9._%+-]+@[a-zA-Z0-9.-]+\.[a-zA-Z]{2,4}"
    Flags="CaseInsensitive"
    Inverse="false"/>
```

How to Use the Average, Count, or Sum to Validate a Collection

You can use collection validation on the average, count, sum, min, or max of a collection. This validator is available only at the entity level. It is useful for validating the aggregate calculation over a collection of associated entities by way of an entity accessor to a child entity (on the many end of the association). You must select the association accessor to define the Collection validator.

Before you begin:

It may be helpful to have a general understanding of the built-in validation rules. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To validate using an aggregate calculation:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select the **Entity** node, and click the **Add** icon.
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **Collection**.
4. In the **Operation** field, specify the operation (sum, average, count, min, or max) to perform on the collection for comparison.
5. Select the appropriate accessor and attribute for the validation.

   The accessor you choose must be a composition association accessor. Only accessors of this type are displayed in the dropdown list.
6. Specify the operator and the comparison type and value.
7. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression. For more information, see Triggering Validation Execution.
8. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails. For more information, see Creating Validation Error Messages.
9. Click **OK**.

What Happens When You Use Collection Validation

When you validate using a Collection validator, a `<CollectionValidationBean>` tag is added to the entity object's XML file, as in the following example.

```
<validation:CollectionValidationBean
    Name="OrdEORule01"
    Accessor="ItemEO"
    CollAttribute="Quantity"
    OperandType="LITERAL"
    Inverse="false"
    CompareType="GREATERTHAN"
    CompareValue="5"
    Operation="min"/>
```

How to Determine Whether a Key Exists

The Key Exists validator is used to determine whether a key value (primary, foreign, or alternate key) exists.

There are a couple of benefits to using the Key Exists validator:

- The Key Exists validator has better performance because it first checks the cache and only goes to the database if necessary.
- Since the Key Exists validator uses the cache, it will find a key value that has been added in the current transaction, but not yet committed to the database. For

example, you add a new `Department` and then you want to link an `Employee` to that new department.

Before you begin:

It may be helpful to have a general understanding of the built-in validation rules. For more information, see Using the Built-in Declarative Validation Rules.

You may also find it useful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To determine whether a value exists:

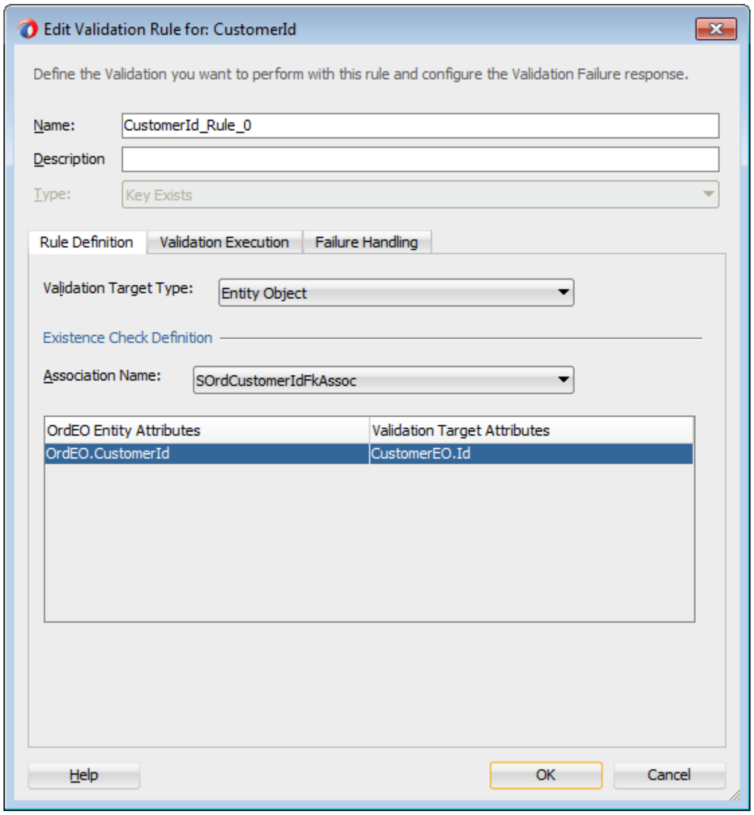
1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select where you want to add the validator, and click the **Add** icon.
   - To add an entity-level validator, select the **Entity** node.
   - To add an attribute-level validator, expand the **Attributes** node and select the appropriate attribute.
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **Key Exists**.
4. Select the type of validation target (**Entity Object**, **View Object**, or **View Accessor**).

   If you want the Key Exists validator to be used for all view objects that use this entity attribute, select **Entity Object**.
5. Depending on the validation target, you can choose either an association or a key value.

   If you are searching for an attribute that does not exist in the **Validation Target Attributes** list, it is probably not defined as a key value. To create alternate keys, see How to Define Alternate Key Values.
6. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and the validation level (entity or transaction). For more information, see Triggering Validation Execution.
7. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails. For more information, see Creating Validation Error Messages.
8. Click **OK**.

Figure 10-5 shows a Key Exists validator that validates whether the `MembershipId` entered in the `PersonEO` entity object exists in the `MembershipBaseEO` entity object.

Figure 10-5   Key Exists Validator on an Entity Attribute



Edit Validation Rule for: CustomerId

Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: CustomerId_Rule_0

Description:

Type: Key Exists

Validation Target Type: Entity Object

Association Name: SOrdCustomerIdFkAssoc

OrdEO Entity Attributes	Validation Target Attributes
OrdEO.CustomerId	CustomerEO.Id

What Happens When You Use a Key Exists Validator

When you use a Key Exists validator, an `<ExistsValidationBean>` tag is created in the XML file for the entity object, as in the following example.

```
<validation:ExistsValidationBean
      Name="CustomerId_Rule_0"
      ResId="oracle.summit.model.entities.OrdEO.CustomerId_Rule_0"
      OperandType="EO"
      AssocName="oracle.summit.model.entities.assoc.SOrdCustomerIdFkAssoc"/>
```

What You May Need to Know About Declarative Validators and View Accessors

When using declarative validators you must consider how your validation will interact with expected input. The combination of declarative validators and view accessors provides a simple yet powerful alternative to coding. But, as powerful as the combination is, you still need to consider how data composition can impact performance.

Consider a scenario where you have the following:

- A `ServiceRequestEO` entity object with `Product` and `RequestType` attributes, and a view accessor that allows it to access the `RequestTypeVO` view object

- A RequestTypeVO view object with a query specifying the Product attribute as a bind parameter

The valid list of RequestTypes varies by Product. So, to validate the RequestType attribute, you use a List validator using the view accessor.

Now lets add a set of new service requests. For the first service request (row), the List validator binds the value of the Product attribute to the view accessor and executes it. For each subsequent service request the List validator compares the new value of the Product attribute to the currently bound value.

- If the value of Product matches, the current RowSet object is retained.
- If the value of Product has changed, the new value is bound and the view accessor re-executed.

Now consider the expected composition of input data. For example, the same products could appear in the input multiple times. If you simply validate the data in the order received, you might end up with the following:

1. Dryer (initial query)
2. Washing Machine (re-execute view accessor)
3. Dish Washer (re-execute view accessor)
4. Washing Machine (re-execute view accessor)
5. Dryer (re-execute view accessor)

In this case, the validator will execute 5 queries to get 3 distinct row sets. As an alternative, you can add an ORDER BY clause to the RequestTypeVO to sort it by Product. In this case, the validator would execute the query only once each for Washing Machine and Dryer.

1. Dish Washer (initial query)
2. Dryer (re-execute view accessor)
3. Dryer
4. Washing Machine (re-execute view accessor)
5. Washing Machine

A small difference on a data set this size, but multiplied over larger data sets and many users this could easily become an issue. An ORDER BY clause is not a solution to every issue, but this example illustrates how data composition can impact performance.

Using Entity-Level Triggers

ADF Business Components allows you to apply triggers in an entity object's lifecycle. Triggers execute at these set lifecycle events such as before a delete, after it, or before an insert operation.

Entity-level triggers enable you to implement expressions that are executed in response to trigger points in the entity object life cycle, such as before an insert operation or after a delete.

For example, you can evaluate or assert the value of an attribute prior to inserting an entity object or after updating an entity object. For a list of the available trigger points, see the online help.

How to Implement Business Rules Using Entity-Level Triggers

You can use Groovy script to implement business rules that are executed in response to entity-level triggers.

Before you begin:
It may be helpful to have an understanding of entity-level triggers. See Using Entity-Level Triggers.

You may also find it helpful to understand additional functionality that can be added using other validation features. See Additional Functionality for Declarative Validation.

To add a trigger:

1. In the Applications window, double-click the entity object you want to add a trigger to.
2. In the overview editor, click the **Business Rules** navigation tab.
3. On the Business Rules page, select the Entity-Level Triggers node, and click the **Create New Trigger** icon.
4. Select the appropriate trigger point from the **Type** dropdown list.
5. Enter a Groovy expression.
6. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the expression fails.

See Creating Validation Error Messages to read more on creating validation error messages.
When a Groovy expression is evaluated at runtime, it is assumed to be untrusted. For more information, see What You May Need to Know About Untrusted Groovy Expressions.

What Happens When You Create an Entity-Level Trigger

When you create a trigger, a `<Trigger>` tag is added to the entity object's XML file, as shown in the following example.

```
<Trigger
   Name="BeforeUpdate">
   <validation:ExpressionValidationBean
     Name="BeforeUpdateExpression0"
     OperandType="EXPR"
     Inverse="false">
     <validation:TransientExpression
       Name="ValidationRuleScript"
       trustMode="untrusted"
       hasReturn="false"
       CodeSourceName="ItemEORow"/>
   </validation:ExpressionValidationBean>
</Trigger>
```

Using Groovy Expressions For Business Rules and Triggers

You can use Groovy expressions to build business rules and triggers. These expressions are stored as part of the ADF entity object's XML definition as well as the `.bcs` file associated with the entity object.

Groovy expressions are Java-like scripting code stored in the XML definition of an entity object and the `.bcs` file associated with the entity object. Because Groovy scripts are stored in the `.bcs` file, you can change the expression values in this file.

For more information about using Groovy script in your entity object business logic, see Using Groovy Scripting Language with Business Components.

How to Reference Entity Object Methods in Groovy Expressions

You can call methods on the current entity instance using the `source` property of the current object. The `source` property allows you to access to the entity instance.

If the method is a non-boolean type and the method name is `getXyzAbc()` with no arguments, then you access its value as if it were a property named `XyzAbc`. For a boolean-valued property, the same holds true but the JavaBean naming pattern for the getter method changes to recognize `isXyzAbc()` instead of `getXyzAbc()`. If the method on your entity object does not match the JavaBean getter method naming pattern, or if it takes one or more arguments, then you must call it like a method using its complete name.

For example, say you have an entity object with the four methods shown in the following example.

```
public boolean isNewRow() {
 System.out.println("## isNewRow() accessed ##");
 return true;
}

public boolean isNewRow(int n) {
 System.out.println("## isNewRow(int n) accessed ##");
 return true;
}

public boolean testWhetherRowIsNew() {
 System.out.println("## testWhetherRowIsNew() accessed ##");
 return true;
}

public boolean testWhetherRowIsNew(int n) {
 System.out.println("## testWhetherRowIsNew(int n) accessed ##");
 return true;
}
```

Then the following Groovy validation condition would execute them all, one of them being executed twice, as shown in this example.

```
newRow && source.newRow && source.isNewRow(5) && source.testWhetherRowIsNew() &&
source.testWhetherRowIsNew(5)
```

By running this example and forcing entity validation to occur, you would see the following diagnostic output in the log window:

```
## isNewRow() accessed ##
## isNewRow() accessed ##
## isNewRow(int n) accessed ##
## testWhetherRowIsNew() accessed ##
## testWhetherRowIsNew(int n) accessed ##
```

Notice the slightly different syntax for the reference to a method whose name matches the JavaBeans property getter method naming pattern. Both `newRow` and `source.newRow` work to access the boolean-valued, JavaBeans getter-style method that has no arguments. But because the `testWhetherRowIsNew()` method does not match the JavaBeans getter method naming pattern, and the third `isNewRow()` method takes an argument, then you must call them like methods using their complete name.

How to Validate Using a True/False Expression

You can use a Groovy expression to return a true/false statement. The Script Expression validator *requires* that the expression either return `true` or `false`, or that it calls the `adf.error.raise/warn()` method. A common use of this feature would be to validate an attribute value, for example, to make sure that an account number is valid.

> **Note:**
>
> Using the `adf.error.raise/warn()` method (rather than simply returning `true` or `false`) allows you to define the message text to show to the user, and to associate an entity-level validator with a specific attribute. For more information, see How to Conditionally Raise Error Messages Using Groovy.

Before you begin:

It may be helpful to have an understanding of the use of Groovy in validation rules. For more information, see Using Groovy Expressions For Business Rules and Triggers.

You may also find it useful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To validate using a true/false expression:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select where you want to add the validator, and click the dropdown of the plus icon to select **New Validator**.
   - To add an entity-level validator, select the **Entity** node.
   - To add an attribute-level validator, expand the **Attributes** node and select the appropriate attribute.
3. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **Expression**.
4. Enter a validation expression in the **Expression** field.
5. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression in the **Expression** field. For more information, see Triggering Validation Execution.

6. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails. For more information, see Creating Validation Error Messages.
7. Click **OK**.

The following Groovy script example validates account numbers based on the Luhn algorithm, a checksum formula in widespread use.

```
@ValidatorExpression(name="PaymentOptionIdRule0",
attributeName="PaymentOptionId")
def PaymentOptionId_PaymentOptionIdRule0_ValidationRuleScript_ValidationRule()
{
String acctnumber = newValue;
 sumofdigits = 0;
 digit = 0;
 addend = 0;
 timesTwo = false;
 range = acctnumber.length()-1..0
  range.each {i ->
  digit = Integer.parseInt (acctnumber.substring (i, i + 1));
  if (timesTwo) {
   addend = digit * 2;
   if (addend > 9) {
    addend -= 9;
   }
  }
  else {
   addend = digit;
  }
  sumofdigits += addend;
  timesTwo = !timesTwo;
 }
 modulus = sumofdigits % 10;
 return modulus == 0;
}
```

What Happens When You Add a Groovy Expression

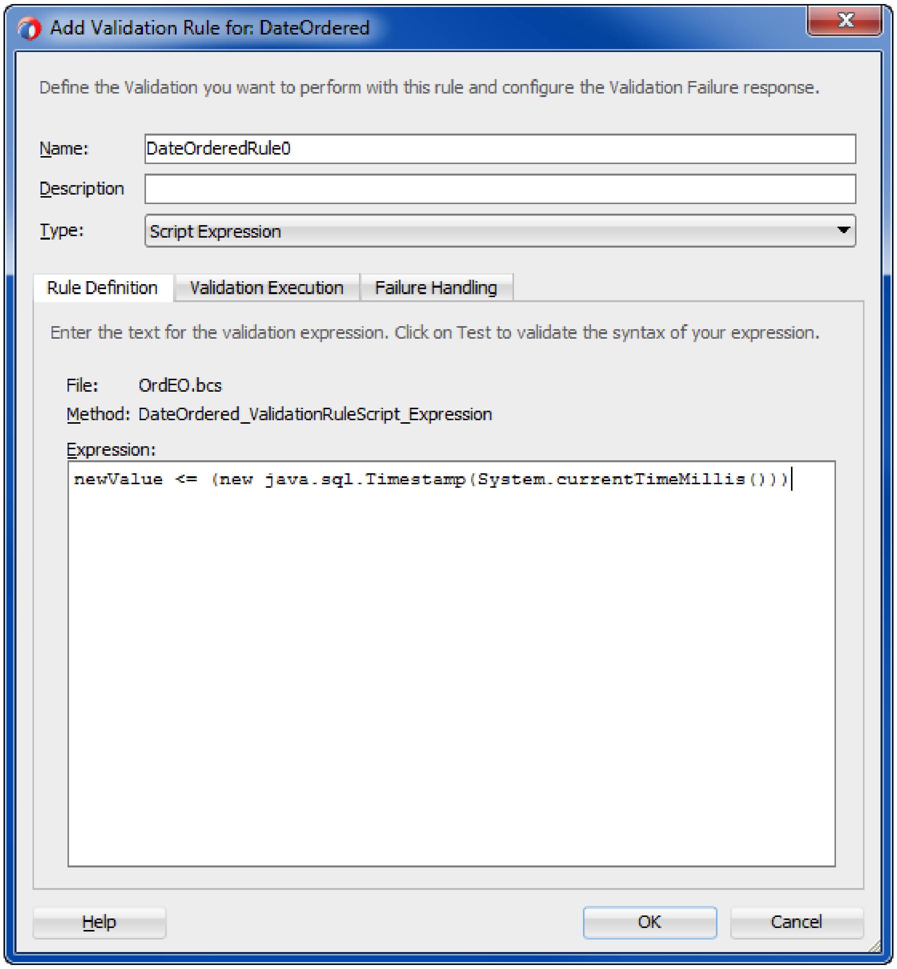
When you create a Groovy expression, it is saved in the entity object's XML component. The following example shows a `DateOrdered` attribute in an entity object. The Groovy expression is wrapped by a `<validation:ExpressionValidationBean>` tag. The Groovy script is enclosed in `OrdEO.bcs` file as indicated by `CodeSourceName="OrdEORow”` in the XML definition.

```
<Attribute
  Name="DateOrdered"
  ColumnName="DATE_ORDERED"
  SQLType="TIMESTAMP"
  Type="java.sql.Date"
  ColumnType="DATE"
  TableName="S_ORD">
  <DesignTime>
    <Attr Name="_DisplaySize" Value="7"/>
  </DesignTime>
  <validation:ExpressionValidationBean
    Name="DateOrderedRule0"
    OperandType="EXPR"
    Inverse="false">
    <validation:TransientExpression
```

```
      Name="ValidationRuleScript"
      trustMode="untrusted"
      CodeSourceName="OrdEORow"/>
  </validation:ExpressionValidationBean>
</Attribute>
```

Figure 10-6 shows the validation expression in the Edit Validation Rule dialog.

Figure 10-6 Validation Expression for Date Ordered Attribute



Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: DateOrderedRule0

Description

Type: Script Expression

Enter the text for the validation expression. Click on Test to validate the syntax of your expression.

File: OrdEO.bcs

Method: DateOrdered_ValidationRuleScript_Expression

Expression:

```
newValue <= (new java.sql.Timestamp(System.currentTimeMillis()))
```

Triggering Validation Execution

ADF Business Components allows you to define attribute level validations, as well as entity-level validations.

JDeveloper allows you to select the attributes that trigger validation, so that validation execution happens only when one of the triggering attributes is dirty. In previous releases of JDeveloper, an entity-level validator would fire on an attribute whenever the entity as a whole was dirty. This feature is described in How to Specify Which Attributes Fire Validation.

JDeveloper also allows you to specify a precondition for the execution of a validator (as described in How to Set Preconditions for Validation) and set transaction-level validation (described in How to Set Transaction-Level Validation).

How to Specify Which Attributes Fire Validation

When defining a validator at the entity level, you have the option of selecting one or more attributes of the entity object that, when changed, trigger execution of the validator.

> **Note:**
>
> When the validity of one attribute is dependent on the value in another attribute, the validation should be performed as entity validation, not attribute validation. You can set validation execution order on the entity level or attribute level.

If you do not specify one or more dependent attributes, the validator will fire whenever the entity is dirty. Firing execution only when required makes your application more performant.

Before you begin:

It may be helpful to have an understanding of how validation rules are triggered. For more information, see Triggering Validation Execution.

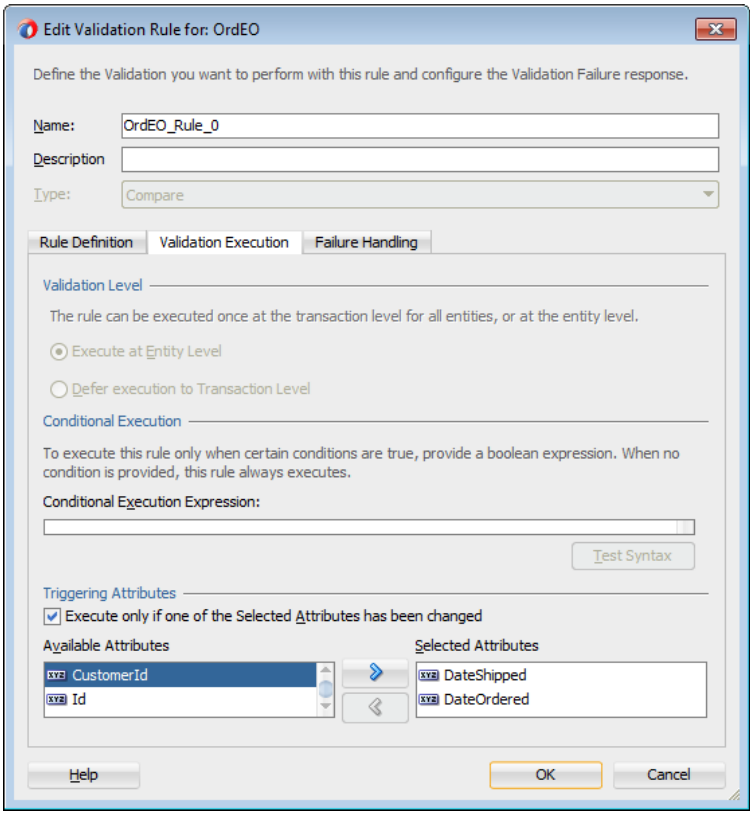
You may also find it useful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To specify which attributes fire validation:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select the **Entity** node, and click the **Edit** icon.
3. In the Edit Validation Rule dialog, click the **Validation Execution** tab.
4. Select the attributes that will fire validation.
5. Click **OK**.

For example, in the `SummitADF` application workspace, the `OrdEO` entity object has an entity-level validator that requires the `DateShipped` attribute to be later than the `DateOrdered` attribute. As shown in Figure 10-7, this validator is set to be executed on the entity object only when either the `DateShipped` attribute or the `DateOrdered` attribute has been changed.

Figure 10-7 Triggering attributes on the Validation Execution tab of the Edit Validation Rule dialog



Edit Validation Rule for: OrdEO

Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: OrdEO_Rule_0

Description

Type: Compare

Validation Level

The rule can be executed once at the transaction level for all entities, or at the entity level.

● Execute at Entity Level

○ Defer execution to Transaction Level

Conditional Execution

To execute this rule only when certain conditions are true, provide a boolean expression. When no condition is provided, this rule always executes.

Conditional Execution Expression:

Triggering Attributes

☑ Execute only if one of the Selected Attributes has been changed

Available Attributes: CustomerId, Id

Selected Attributes: DateShipped, DateOrdered

What Happens When You Constrain Validation Execution with Triggering Attributes

When you specify triggering attributes on the **Validation Execution** tab of the Edit Validation Rule dialog, JDeveloper adds a `<validation:OnAttributes>` tag to the validator definition in the entity object's XML file. The following example shows the XML code for the entity-level validator for the `OrdEO` entity object in the core Summit ADF sample application.

```
<validation:CompareValidationBean
   Name="OrdEO_Rule_0"
   ResId="oracle.summit.model.entities.OrdEO_Rule_0"
   OnAttribute="DateShipped"
   OperandType="ATTR"
   Inverse="false"
   CompareType="GREATERTHANEQUALTO"
   CompareValue="DateOrdered">
   <validation:OnAttributes>
     <validation:Item
       Value="DateShipped"/>
     <validation:Item
       Value="DateOrdered"/>
   </validation:OnAttributes>
</validation:CompareValidationBean>
```

How to Set Preconditions for Validation

The **Validation Execution** tab (on the Add/Edit Validation Rule dialog) allows you to add a Groovy expression that serves as a precondition. If you enter an expression in the **Conditional Execution Expression** box, the validator is executed only if the condition evaluates `True`.

> **Best Practice:**
>
> While it is possible to add a precondition for a Unique Key validator, it is not a best practice. If a Unique Key validator fails to fire, for whatever reason, the cache consistency check is still performed and an error will be returned. It is generally better to add the validator and a meaningful error message.

How to Set Transaction-Level Validation

Performing a validation during the transaction level (rather than entity level) means that the validation will be performed after all entity-level validation is performed. For this reason, it may be useful if you want to ensure that a validator is performed at the end of the process.

In addition, the Key Exists validator is more performant with bulk transactions if it is run as a transaction level validator since it will be run only once for all entities in the transaction (of the same type), rather than once per entity. This will result in improved performance if the validator has to go to the database.

> **Note:**
>
> Transaction-level validation is only applicable to Key Exists and Method entity validators.

Before you begin:

It may be helpful to have an understanding of how validation rules are triggered. For more information, see Triggering Validation Execution.

You may also find it useful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To specify entity-level or transaction-level validation:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select an entity-level validation rule, and click the **Edit** icon.
3. In the Edit Validation Rule dialog, click the **Validation Execution** tab.
4. Select **Execute at Entity Level** or **Defer Execution to Transaction Level**.

5. Click **OK**.

What You May Need to Know About the Order of Validation Execution

You cannot control the order in which attributes are validated – they are always validated in the order they appear in the entity definition. You can order validations for a given attribute (or for the entity), but you cannot reorder the attributes themselves.

Creating Validation Error Messages

ADF Business Components allows you to create validation error messages by entering text that provides self-explanatory information to the end-user on the problem and troubleshooting tips.

Validation error messages provide important information for the user: the message should convey what went wrong and how to fix it.

How to Create Error Messages for Validators and Triggers

When you create or edit a validation rule or trigger, you can enter text to help the user determine what caused the error.

Before you begin:

It may be helpful to have an understanding of error messages in validation rules. For more information, see Creating Validation Error Messages.

You may also find it useful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Declarative Validation.

To create error messages for validators or triggers:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab, select a validation rule or trigger, and click the **Edit** icon.
3. In the Edit dialog, click the **Failure Handling** tab.
4. In the **Message Text** field, enter your error message.

   You can also define error messages in a message bundle file. To select a previously defined error message or to define a new one in a message bundle file, click the **Select Message** icon.

   > **Note:**
   >
   > Triggers and Script Expression validators allow you to enter more than one error message. This is useful if the validation script conditionally returns different error or warning messages. For more information, see How to Conditionally Raise Error Messages Using Groovy.

5. You can optionally include message tokens in the body of the message, and define them in the **Token Message Expressions** list.

Figure 10-8 shows the failure message for a validation rule in the OrdEO entity object that contains message tokens. For more information on this feature, see How to Embed a Groovy Expression in an Error Message.

6. Click **OK**.

How to Localize Validation Messages

The error message is a translatable string and is managed in the same way as translatable UI **control hints** in an entity object message bundle class. To view the error message for the defined rule in the message bundle class, locate the String key in the message bundle that corresponds to the ResId property in the XML document entry for the validator. For example, The following example shows a message bundle where the NAME_CANNOT_BEGIN_WITH_U key appears with the error message for the default locale.

Resource bundles can be created for your applications either as a list resource bundle (as shown in the sample below), as a properties bundle, or as an XLIFF resource bundle. For more information about using translatable strings in a resource bundle, see Working with Resource Bundles.

```
package devguide.advanced.customerrors;
import java.util.ListResourceBundle;

public class CustomMessageBundle extends ListResourceBundle {
  private static final Object[][] sMessageStrings = new String[][] {
  // other strings here
  {"NAME_CANNOT_BEGIN_WITH_U", "The name cannot begin with the letter u!"},
  // other strings here
  };
  // etc.
}
```

How to Conditionally Raise Error Messages Using Groovy

You can use the adf.error.raise() and adf.error.warn() methods to conditionally raise one error message or another depending upon branching in the Groovy expression. For example, if an attribute value is *x*, then validate as follows, and if the validation fails, raise error messageA; whereas if the attribute value is *y*, then instead validate a different way and if validation fails, raise error messageB.

If the expression returns false (versus raising a specific error message using the raise() method), the validator calls the first error message associated with the validator.

The syntax of the raise() method takes one required parameter (the msgId to use from the message bundle), and optionally can take the attrName parameter. If you pass in the AttrName, the error is associated with that attribute even if the validation is assigned to the entity.

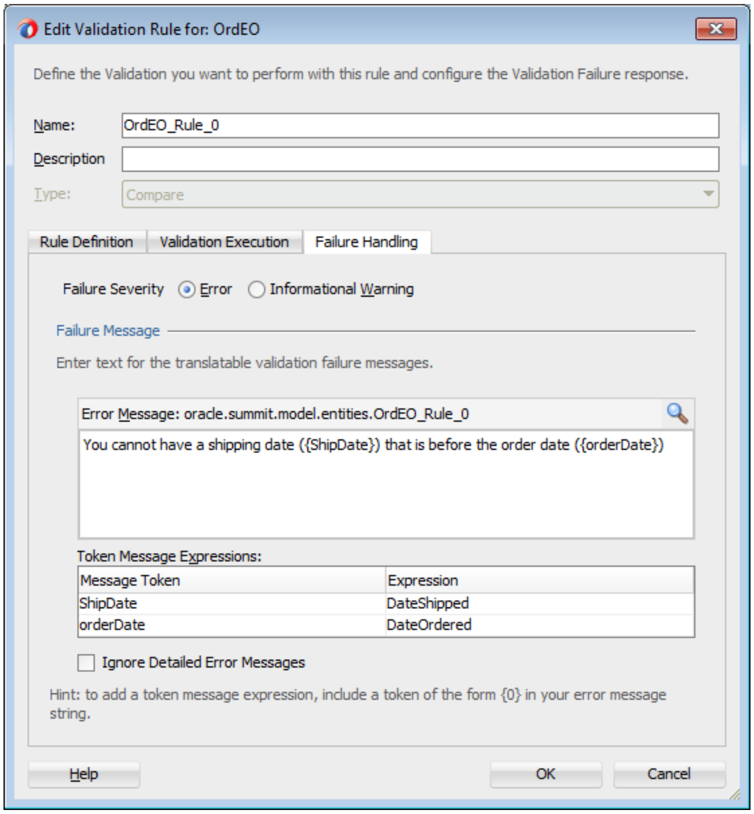
You can use either adf.error.raise() or adf.error.warn() methods, depending on whether you want to throw an exception, or whether you want processing to continue, as described in Setting the Severity Level for Validation Exceptions.

How to Embed a Groovy Expression in an Error Message

A validator's error message can contain embedded expressions that are resolved by the server at runtime. To access this feature, simply enter a named token delimited by curly braces (for example, `{2}` or `{errorParam}`) in the error message text where you want the result of the Groovy expression to appear.

After entering the token into the text of the error message (on the **Failure Handling** tab of the Edit Validation Rule dialog), the **Token Message Expressions** table at the bottom of the dialog displays a row that allows you to enter a Groovy expression for the token. Figure 10-8 shows the failure message for a validation rule in the `OrdEO` entity object that contains message tokens.

Figure 10-8 Using Message Tokens in a Failure Message



Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: OrdEO_Rule_0

Description:

Type: Compare

Failure Severity ● Error ○ Informational Warning

Failure Message

Enter text for the translatable validation failure messages.

Error Message: oracle.summit.model.entities.OrdEO_Rule_0

You cannot have a shipping date ({ShipDate}) that is before the order date ({orderDate})

Token Message Expressions:

Message Token	Expression
ShipDate	DateShipped
orderDate	DateOrdered

☐ Ignore Detailed Error Messages

Hint: to add a token message expression, include a token of the form {0} in your error message string.

The expressions shown in Figure 10-8 are Groovy expressions that return the labels of the specified fields. You can also use Groovy expressions to access attribute values and other business components objects. For example, you can use the Groovy expression `newValue` to return the entered value.

The Groovy syntax to retrieve a value from a view accessor is *`accessorName`*`.currentRow.`*`AttributeName`*. For example, the Groovy expression `MyEmpAccessor.currentRow.Job` returns the value of the `Job` attribute in the current row of the `MyEmpAccessor` view accessor.

The Groovy expression can also be more complex, as in the following example, which shows an expression in the error message for the List validation rule for the `PaymentTypeId` attribute in the `OrdEO` entity object.

```
cr = CustomerEO.CreditRatingId
ratings = [1, 2]
if (cr  in ratings)
{return true}
else
{return false}
```

For more information about accessing business components objects using Groovy, see Using Groovy Scripting Language with Business Components.

Setting the Severity Level for Validation Exceptions

ADF Business Components allows you to set severity levels for validations exceptions as Informational Warning or Error. The latter level if set does not allow the end-user to proceed without fixing the issue.

You can set the severity level for validation exceptions to two levels, Informational Warning and Error. If you set the severity level to Informational Warning, an error message will display, but processing will continue. If you set the validation level to Error, the user will not be able to proceed until you have fixed the error.

Under most circumstances you will use the Error level for validation exceptions, so this is the default setting. However, you might want to implement a Informational Warning message if the user has a certain security clearance. For example, a store manager may want to be able to make changes that would surface as an error if a clerk tried to do the same thing.

When the severity level is set to **Informational Warning**, the error message is presented with a warning icon rather than an error icon and after acknowledging the warning, you can proceed to save the changes.

To set the severity level for validation exceptions, use the **Failure Handling** tab of the Add Validation Rule dialog.

To set the severity level of a validation exception:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab.
3. On the Business Rules page, select an existing validation rule and click the **Edit** icon, or click the **Add** icon to create a new rule.
4. In the Edit/Add Validation Rule dialog, click the **Failure Handling** tab and select the option for either **Error** or **Informational Warning**.
5. Click **OK**.

Bulk Validation in SQL

ADF Business Components provides bulk validation facility to improve performance of batch-load applications. The validation is applied on primary keys, alternative keys and foreign keys.

To improve the performance of batch-load applications, such as data synchronization programs, Oracle ADF employs bulk validation for primary keys (including alternate keys) and foreign keys.

When the Key Exists validator is configured to defer validation until the transaction commits, or when the rows are being updated or inserted through the `process`*`XXX`* methods of the ADF Business Components service layer, the validation cache is preloaded. This behavior uses the normal row-by-row derivation and validation logic, but uses validation logic that checks a memory cache before making queries to the database. Performance is improved by preloading the memory cache using bulk SQL operations based on the inbound data.

11 Working Programmatically with View Objects

This chapter describes programmatic uses of the ADF Business Components API that you can use while designing and working with ADF view objects in an Oracle ADF application.
This chapter includes the following sections:

Generating Custom Java Classes for a View Object

Use custom Java code in a custom Java class associated with an ADF Business Components view object to add custom logic and validation methods.

As you've seen, all of the basic querying functionality of a view object can be achieved without using custom Java code. Clients can retrieve and iterate through the data of any SQL query without resorting to any custom code on the **view object** developer's part. In short, for many view objects, once you have defined the SQL statement, you're done. However, it's important to understand how to enable custom Java generation for a view object when your needs might require it. For example, reasons you might write code in a custom Java class include:

- To add validation methods (although Groovy Script expressions can provide this support without needing Java)
- To add custom logic
- To augment built-in behavior

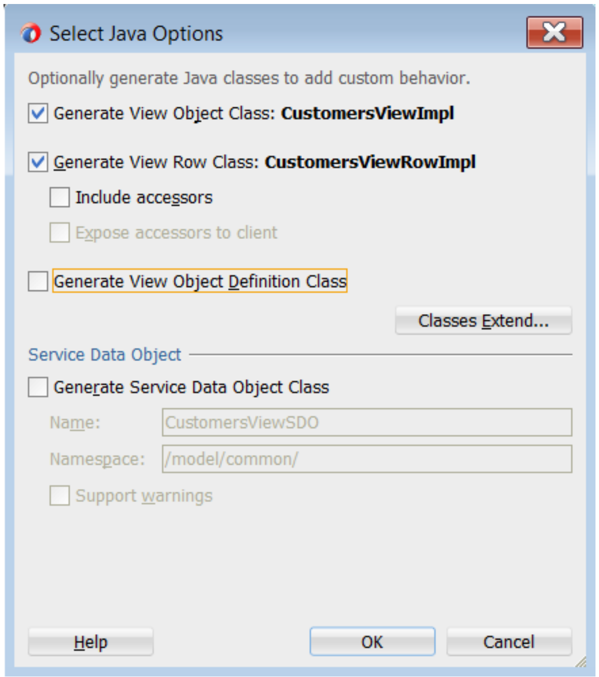
Most Commonly Used ADF Business Components Methods provides a quick reference to the most common code that you will typically write, use, and override in your custom view object and view row classes.

How To Generate Custom Classes

To enable the generation of custom Java classes for a view object, use the **Java** page of the view object overview editor. As shown in the figure below, there are three optional Java classes that can be related to a view object. The first two in the list are the most commonly used:

- **View object class**, which represents the component that performs the query and controls the execution lifecycle
- **View row class**, which represents each row in the query result

Figure 11-1 View Object Custom Java Generation Options



Select Java Options

Optionally generate Java classes to add custom behavior.

☑ Generate View Object Class: **CustomersViewImpl**

☑ Generate View Row Class: **CustomersViewRowImpl**

□ Include accessors

□ Expose accessors to client

□ Generate View Object Definition Class

Service Data Object

□ Generate Service Data Object Class

Name: CustomersViewSDO

Namespace: /model/common/

□ Support warnings

Generating View Row Attribute Accessors

When you enable the generation of a custom view row class, if you also select the **Include Accessors** checkbox, as shown in the Select Java Options dialog, then JDeveloper generates getter and setter methods for each attribute in the view row. For example, for the `ProductView` view object, the corresponding custom `ProductViewRowImpl.java` class might have methods like this generated in it:

```
public String getName() {...}
public void setName(String value) {...}
public String getShortDesc() {...}
public void setShortDesc(String value) {...}
public String getImageId() {...}
public void setImageId(Integer value) {...}
public String getSuggestedWhlslPrice() {...}
public void setSuggestedWhlslPrice(BigDecimal value) {...}
```

These methods allow you to work with the row data with compile-time checking of the correct datatype usage. That is, instead of writing a line like this one that gets the value of the Name attribute:

```
String name = row.getAttribute("Name");
```

you can write the code like:

```
String name = row.getName();
```

You can see that with the latter approach, the Java compiler would catch a typographical error had you accidentally typed FullName instead of Name:

```
// spelling name wrong gives compile error
String name = row.getFullName();
```

Without the generated view row accessor methods, an incorrect line of code like the following cannot be caught by the compiler:

```
// Both attribute name and type cast are wrong, but compiler cannot catch it
Integer name = (Integer)row.getAttribute("FullName");
```

It contains both an incorrectly spelled attribute name, as well as an incorrectly typed cast of the getAttribute() return value. Using the generic APIs on the Row interface, errors of this kind will raise exceptions at runtime instead of being caught at compile time.

Exposing View Row Accessors to Clients

When enabling the generation of a custom view row class, if you would like to generate a view row attribute accessor, select the **Expose Accessor to the Client** checkbox. This causes an additional custom row interface to be generated which application clients can use to access custom methods on the row without depending directly on the implementation class.

> **Best Practice:**
>
> When you create client code for business components, you should use business service interfaces rather than concrete classes. Using the interface instead of the implementation class, ensures that client code does not need to change when your server-side implementation does. For more details working with client code, see in What You May Need to Know About Custom Interface Support.

For example, in the case of the ProductView view object, exposing the accessors to the client will generate a custom row interface named ProductViewRow. This interface is created in the common subpackage of the package in which the view object resides. Having the row interface allows clients to write code that accesses the attributes of query results in a strongly typed manner. The following example shows a TestClient sample client program that casts the results of the productByName.first() method to the ProductViewRow interface so that it can make method calls like printAllAttributes() and testSomethingOnProductRows().

```
package oracle.summit.model.extend;
```

```
import oracle.jbo.*;
import oracle.jbo.client.Configuration;

import oracle.summit.model.extend.common.ProductView;
import oracle.summit.model.extend.common.ProductViewEx;
import oracle.summit.model.extend.common.ProductViewExRow;
import oracle.summit.model.extend.common.ProductViewRow;

public class TestClient {
  public static void main(String[] args) {
    String amDef = "oracle.summit.model.extend.AppModule";
    String config = "AppModuleLocal";
    ApplicationModule am =
                  Configuration.createRootApplicationModule(amDef,config);
    ProductView products = (ProductView)am.findViewObject("ProductView1");
    products.executeQuery();
    ProductViewRow product = (ProductViewRow)products.first();
    printAllAttributes(products,product);
    testSomethingOnProductsRow(product);
    products = (ProductView)am.findViewObject("ProductViewEx1");
    ProductViewEx productsByName = (ProductViewEx)products;
    productsByName.setbv_ProductName("bunny");
    productsByName.executeQuery();
    product = (ProductViewRow)productsByName.first();
    printAllAttributes(productsByName,product);
    testSomethingOnProductsRow(product);
    am.getTransaction().rollback();
    Configuration.releaseRootApplicationModule(am,true);
  }
  private static void testSomethingOnProductsRow(ProductViewRow product) {
    try {
      if (product instanceof ProductViewExRow) {
        ProductViewExRow productByName = (ProductViewExRow)product;
        productByName.someExtraFeature("Test");
      }
      product.setName("Q");
      System.out.println("Setting the Name attribute to 'Q' succeeded.");
    }
    catch (ValidationException v) {
      System.out.println(v.getLocalizedMessage());
    }
  }
  private static void printAllAttributes(ViewObject vo, Row r) {
    String viewObjName = vo.getName();
    System.out.println("Printing attribute for a row in VO '"+ viewObjName+"'");
    StructureDef def = r.getStructureDef();
    StringBuilder sb = new StringBuilder();
    int numAttrs = def.getAttributeCount();
    AttributeDef[] attrDefs = def.getAttributeDefs();
    for (int z = 0; z < numAttrs; z++) {
      Object value = r.getAttribute(z);
      sb.append(z > 0 ? "  " : "")
        .append(attrDefs[z].getName())
        .append("=")
        .append(value == null ? "<null>" : value)
        .append(z < numAttrs - 1 ? "\n" : "");
    }
    System.out.println(sb.toString());
  }
}
```

Configuring Default Java Generation Preferences

You've seen how to generate custom Java classes for your view objects when you need to customize their runtime behavior, or if you simply prefer to have strongly typed access to bind variables or view row attributes.

To change the default settings that control how JDeveloper generates Java classes, choose **Tools | Preferences** and open the **ADF Business Components** page. The settings you choose will apply to all future business components you create.

Oracle recommends that developers getting started with ADF Business Components set their preference to generate no custom Java classes by default. As you run into specific needs, you can enable just the bit of custom Java you need for that one component. Over time, you'll discover which set of defaults works best for you.

What Happens When You Generate Custom Classes

When you choose to generate one or more custom Java classes, JDeveloper creates the Java file(s) you've indicated.

For example, in the case of a view object named `oracle.summit.model.extend.ProductView`, the default names for its custom Java files will be `ProductViewImpl.java` for the view object class and `ProductViewRowImpl.java` for the view row class. Both files get created in the same `./model/extend` directory as the component's XML document file.

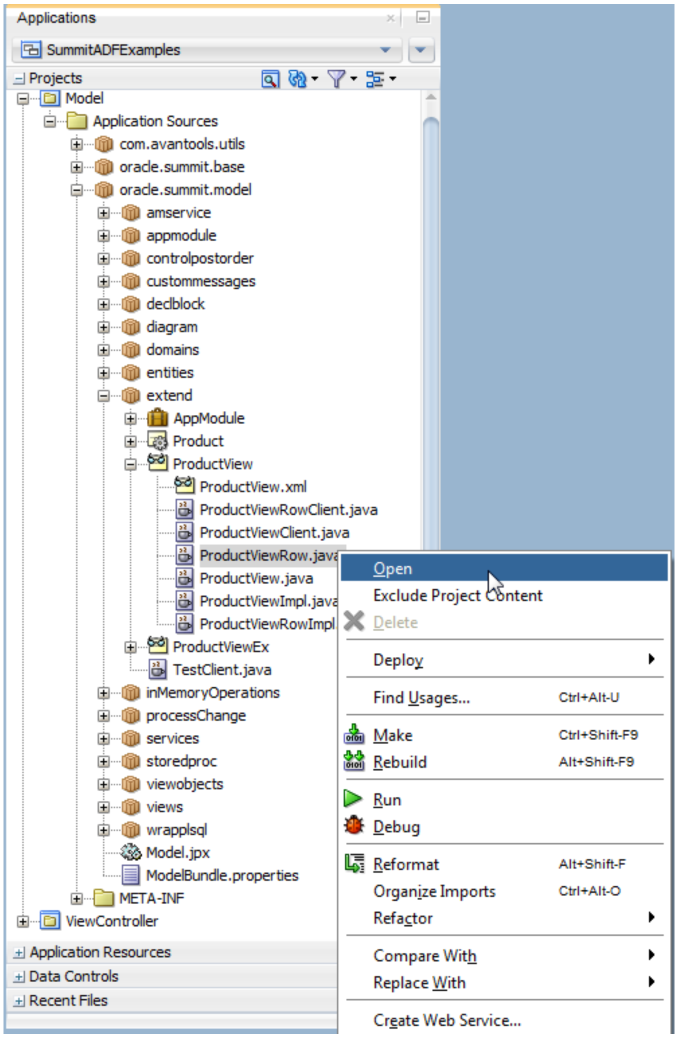
The Java generation options for the view object continue to be reflected on the Java page on subsequent visits to the view object overview editor. Just as with the XML definition file, JDeveloper keeps the generated code in your custom Java classes up to date with any changes you make in the editor. If later you decide you didn't require a custom Java file for any reason, unchecking the relevant options in the Java page causes the custom Java files to be removed.

Viewing and Navigating to Custom Java Files

As shown in Figure 11-2, when you've enabled generation of custom Java classes, they also appear under the node for the view object. When you need to see or work with the source code for a custom Java file, there are two ways to open the file in the source editor:

- Choose **Open** in the context menu, as shown in Figure 11-2
- With the Java file node selected in the Applications window, double-click a node in the Structure window

Figure 11-2 Viewing and Navigating to Custom Java Classes for a View Object



What You May Need to Know About Custom Classes

This section provides additional information to help you use custom Java classes.

About the Framework Base Classes for a View Object

When you use an "XML-only" view object, at runtime its functionality is provided by the default ADF Business Components implementation classes. Each custom Java class that gets generated will automatically extend the appropriate ADF Business Components base class so that your code inherits the default behavior and can easily add or customize it. A view object class will extend `ViewObjectImpl`, while the view row class will extend `ViewRowImpl` (both in the `oracle.jbo.server` package).

You Can Safely Add Code to the Custom Component File

Based perhaps on previous negative experiences, some developers are hesitant to add their own code to generated Java source files. Each custom Java source code file that JDeveloper creates and maintains for you includes the following comment at the top of the file to clarify that it is safe to add your own custom code to this file:

```
// ---------------------------------------------------------------------
// ---    File generated by ADF Business Components Design Time.
// ---    Custom code may be added to this class.
// ---    Warning: Do not modify method signatures of generated methods.
// ---------------------------------------------------------------------
```

JDeveloper does not blindly regenerate the file when you click the **OK** or **Apply** button in the component dialogs. Instead, it performs a smart update to the methods that it needs to maintain, leaving your own custom code intact.

Attribute Indexes and InvokeAccessor Generated Code

The view object is designed to function either in an XML-only mode or using a combination of an XML document and a custom Java class. Since attribute values are not stored in private member fields of a view row class, such a class is not present in the XML-only situation. Instead, attributes are defined as an AttributesEnum type, which specifies attribute names (and accessors for each attribute) based on the view object's XML document, in sequential order of the <ViewAttribute> tag, the association-related <ViewLinkAccessor> tag, and the <ViewAccessor> tag in that file. At runtime, the attribute values in an view row are stored in a structure that is managed by the base ViewRowImpl class, indexed by the attribute's numerical position in the view object's attribute list.

For the most part this private implementation detail is unimportant. However, when you enable a custom Java class for your view row, this implementation detail is related to some of the generated code that JDeveloper automatically maintains in your view row class, and you may want to understand what that code is used for. For example, in the custom Java class for the Users view row, the following example shows that each attribute, **view link accessor** attribute, or **view accessor** attribute has a corresponding generated AttributesEnum enum. JDeveloper defines enums instead of constants in order to prevent merge conflicts that could result when multiple developers add new attributes to the XML document.

```
public class RowImpl extends SummitViewRowImpl implements ProductViewRow {
/**
 * AttributesEnum: generated enum for identifying attributes and accessors.
 * Do not modify.
 */
public enum AttributesEnum {...}
  public static final int ID = AttributesEnum.Id.index();
  public static final int NAME = AttributesEnum.Name.index();
  public static final int SHORTDESC = AttributesEnum.ShortDesc.index();
  public static final int LONGTEXTID = AttributesEnum.LongtextId.index();
  public static final int IMAGEID = AttributesEnum.ImageId.index();
  public static final int SUGGESTEDWHLSLPRICE =
                             AttributesEnum.SuggestedWhlslPrice.index();
  public static final int WHLSLUNITS = AttributesEnum.WhlslUnits.index();
  public static final int SOMEVALUE = AttributesEnum.SomeValue.index();
  public static final int SFADSF = AttributesEnum.sfadsf.index();
  ...
```

You'll also notice that the automatically maintained, strongly typed getter and setter methods in the view row class use these attribute constants like this:

```
public Integer getId() {
  return (Integer) getAttributeInternal(ID); // <-- Attribute constant
}
public void setId(Integer value) {
  setAttributeInternal(ID, value);// <-- Attribute constant
}
```

The last two aspects of the automatically maintained code related to view row attribute constants defined by the `AttributesEnum` type are the `getAttrInvokeAccessor()` and `setAttrInvokeAccessor()` methods. These methods optimize the performance of attribute access by numerical index, which is how generic code in the `ViewRowImpl` base class typically accesses attribute values. An example of the `getAttrInvokeAccessor()` method looks like the following from the `ProductViewRowImpl.java` class. The companion `setAttrInvokeAccessor()` method looks similar.

```
protected Object getAttrInvokeAccessor(int index, AttributeDefImpl attrDef) throws Exception {
    if ((index >= AttributesEnum.firstIndex()) && (index < AttributesEnum.count())) {
        return AttributesEnum.staticValues()[index - AttributesEnum.firstIndex()].get(this);
    }
    return super.getAttrInvokeAccessor(index, attrDef);
}
```

The rules of thumb to remember about this generated attribute-related code are the following.

The Do's

- Add custom code if needed inside the strongly typed attribute getter and setter methods
- Use the view object overview editor to change the order or type of view object attributes

  JDeveloper will change the Java signature of getter and setter methods, as well as the related XML document for you.

The Don'ts

- Don't modify the list of enums in the generated `AttributesEnum` enum
- Don't modify the `getAttrInvokeAccessor()` and `setAttrInvokeAccessor()` methods

Avoid Creating Dependencies on Parent Application Module Types

Custom methods that you implement in the view object class or view object row class must not be dependent on the return type of an **application module**. At runtime, in specific cases, methods that execute with such a dependency may throw a `ClassCastException` because the returned application module does not match the expected type. It is therefore recommended that custom methods that you implement should not have code to get a specific application module implementation or view object implementation as shown below.

```
((MyAM)getRootApplicationModule()).getMyVO
```

Specifically, the above code fails with a `ClassCastException` in the following scenarios:

- When the ADF Business Components framework instantiates the view object in a different container application module than its defining container. While view objects are typically instantiated in the container application module that declares their view usage (XML definition), the ADF Business Components runtime does not guarantee that the containers associated with each application module will remain fixed. Thus, if you implement methods with dependencies on the parent application module type, your methods may not execute consistently.

- When you manually nest an application module under a **root application module**. In this case, the nested application modules share the same `Transaction` object and there is no guarantee that the expected application module type is returned with the above code.
- When the ADF Business Components framework implementation changes with releases. For example, in previous releases, the framework created an internal root application module in order to control declarative transactions that the application defined using **ADF task flows**.

Working Programmatically with Multiple Named View Criteria

ADF Business Components allows you to define multiple view criteria and apply combinations of them to a view object at runtime.

You can define *multiple* named **view criteria** in the overview editor for a view object and then selectively apply any combination of them to your view object at runtime as needed. For information about working with named view criteria at design time, see How to Create Named View Criteria Declaratively.

> **Note:**
>
> The example in this section refers to the `oracle.summit.model.multinamedviewcriteria` package in the `SummitADF_Examples` application workspace.

Applying One or More Named View Criteria

To apply one or more named view criteria, use the `setApplyViewCriteriaNames()` method. This method accepts a String array of the names of the criteria you want to apply. If you apply more than one named criteria, they are `AND`-ed together in the WHERE clause produced at runtime. New view criteria that you apply with the `setApplyViewCriteriaNames()` method will overwrite all previously applied view criteria. Alternatively, you can use the `setApplyViewCriteriaName()` method when you want to append a single view criteria to those that were previously applied.

When you need to apply more than one named view criteria, you can expose custom methods on the client interface of the view object to encapsulate applying combinations of the named view criteria. For example, the following example shows custom methods `showCustomersForSalesRep()`, `showCustomersForCreditRating()`, and `showCustomersForSalesRepForCreditRating()`, each of which uses the `setApplyViewCriteriaNames()` method to apply an appropriate combination of named view criteria. Once these methods are exposed on the view object's client interface, at runtime clients can invoke these methods as needed to change the information displayed by the view object.

```
// In CustomerViewImpl.java
   public void showCustomersForSalesRep() {
   // reset the view criteria
      setApplyViewCriteriaNames(null);
   // set the view criteria to show all the customers for the given sales rep
      setApplyViewCriteriaName("SalesRepIsCriteria");
      executeQuery();
   }

   public void showCustomersForCreditRating() {
      setApplyViewCriteriaNames(null);
      setApplyViewCriteriaName("CreditRatingIsCriteria");
      executeQuery();
   }

   public void showCustomersForSalesRepForCreditRating() {
   // reset the view criteria
      setApplyViewCriteriaNames(null);
   // apply both view criteria to show all the customers that match both
      setApplyViewCriteriaNames(new String[]{"SalesRepIsCriteria",
                                          "CreditRatingIsCriteria"});
      executeQuery();
   }
```

What You May Need to Know about Applying One or More Named View Criteria

You can also use the `appendViewCriteriaName()` method instead of `setApplyViewCriteriaNames()` to apply one or more named view criteria. This method works the same way as `setApplyViewCriteriaNames()` that accepts a String array of the names of the criteria you want to apply. If you apply more than one named criteria, they are `AND`-ed together in the WHERE clause produced at runtime. New view criteria that you apply with the `appendViewCriteriaName()` method will append the new view criteria to the already applied view criteria list of the view object. Alternatively, you can use the `appendViewCriteriaName()` method when you want to append a single view criteria to those that were previously applied.

The following code examples show the different new APIs that you can add to a view object.

- To append a given view criteria name to an existing list of applied view criteria.

  ```
   public void appendViewCriteriaName(String criteria);
  ```

- To append a list of given view criteria name to an existing list of view criteria.

  ```
  public void appendViewCriteriaName(String[] criterias);
  ```

- To append a given view criteria object to an existing list of criteria.

  ```
  public void appendViewCriteriaObject(ViewCriteria criteria);
  ```

- To append a list of given view criteria object to an existing list of applied view criteria.

  ```
  public void appendViewCriteriaObject(ViewCriteria[] criterias);
  ```

- To append a given view criteria expression to an existing list of applied view criteria.

  ```
     public void appendViewCriteriaExpression(String expr);
  ```

- To reset all the view criteria objects to their definition state.

  ```
   public void resetAllViewCriteria();
  ```

  This also removes any view criteria created at runtime.

- To reset a given view criteria object to its definition state.

  ```
  public void resetViewCriteriaName(String viewcriteria);
  ```

Removing All Applied Named View Criteria

To remove any currently applied named view criteria, use `setApplyViewCriteriaNames(null)`. For example, you could add the `showAllCustomers()` method in the following example to the `CustomersView` view object and expose it on the client interface. This would allow clients to return to an unfiltered view of the data when needed.

Do not remove any design time view criteria because the row level bind variable values may already be applied on the row set. To help ensure this, named view criteria that get defined for a view accessor in the design time, will be applied as "required" view criteria on the view object instance so that it does not get removed by the view criteria's life cycle methods.

```
// In CustomerViewImpl.java
public void showAllCustomers() {
  setApplyViewCriteriaNames(null);
  executeQuery();
}
```

> **Note:**
>
> The `setApplyViewCriterias(null)` removes all applied view criteria, but allows you to later reapply any combination of them. In contrast, the `clearViewCriterias()` method *deletes* all named view criteria. After calling `clearViewCriterias()` you would have to use `putViewCriteria()` again to define new named criteria before you could apply them.

Using the Named Criteria at Runtime

At runtime, your application can invoke different client methods on a single view object interface to return different filtered sets of data. The following example shows the interesting lines of a test client class that works with the `CustomerView` view object described above. The `showResults()` method is a helper method that iterates over the rows in the view object to display some attributes.

```
// In MultiNamedViewCriteriaTestClient.java
   CustomerView vo = (CustomerView) am.findViewObject("CustomerView");

// Show list of all rows in the CustomerView, without applying any view criteria.
   showResults(vo,"All Customers");

// Use  type safe set method to set the value of the bind variable used by the
// view criteria
   vo.setbv_SalesRepId(12);
   vo.showCustomersForSalesRep();
   showResults(vo, "All Customers with SalesRepId = 12");

// Set the sales rep id to 11 and show the results.
   vo.setbv_SalesRepId(11);
   vo.showCustomersForSalesRep();
   showResults(vo, "All Customers with SalesRepId = 11");

// use type safe method to set value of bind variable used by the view criteria
   vo.setbv_CreditRatingId(2);

// This method applies both view criteria to the VO so the results match
// both criteria, but we do not set the bind variable for sales rep as it
// was already set. The results will show all the customers with a sales
// rep of 11 and a credit rating of 2.
   vo.showCustomersForSalesRepForCreditRating();
   showResults(vo, "Customers with SalesRepId = 11 and CreditRating = 2");

// Now show all the customers again. The showAllCustomers method resets
// the view criteria.
   vo.showAllCustomers();
   showResults(vo, "All Customers");
```

Running `MultiNamedViewCriteriaTestClient.java` produces output as follows:

```
---All Customers ---

Unisports Sao Paulo [12, 1]
Simms Athletics Osaka [14, 4]
Delhi Sports New Delhi [14, 2]
...
---All Customers with SalesRepId = 12 ---

Unisports Sao Paulo [12, 1]
Futbol Sonora Nogales [12, 1]
Stuffz Sporting Goods Madison [12, 3]
...
---All Customers with SalesRepId = 11 ---

Womansport Seattle [11, 3]
Beisbol Si! San Pedro de Macon's [11, 1]
Big John's Sports Emporium San Francisco [11, 1]
```

```
Ojibway Retail Buffalo [11, 3]
...
---Customers with SalesRepId = 11 and CreditRating = 2 ---

Max Gear New York [11, 2]
MoreAndMoreStuffz Dallas [11, 2]
Schindler's Sports St Louis [11, 2]
...
---All Customers ---

Unisports Sao Paulo [12, 1]
Simms Athletics Osaka [14, 4]
Delhi Sports New Delhi [14, 2]
...
```

Performing In-Memory Sorting and Filtering of Row Sets

ADF Business Components allows you to configure view objects to search for data in-memory as opposed to from the database. In-memory searching and sorting is transaction-efficient and cost-effective.

View Object rows can be sorted by using the following APIs:

- `setSortBy`
- `setOrderByClause`
- `setOrderByorSortBy`

The `SortBy()` method is used to deal with in-memory sorting and the `OrderBy()` method is used to sort rows in the database layer.

By default a view object performs its query against the database to retrieve the rows in its resulting row set. However, you can also use view objects to perform in-memory searches and sorting to avoid unnecessary trips to the database. If transient attributes are passed to `setSortBy` API, then the rows will be sorted only in memory. This type of operation is ideal for sorting and filtering the new, as yet unposted rows of the view object row set; otherwise, unposted rows are added to the top of the row set. If any persistent attributes are passed to `setSortBy` API, then only for those persistent attributes a database order by clause is generated, so that rows are first sorted in database layer. If both transient and persistent attributes are passed , then for the persistent attributes a database order by clause is generated, database sorted rows are fetched into memory and then ADF BC will sort the fetched rows using both the transient and persistent attributes in the order specified.

> **Note:**
>
> The example in this section refers to to the `oracle.summit.model.inMemoryOperations` package in the `SummitADF_Examples` application workspace.

Understanding the View Object's SQL Mode

The view object's SQL mode controls the source used to retrieve rows to populate its row set. The `setQueryMode()` allows you to control which mode, or combination of modes, are used:

- `ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES`

  This is the default mode that retrieves results from the database.
- `ViewObject.QUERY_MODE_SCAN_VIEW_ROWS`

  This mode uses rows already in the row set as the source, allowing you to progressively refine the row set's contents through in-memory filtering.
- `ViewObject.QUERY_MODE_SCAN_ENTITY_ROWS`

  This mode, valid only for entity-based view objects, uses the entity rows presently in the entity cache as the source to produce results based on the contents of the cache.

You can use the modes individually, or combine them using Java's logical `OR` operator (*X* `|` *Y*). For example, to create a view object that queries the entity cache for unposted new entity rows, as well as the database for existing rows, you could write code like:

```
setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES |
             ViewObject.QUERY_MODE_SCAN_ENTITY_ROWS)
```

If you combine the SQL modes, the view object automatically handles skipping of duplicate rows. In addition, there is an implied order to the results that are found:

1. Scan view rows (if specified)
2. Scan entity cache (if specified)
3. Scan database tables (if specified) by issuing a SQL query

If you call the `setQueryMode()` method to change the SQL mode, your new setting takes effect the next time you call the `executeQuery()` method.

Sorting View Object Rows In Memory

To sort the rows in a view object at runtime, use the `setSortBy()` method to control the sort order or you can set the view object property `PROP_ALWAYS_USE_SORT` to `true` to allow the system to handle in-memory sorting by default.

When you want to control the sort order, you pass a sort expression that looks like a SQL ORDER BY clause. However, instead of referencing the column names of the table, you use the view object's attribute names. For example, for a view object containing attributes named `CreditRatingId` and `ZipCode`, you could sort the view object first by `Customer` descending, then by `DaysOpen` by calling:

```
setSortBy("CreditRatingId desc, ZipCode");
```

Alternatively, you can use the *zero-based* attribute index position in the sorting clause like this:

```
setSortBy("3 desc, 2");
```

After calling the `setSortBy()` method, the rows will be sorted the next time you call the `executeQuery()` method. The view object translates this sorting clause into an appropriate format to use for ordering the rows depending on the SQL mode of the view object. If you use the default SQL mode, the `SortBy` clause is translated into an appropriate `ORDER BY` clause and used as part of the SQL statement sent to the database. If you use either of the in-memory SQL modes, then the `SortBy` by clause is translated into one or more `SortCriteria` objects for use in performing the in-memory sort.

> **Note:**
>
> While SQL ORDER BY expressions treat column names in a case-insensitive way, the attribute names in a `SortBy` expression are case-*sensitive*.

Combining setSortBy and setQueryMode for In-Memory Sorting

You can perform an in-memory sort on the rows produced by a read-only view object using the `setSortBy()` and `setQueryMode()` methods. The following example shows the interesting lines of code from the `TestClientSetSortBy` class that uses `setSortBy()` and `setQueryMode()` to perform an in-memory sort on the rows produced by a read-only view object `CustomersInTx`.

```
// In TestClientSetSortBy.java
am.getTransaction().executeCommand("ALTER SESSION SET SQL_TRACE TRUE");
ViewObject vo = am.findViewObject("CustomersInTx");
vo.executeQuery();
showRows(vo,"Initial database results");
vo.setSortBy("Name");
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
vo.executeQuery();
showRows(vo,"After in-memory sorting by Customer Name ");
vo.setSortBy("CreditRatingId desc, ZipCode");
vo.executeQuery();
showRows(vo,"After in-memory sorting by CreditRating desc, and ZipCode");
```

Running the example produces the results:

```
--- Initial database results ---

36,Great Gear,1500 Barton Springs Rd,78704, 2, TX
37,Acme Outfitters,3500 Guadalupe St,78705, 3, TX
38,Athena's Closet,1209 Red River St,78701, 1, TX
39,BuyMyJunk,5610 E Mockingbird Ln,75206, 3, TX
...

--- After in-memory sorting by Customer Name  ---

37,Acme Outfitters,3500 Guadalupe St,78705, 3, TX
38,Athena's Closet,1209 Red River St,78701, 1, TX
43,Big Bad Sports,2920 Hillcroft St,77057, 1, TX
39,BuyMyJunk,5610 E Mockingbird Ln,75206, 3, TX
...

--- After in-memory sorting by CreditRating desc, and ZipCode ---
```

```
42,Field Importers,2111 Norfolk St,77098, 4, TX
39,BuyMyJunk,5610 E Mockingbird Ln,75206, 3, TX
37,Acme Outfitters,3500 Guadalupe St,78705, 3, TX
41,MoreAndMoreStuffz,3501 McKinney Ave,75204, 2, TX
...
```

The first line in the above test client containing the `executeCommand()` call issues the `ALTER SESSION SET SQL TRACE` command to enable SQL tracing for the current database session. This causes the Oracle database to log every SQL statement performed to a server-side trace file. It records information about the text of each SQL statement, including how many times the database parsed the statement and how many round-trips the client made to fetch batches of rows while retrieving the query result.

> **Note:**
>
> You might need a DBA to grant permission to the `Summit` account to perform the `ALTER SESSION` command to do the tracing of SQL output.

Once you've produced a trace file, you can use the `TKPROF` utility that comes with the database to format the file:

```
tkprof xe_ora_3916.trc trace.prf
```

For details about working with the `TKPROF` utility, see sections "Understanding SQL Trace and TKPROF" and "Using the SQL Trace Facility and TKPROF" in the "Performing Application Tracing" chapter of the *Oracle Database SQL Tuning Guide*.

This will produces a `trace.prf` file containing the interesting information shown in the following example about the SQL statement performed by the `CustomersInTx` view object. You can see that after initially querying six rows of data in a single execute and fetch from the database, the two subsequent sorts of those results did not cause any further executions. Since the code set the SQL mode to `ViewObject.QUERY_MODE_SCAN_VIEW_ROWS` the `setSortBy()` followed by the `executeQuery()` performed the sort in memory.

```

```

Simplified In-Memory Sorting

Should you not require control over the way that rows are sorted in memory, the view object interface provides the PROP_ALWAYS_USE_SORT property that enforces sorting when you change the view object query mode to use in-memory rows as the source. You can use this property when a view object has a small row set and the client needs to have in-memory sorting performed. Set the view object property to specify default in-memory sorting after you set the query mode:

```
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_ENTITY_ROWS);
vo.setProperty(ViewObject.PROP_ALWAYS_USE_SORT, "true");
```

Extensibility Points for In-Memory Sorting

Should you need to customize the way that rows are sorted in memory, you have the following means at your disposal:

- You can override the method:

  ```
  public void sortRows(Row[] rows)
  ```

  This method performs the actual in-memory sorting of rows. By overriding this method you can plug in an alternative sorting approach if needed.
- You can override the method:

  ```
  public Comparator getRowComparator()
  ```

  The default implementation of this method returns an oracle.jbo.RowComparator. RowComparator invokes the compareTo() method to compare two data values. These methods/objects can be overridden to provide custom compare routines.

Performing In-Memory Filtering with View Criteria

To filter the contents of a row set using ViewCriteria, you can call:

- applyViewCriteria() or setApplyViewCriteriaNames() followed by executeQuery() to produce a new, filtered row set.
- findByViewCriteria() to retrieve a new row set to process programmatically without changing the contents of the original row set.

Both of these approaches can be used against the database or to perform in-memory filtering, or both, depending on the view criteria mode. You set the criteria mode using the setCriteriaMode() method on the ViewCriteria object, to which you can pass either of the following integer flags, or the logical OR of both:

- ViewCriteria.CRITERIA_MODE_QUERY
- ViewCriteria.CRITERIA_MODE_CACHE

When used for in-memory filtering with view criteria, the operators supported are shown in Table 11-1. You can group subexpressions with parenthesis and use the AND and OR operators between subexpressions.

Table 11-1   SQL Operators Supported By In-Memory Filtering with View Criteria

Operator	Operation
=, >, <, <=, >=, <>, LIKE, BETWEEN, IN	Comparison
NOT	Logical negation
AND	Conjunction
OR	Disjunction

The following example shows the interesting lines from a TestClientFindByViewCriteria class that uses the two features described above both against the database and in-memory. It uses a CustomerList view object instance and performs the following basic steps:

1. Queries customers from the database with a last name starting with a 'C', producing the output:

   ```
   --- Initial database results with applied view criteria ---
   John Chen
   Emerson Clabe
   Karen Colmenares
   ```

2. Subsets the results from step 1 in memory to only those with a first name starting with 'J'. It does this by adding a second view criteria row to the view criteria and setting the conjunction to use "AND". This produces the output:

   ```
   --- After augmenting view criteria and applying in-memory ---
   John Chen
   ```

3. Sets the conjunction back to OR and reapplies the criteria to the database to query customers with last name like 'J%' or first name like 'C%'. This produces the output:

   ```
   --- After changing view criteria and applying to database again ---
   John Chen
   Jose Manuel Urman
   Emerson Clabe
   Karen Colmenares
   Jennifer Whalen
   ```

4. Defines a new criteria to find customers in-memory with first or last name that contain a letter 'o'

5. Uses findByViewCriteria() to produce new a row set (instead of subsetting), producing the output:

   ```
   --- Rows returned from in-memory findByViewCriteria ---
   John Chen
   Jose Manuel Urman
   Emerson Clabe
   Karen Colmenares
   ```

6. Shows that original row set hasn't changed when findByViewCriteria() was used, producing the output:

   ```
   --- Note findByViewCriteria didn't change rows in the view ---
   John Chen
   Jose Manuel Urman
   Emerson Clabe
   ```

```
    Karen Colmenares
    Jennifer Whalen
```

```
// In TestClientFindByViewCriteria.java
ViewObject vo = am.findViewObject("CustomerList");
// 1. Show customers with a last name starting with a 'M'
ViewCriteria vc = vo.createViewCriteria();
ViewCriteriaRow vcr1 = vc.createViewCriteriaRow();
vcr1.setAttribute("LastName","LIKE 'M%'");
vo.applyViewCriteria(vc);
vo.executeQuery();
vc.add(vcr1);
vo.executeQuery();
showRows(vo, "Initial database results with applied view criteria");
// 2. Subset results in memory to those with first name starting with 'S'
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
ViewCriteriaRow vcr2 = vc.createViewCriteriaRow();
vcr2.setAttribute("FirstName","LIKE 'S%'");
vcr2.setConjunction(ViewCriteriaRow.VCROW_CONJ_AND);
vc.setCriteriaMode(ViewCriteria.CRITERIA_MODE_CACHE);
vc.add(vcr2);
vo.executeQuery();
showRows(vo,"After augmenting view criteria and applying in-memory");
// 3. Set conjuction back to OR and reapply to database query to find
// customers with last name like 'H%' or first name like 'S%'
vc.setCriteriaMode(ViewCriteria.CRITERIA_MODE_QUERY);
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES);
vcr2.setConjunction(ViewCriteriaRow.VCROW_CONJ_OR);
vo.executeQuery();
showRows(vo,"After changing view criteria and applying to database again");
// 4. Define new critera to find customers with first or last name like '%o%'
ViewCriteria nameContainsO = vo.createViewCriteria();
ViewCriteriaRow lastContainsO = nameContainsO.createViewCriteriaRow();
lastContainsO.setAttribute("LastName","LIKE '%o%'");
ViewCriteriaRow firstContainsO = nameContainsO.createViewCriteriaRow();
firstContainsO.setAttribute("FirstName","LIKE '%o%'");
nameContainsO.add(firstContainsO);
nameContainsO.add(lastContainsO);
// 5. Use findByViewCriteria() to produce new rowset instead of subsetting
nameContainsO.setCriteriaMode(ViewCriteria.CRITERIA_MODE_CACHE);
RowSet rs = (RowSet)vo.findByViewCriteria(nameContainsO,
                         -1,ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
showRows(rs,"Rows returned from in-memory findByViewCriteria");
// 6. Show that original rowset hasn't changed
showRows(vo,"Note findByViewCriteria didn't change rows in the view");
```

Performing In-Memory Filtering with RowMatch

The `RowMatch` object provides an even more convenient way to express in-memory filtering conditions. You create a `RowMatch` object by passing a query predicate expression to the constructor like this:

```
RowMatch rm =
 new RowMatch("LastName = 'Popp' or (FirstName like 'A%' and LastName like 'K%')"
);
```

As you do with the `SortBy` clause, you phrase the `RowMatch` expression in terms of the view object attribute names, using the supported operators shown in Table 11-2. You can group subexpressions with parenthesis and use the `AND` and `OR` operators between subexpressions.

Table 11-2 SQL Operators Supported By In-Memory Filtering with RowMatch

Operator	Operation
=, >, <, <=, >=, <>, LIKE, BETWEEN, IN	Comparison
NOT	Logical negation Note that logical negation operations NOT IN are not supported by the RowMatch expression. To negate the IN operator, use this construction instead (note the use of brackets): NOT (EmpID IN ('VP','PU'))
AND	Conjunction
OR	Disjunction

You can also use a limited set of SQL functions in the RowMatch expression, as shown in Table 11-3.

Table 11-3 SQL Functions Supported By In-Memory Filtering with RowMatch

Operator	Operation
UPPER	Converts all letters in a string to uppercase.
TO_CHAR	Converts a number or date to a string.
TO_DATE	Converts a character string to a date format.
TO_TIMESTAMP	Converts a string to timestamp.

> **Note:**
>
> While SQL query predicates treat column names in a case-insensitive way, the attribute names in a RowMatch expression are case-*sensitive*.

Applying a RowMatch to a View Object

To apply a RowMatch to your view object, call the setRowMatch() method. In contrast to a ViewCriteria, the RowMatch is only used for *in-memory* filtering, so there is no "match mode" to set. You can use a RowMatch on view objects in any supported SQL mode, and you will see the results of applying it the next time you call the executeQuery() method.

When you apply a RowMatch to a view object, the RowMatch expression can reference the view object's named bind variables using the same :VarName notation that you would use in a SQL statement. For example, if a view object had a named bind variable named StatusCode, you could apply a RowMatch to it with an expression like:

```
Status = :StatusCode or :StatusCode = '%'
```

The following example shows the interesting lines of a `TestClientRowMatch` class that illustrate the `RowMatch` in action. The CustomerList view object used in the example has a transient `Boolean` attribute named `Selected`. The code performs the following basic steps:

1. Queries the full customer list, producing the output:

   ```
   --- Initial database results ---
   Neena Kochhar [null]
   Lex De Haan [null]
   Nancy Greenberg [null]
   :
   ```

2. Marks odd-numbered rows selected by setting the `Selected` attribute of odd rows to `Boolean.TRUE`, producing the output:

   ```
   --- After marking odd rows selected ---
   Neena Kochhar [null]
   Lex De Haan [true]
   Nancy Greenberg [null]
   Daniel Faviet [true]
   John Chen [null]
   Ismael Sciarra [true]
   :
   ```

3. Uses a `RowMatch` to subset the row set to contain only the select rows, that is, those with `Selected = true`. This produces the output:

   ```
   --- After in-memory filtering on only selected rows ---
   Lex De Haan [true]
   Daniel Faviet [true]
   Ismael Sciarra [true]
   Luis Popp [true]
   :
   ```

4. Further subsets the row set using a more complicated `RowMatch` expression, producing the output:

   ```
   --- After in-memory filtering with more complex expression ---
   Lex De Haan [true]
   Luis Popp [true]
   ```

```
// In TestClientRowMatch.java
// 1. Query the full customer list
ViewObject vo = am.findViewObject("CustomerList");
vo.executeQuery();
showRows(vo,"Initial database results");
// 2. Mark odd-numbered rows selected by setting Selected = Boolean.TRUE
markOddRowsAsSelected(vo);
showRows(vo,"After marking odd rows selected");
// 3. Use a RowMatch to subset row set to only those with Selected = true
RowMatch rm = new RowMatch("Selected = true");
vo.setRowMatch(rm);
// Note: Only need to set SQL mode when not defined at design time
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_VIEW_ROWS);
vo.executeQuery();
showRows(vo, "After in-memory filtering on only selected rows");
// 5. Further subset rowset using more complicated RowMatch expression
rm = new RowMatch("LastName = 'Popp' "+
                  "or (FirstName like 'A%' and LastName like 'K%')");
vo.setRowMatch(rm);
vo.executeQuery();
showRows(vo,"After in-memory filtering with more complex expression");
```

```
// 5. Remove RowMatch, set query mode back to database, requery to see full list
vo.setRowMatch(null);
vo.setQueryMode(ViewObject.QUERY_MODE_SCAN_DATABASE_TABLES);
vo.executeQuery();
showRows(vo,"After requerying to see a full list again");
```

Using RowMatch to Test an Individual Row

In addition to using a RowMatch to filter a row set, you can also use its rowQualifies() method to test whether any individual row matches the criteria it encapsulates. For example:

```
RowMatch rowMatch = new RowMatch("CountryId = 'US'");
if (rowMatch.rowQualifies(row)) {
  System.out.println("Customer is from the United States ");
}
```

How a RowMatch Affects Rows Fetched from the Database

Once you apply a RowMatch, if the view object's SQL mode is set to retrieve rows from the database, when you call executeQuery() the RowMatch is applied to rows as they are fetched. If a fetched row does not qualify, it is not added to the row set.

Unlike a SQL WHERE clause, a RowMatch can evaluate expressions involving transient view object attributes and not-yet-posted attribute values. This can be useful to filter queried rows based on RowMatch expressions involving transient view row attributes whose values are calculated in Java. This interesting aspect should be used with care, however, if your application needs to process a large row set. Oracle recommends using database-level filtering to retrieve the smallest-possible row set first, and then using RowMatch as appropriate to subset that list in memory.

Reading and Writing XML

View objects in ADF Business Components support reading and writing of data in XML documents. This allows view objects to perform CRUD operations based on XML documents.

The Extensible Markup Language (XML) standard from the Worldwide Web Consortium (W3C) defines a language-neutral approach for electronic data exchange. Its rigorous set of rules enables the structure inherent in data to be easily encoded and unambiguously interpreted using human-readable text documents.

View objects support the ability to write these XML documents based on their queried data. View objects also support the ability to read XML documents in order to apply changes to data including inserts, updates, and deletes. When you've introduced a **view link**, this XML capability supports reading and writing multi-level nested information for master-detail hierarchies of any complexity. While the XML produced and consumed by view objects follows a canonical format, you can combine the view object's XML features with XML Stylesheet Language Transformations (XSLT) to easily convert between this canonical XML format and any format you need to work with.

Note:

The example in this section refers to the `oracle.summit.model.readandwrite` package in the `SummitADF_Examples` application workspace.

How to Produce XML for Queried Data

To produce XML from a view object, use the `writeXML()` method. If offers two ways to control the XML produced:

1. For precise control over the XML produced, you can specify a view object attribute map indicating which attributes should appear, including which view link accessor attributes should be accessed for nested, detail information:

   ```
   Node writeXML(long options, HashMap voAttrMap)
   ```

2. To producing XML that includes all attributes, you can simply specify a depth level that indicates how many levels of view link accessor attributes should be traversed to produce the result:

   ```
   Node writeXML(int depthCount, long options)
   ```

The `options` parameter is an integer flag field that can be set to one of the following bit flags:

- `XMLInterface.XML_OPT_ALL_ROWS`

  Includes all rows in the view object's row set in the XML.

- `XMLInterface.XML_OPT_LIMIT_RANGE`

  Includes only the rows in the current range in the XML.

Using the logical OR operation, you can combine either of the above flags with the `XMLInterface.XML_OPT_ASSOC_CONSISTENT` flag when you want to include new, unposted rows in the current transaction in the XML output.

Both versions of the `writeXML()` method accept an optional third argument which is an XSLT stylesheet that, if supplied, is used to transform the XML output before returning it.

Additionally, both versions of the `writeXML()` method allow you to set the argument `depthCount=ignore` to indicate to ignore the depth count and just render what is in the data model based on the specified `options` parameter flags.

What Happens When You Produce XML

When you produce XML using `writeXML()`, the view object begins by creating a wrapping XML element whose default name matches the name of the view object definition. For example, for a `CustomersView` view object, the XML produced will be wrapped in an outermost CustomersView tag.

Then, it converts the attribute data for the appropriate rows into XML elements. By default, each row's data is wrapped in an row element whose name is the name of the view object with the `Row` suffix. For example, each row of data from a view object named `CustomersView` is wrapped in an `CustomersViewRow` element. The elements representing the attribute data for each row appear as nested children inside this row element.

If any of the attributes is a view link accessor attribute, and if the parameters passed to `writeXML()` enable it, the view object will include the data for the detail row set returned by the view link accessor. This nested data is wrapped by an element whose name is determined by the name of the view link accessor attribute. The return value of the `writeXML()` method is an object that implements the standard W3C `Node` interface, representing the root element of the generated XML.

> **Note:**
>
> The `writeXML()` method uses view link accessor attributes to programmatically access detail collections. It does not require adding view link instances in the data model.

For example, to produce an XML element for all rows of a `CustomersView` view object instance, and following view link accessors as many levels deep as exists, the following example shows the code required.

```
ViewObject vo = am.findViewObject("CustomersView");
printXML(vo.writeXML(-1,XMLInterface.XML_OPT_ALL_ROWS));
```

The `CustomersView` view object is linked to a `Orders` view object showing the orders created by that person. In turn, the `Orders` view object is linked to a `OrderItems` view object providing details on the items ordered by customers. Running the code in the following example produces the XML shown in the following example, reflecting the nested structure defined by the view links.

```
 ...
   <CustomersViewRow>
      <Id>211</Id>
      <Name>Kuhn's Sports</Name>
      <Phone>42-111292</Phone>
      <Address>7 Modrany</Address>
      <City>Prague</City>
      <CountryId>11</CountryId>
      <CreditRatingId>2</CreditRatingId>
      <SalesRepId>15</SalesRepId>
      <OrdersView>
         <OrdersViewRow>
            <Id>107</Id>
            <CustomerId>211</CustomerId>
            <DateOrdered>2012-12-13</DateOrdered>
            <DateShipped>2012-12-14</DateShipped>
            <SalesRepId>15</SalesRepId>
            <Total>142171</Total>
            <PaymentTypeId>2</PaymentTypeId>
            <PaymentOptionId>1082</PaymentOptionId>
            <OrderFilled>Y</OrderFilled>
         </OrdersViewRow>
         <OrdersViewRow>
            <Id>183</Id>
            <CustomerId>211</CustomerId>
            <DateOrdered>2013-02-24</DateOrdered>
            <DateShipped>2013-02-27</DateShipped>
            <SalesRepId>13</SalesRepId>
            <Total>3742</Total>
            <PaymentTypeId>1</PaymentTypeId>
            <OrderFilled>Y</OrderFilled>
         </OrdersViewRow>
         <OrdersViewRow>
            <Id>184</Id>
            <CustomerId>211</CustomerId>

         </OrdersViewRow>
         ...
      </OrdersView>
   </CustomersViewRow>
...
```

What You May Need to Know About Reading and Writing XML

This section provides additional information to help you work with XML.

Controlling XML Element Names

You can use the Properties window to change the default XML element names used in the view object's canonical XML format by setting several properties. To accomplish this, open the overview editor for the view object, then:

- Select the attribute on the Attributes page and in the Properties window, select the Custom Properties navigation tab and set the custom *attribute*-level property named **Xml Element** to a value *SomeOtherName* to change the XML element name used for that attribute to <SomeOtherName>

  For example, the Email attribute in the CustomersView view object defines this property to change the XML element described in What Happens When You Produce XML to be <EmailAddress> instead of <Email>.

- Select the General navigation tab in the Properties window and set the custom *view object*-level property named **Xml Row Element** to a value *SomeOtherRowName* to change the XML element name used for that view object to <SomeOtherRowName>.

  For example, the CustomersView view object defines this property to change the XML element name for the rows described in What Happens When You Produce XML to be <Customer> instead of <CustomersViewRow>.

- To change the name of the element names that wrapper nested row set data from view link attribute accessors, use the View Link Properties dialog. To open the dialog, in the view link overview editor, click the **Edit accessors** icon in the Accessors section of the Relationship page. Enter the desired name of the view link accessor attribute in the **Accessor Name** field.

Controlling Element Suppression for Null-Valued Attributes

By default, if a view row attribute is null, then its corresponding element is omitted from the generated XML. Select the attribute on the Attributes page of the overview editor and in the Properties window, select the Custom Properties navigation tab and set the custom *attribute*-level property named **Xml Explicit Null** to any value (e.g. "true" or "yes") to cause an element to be included for the attribute if its value is null. For example, if an attribute named AssignedDate has this property set, then a row containing a null assigned date will contain a corresponding AssignedDate null="true"/ element. If you want this behavior for all attributes of a view object, you can define the **Xml Explicit Null** custom property at the view object level as a shortcut for defining it on each attribute.

Printing or Searching the Generated XML Using XPath

Two of the most common things you might want to do with the XML Node object returned from writeXML() are:

1. Printing the node to its serialized text representation — to send across the network or save in a file, for example
2. Searching the generated XML using W3C XPath expressions

Unfortunately, the standard W3C Document Object Model (DOM) API does not include methods for doing *either* of these useful operations. But there is hope. Since ADF Business Components uses the Oracle XML parser's implementation of the DOM, you can cast the Node return value from writeXML() to the Oracle specific classes XMLNode or XMLElement (in the oracle.xml.parser.v2 package) to access additional useful functionality like:

- Printing the XML element to its serialized text format using the print() method
- Searching the XML element in memory with XPath expressions using the selectNodes() method
- Finding the value of an XPath expression related to the XML element using the valueOf() method.

The following example shows the printXML() method in the TestClientWriteXML. It casts the Node parameter to an XMLNode and calls the print() method to dump the XML to the console.

```
// In TestClientWriteXML.java
private static void printXML(Node n) throws IOException {
  ((XMLNode)n).print(System.out);
}
```

Using the Attribute Map For Fine Control Over Generated XML

When you need fine control over which attributes appear in the generated XML, use the version of the writeXML() method that accepts a HashMap. The following example shows the interesting lines from a TestClientWriteXML class that use this technique. After creating the HashMap, you put String[]-valued entries into it containing the names of the attributes you want to include in the XML, keyed by the fully qualified name of the view definition those attributes belong to. The example includes the Name, City, and OrdersView attributes from the CustomersView view object, and the Id, DateOrdered, and Total attributes from the OrdersView view object.

Note:

For upward compatibility reasons with earlier versions of ADF Business Components the HashMap expected by the writeXML() method is the one in the com.sun.java.util.collections package.

While processing the view rows for a given view object instance:

- If an entry exists in the attribute map with a key matching the fully qualified view definition name for that view object, then only the attributes named in the corresponding String array are included in the XML.

  Furthermore, if the string array includes the name of a view link accessor attribute, then the nested contents of its detail row set are included in the XML. If a view link accessor attribute name does not appear in the string array, then the contents of its detail row set are not included.
- If no such entry exists in the map, then *all* attributes for that row are included in the XML.

```
HashMap viewDefMap = new HashMap();
viewDefMap.put("oracle.summit.model.readandwritexml.queries.CustomersView",
        new String[]{"Name","City",
                     "OrdersView" /* View link accessor attribute */
                     });
viewDefMap.put("oracle.summit.model.readandwritexml.queries.OrdersView",
        new String[]{"Id","DateOrdered","Total"});
printXML(vo.writeXML(XMLInterface.XML_OPT_ALL_ROWS,viewDefMap));
```

Running the above example produces the following XML, including only the exact attributes and view link accessors indicated by the supplied attribute map.

```
   <CustomersViewRow>
      <Id>211</Id>
      <Name>Kuhn's Sports</Name>
      <City>Prague</City>
      <OrdersView>
         <OrdersViewRow>
            <Id>107</Id>
            <DateOrdered>2012-12-13</DateOrdered>
            <Total>142171</Total>
         </OrdersViewRow>
         <OrdersViewRow>
            <Id>183</Id>
            <DateOrdered>2013-02-24</DateOrdered>
            <Total>3742</Total>
         </OrdersViewRow>
         <OrdersViewRow>
            <Id>184</Id>
            <DateOrdered>2012-11-19</DateOrdered>
            <Total>987</Total>
         </OrdersViewRow>
         <OrdersViewRow>
            <Id>185</Id>
            <DateOrdered>2012-08-08</DateOrdered>
            <Total>2525.25</Total>
         </OrdersViewRow>
         <OrdersViewRow>
            <Id>186</Id>
            <DateOrdered>2012-04-26</DateOrdered>
            <Total>307.25</Total>
         </OrdersViewRow>
         <OrdersViewRow>
            <Id>187</Id>
            <DateOrdered>2012-12-23</DateOrdered>
            <Total>3872.9</Total>
         </OrdersViewRow>
         <OrdersViewRow>
            <Id>188</Id>
            <DateOrdered>2013-01-14</DateOrdered>
            <Total>12492</Total>
         </OrdersViewRow>
         ...
      </OrdersView>
   </CustomersViewRow>
...
```

Use the Attribute Map Approach with Bi-Directional View Links

If your view objects are related through a view link that you have configured to be bi-directional, then you must use the `writeXML()` approach that uses the attribute map. If you were to use the `writeXML()` approach in the presence of bi-directional view links and were to supply a maximum depth of `-1` to include all levels of view links that exist, the `writeXML()` method will go into an infinite loop as it follows the bi-directional view links back and forth, generating deeply nested XML containing duplicate data until it runs out of memory. Use `writeXML()` with an attribute map instead in this situation. Only by using this approach can you control which view link accessors are included in the XML and which are not to avoid infinite recursion while generating the XML.

Transforming Generated XML Using an XSLT Stylesheet

When the canonical XML format produced by `writeXML()` does not meet your needs, you can supply an XSLT stylesheet as an optional argument. It will produce the XML as it would normally, but then transform that result using the supplied stylesheet before returning the final XML to the caller.

Consider the XSLT stylesheet shown in the following example. It is a simple transformation with a single template that matches the root element of the generated XML described in Using the Attribute Map For Fine Control Over Generated XML to create a new `CustomerNames` element in the result. The template uses the `xsl:for-each` instruction to process all `CustomersView` elements. For each `CustomersView` element that qualifies, it creates a `CustomerNames` element in the result whose `Contact` attribute is populated from the value of the `Name` child element of the `CustomersView`.

```
<?xml version="1.0" encoding="windows-1252" ?>
<xsl:stylesheet version="1.0" xmlns:xsl="http://www.w3.org/1999/XSL/Transform">
  <xsl:template match="/">
    <CustomerNames>
      <xsl:for-each
           select="/CustomersView/CustomersViewRow)">
        <xsl:sort select="Name"/>
        <Customer Contact="{Name}"/>
      </xsl:for-each>
    </CustomerNames>
  </xsl:template>
</xsl:stylesheet>
```

The following example shows the interesting lines from a `TestClientWriteXML` class that put this XSLT stylesheet into action when calling `writeXML()`.

```
// In TestClientWriteXML.java
XSLStylesheet xsl = getXSLStylesheet();
printXML(vo.writeXML(XMLInterface.XML_OPT_ALL_ROWS,viewDefMap,xsl));
```

Running the code in the above example produces the transformed XML shown here:

```
<CustomerNames>
   <Customer Contact="ABC Company"/>
   <Customer Contact="Acme Outfitters"/>
   <Customer Contact="Acme Sporting Goods"/>
   <Customer Contact="All Baseball"/>
   ...
   <Customer Contact="The Sports Emporium"/>
   <Customer Contact="Unisports"/>
   <Customer Contact="Value Valley"/>
   <Customer Contact="Wally's Mart"/>
   <Customer Contact="Wally's Weights"/>
   <Customer Contact="Westwind Sports"/>
   <Customer Contact="Womansport"/>
   <Customer Contact="Your Choice Sporting Goods"/>
   <Customer Contact="Z-Mart"/>
   <Customer Contact="Zibbers"/>
   <Customer Contact="Zip City"/>
</CustomerNames>
```

The getXSLStylesheet() helper method shown in the following example is also interesting to study since it illustrates how to read a resource like an XSLT stylesheet from the classpath at runtime. The code expects the Example.xsl stylesheet to be in the same directory as the TestClientWriteXML class. By referencing the Class object for the TestClientWriteXML class using the .class operator, the code uses the getResource() method to get a URL to the resource. Then, it passes the URL to the newXSLStylesheet() method of the XSLProcessor class to create a new XSLStylesheet object to return. That object represents the compiled version of the XSLT stylesheet read in from the *.xslfile.

```
private static XSLStylesheet getXSLStylesheet()
        throws XMLParseException, SAXException,IOException,XSLException {
  String xslurl = "Example.xsl";
  URL xslURL = TestClientWriteXML.class.getResource(xslurl);
  XSLProcessor xslProc = new XSLProcessor();
  return xslProc.newXSLStylesheet(xslURL);
}
```

Note:

When working with resources like XSLT stylesheets that you want to be included in the output directory along with your compiled Java classes and XML metadata, you can use the **Compiler** page of the **Project Properties** dialog to update the **Copy File Types to Output Directory** field to include .xsl in the semicolon-separated list.

Generating XML for a Single Row

In addition to calling writeXML() on a view object, you can call the same method with the same parameters and options on any Row as well. If the Row object on which you call writeXML() is a entity row, you can bitwise-OR the additional XMLInterface.XML_OPT_CHANGES_ONLY flag if you only want the changed entity attributes to appear in the XML.

How to Consume XML Documents to Apply Changes

To have a view object consume an XML document to process inserts, updates, and deletes, use the readXML() method:

```
void readXML(Element elem, int depthcount)
```

The canonical format expected by readXML() is the same as what would be produced by a call to the writeXML() method on the same view object. If the XML document to process does not correspond to this canonical format, you can supply an XSLT stylesheet as an optional third argument to `readXML()` to transform the incoming XML document *into* the canonical format before it is read for processing.

What Happens When You Consume XML Documents

When a view object consumes an XML document in canonical format, it processes the document to recognize row elements, their attribute element children, and any nested elements representing view link accessor attributes. It processes the document recursively to a maximum level indicated by the `depthcount` parameter. Passing `-1` for the `depthcount` to request that it process all levels of the XML document.

How ViewObject.readXML() Processes an XML Document

For each row element it recognizes, the `readXML()` method does the following:

- Identifies the related view object to process the row.
- Reads the children attribute elements to get the values of the primary key attributes for the row.
- Performs a `findByKey()` using the primary key attributes to detect whether the row already exists or not.
- If the row exists:
  - If the row element contains the marker attribute `bc4j-action="remove"`, then the existing row is deleted.
  - Otherwise, the row's attributes are updated using the values in any attribute element children of the current row element in the XML
- If the row does not exist, then a new row is created, inserted into the view object's row set. Its attributes are populated using the values in any attribute element children of the current row element in the XML.

Using readXML() to Processes XML for a Single Row

The same `readXML()` method is also supported on any `Row` object. The canonical XML format it expects is the same format produced by a call to `writeXML()` on the same row. You can invoke `readXML()` method on a row to:

- Update its attribute values from XML
- Remove the row, if the `bc4j-action="remove"` marker attribute is present on the corresponding row element.
- Insert, update, or delete any nested rows via view link accessors

Consider the XML document shown in the following example. It is in the canonical format expected by a single row in the `CustomersView` view object. Nested inside the root `CustomersViewRow` element, the `City` attribute represents the customer's city. The nested `OrdersView` element corresponds to the `OrdersView` view link accessor attribute and contains three `OrdersViewRow` elements. Each of these includes `Id` elements representing the primary key of a `OrdersView` row.

```
<CustomersViewRow>
   <Id>16</Id>
   <!-- This will update Customer's ConfirmedEmail attribute -->
   <City>Houston</City>
   <OrdersView>
      <!-- This will be an update since it does exist -->
      <OrdersViewRow>
         <Id>1018</Id>
         <DateShipped>2013-03-13</DateShipped>
      </OrdersViewRow>
      <!-- This will be an insert since it doesn't exist -->
      <OrdersViewRow>
         <Id>9999</Id>
         <CustomerId>16</CustomerId>
         <Total>9999.00</Total>
      </OrdersViewRow>
      <!-- This will be deleted -->
      <OrdersViewRow bc4j-action="remove">
         <Id>1008</Id>
      </OrdersViewRow>
   </OrdersView>
</CustomersViewRow>
```

The following example shows the interesting lines of code from a `TestClientReadXML` class that applies this XML datagram to a particular row in the `CustomersView` view object. `TestClientReadXML` class performs the following basic steps:

1. Finds a target row by key (e.g. for customer "The Sports Emporium").
2. Shows the XML produced for the row before changes are applied.
3. Obtains the parsed XML document with changes to apply using a helper method.
4. Reads the XML document to apply changes to the row.
5. Shows the XML with the pending changes applied.

   `TestClientReadXML` class is using the `XMLInterface.XML_OPT_ASSOC_CONSISTENT` flag described in How to Produce XML for Queried Data to ensure that new, unposted rows are included in the XML.

```
ViewObject vo = am.findViewObject("CustomersView");
Key k = new Key(new Object[] { 16 });
// 1. Find a target row by key (e.g. for customer "The Sports Emporium")
Row sports = vo.findByKey(k, 1)[0];
// 2. Show the XML produced for the row before changes are applied
printXML(sports.writeXML(-1, XMLInterface.XML_OPT_ALL_ROWS));
// 3. Obtain parsed XML document with changes to apply using helper method
Element xmlToRead = getInsertUpdateDeleteXMLGram();
printXML(xmlToRead);
// 4. Read the XML document to apply changes to the row
sports.readXML(getInsertUpdateDeleteXMLGram(), -1);
// 5. Show the XML with the pending changes applied
printXML(sports.writeXML(-1, XMLInterface.XML_OPT_ALL_ROWS |
                              XMLInterface.XML_OPT_ASSOC_CONSISTENT));
```

Running the code in the above example initially displays the "before" version of The Sports Emporium information. Notice that:

- The `City` attribute has a value of "Lapeer"
- There is no `ShippedDate` attribute for order ID `1018`
- There is an orders row for order ID `1008`, and
- There is no orders row related to order ID `9999`.

```
<CustomersViewRow>
   <Id>16</Id>
   <Name>The Sports Emporium</Name>
   <Address>222 E Nepessing St</Address>
   <City>Lapeer</City>
   <State>MI</State>
   <CountryId>4</CountryId>
   <ZipCode>48446</ZipCode>
   <CreditRatingId>1</CreditRatingId>
   <SalesRepId>13</SalesRepId>
   <OrdersView>
      <OrdersViewRow>
         <Id>1018</Id>
         <CustomerId>16</CustomerId>
         <DateOrdered>2013-02-25</DateOrdered>
         <SalesRepId>11</SalesRepId>
         <Total>195.99</Total>
         <PaymentTypeId>2</PaymentTypeId>
         <PaymentOptionId>1009</PaymentOptionId>
         <OrderFilled>Y</OrderFilled>
      </OrdersViewRow>
      <OrdersViewRow>
         <Id>1008</Id>
         <CustomerId>16</CustomerId>
         <DateOrdered>2013-02-26</DateOrdered>
         <SalesRepId>14</SalesRepId>
         <Total>100.97</Total>
         <PaymentTypeId>2</PaymentTypeId>
         <PaymentOptionId>1009</PaymentOptionId>
         <OrderFilled>N</OrderFilled>
      </OrdersViewRow>
      <OrdersViewRow>
         <Id>1023</Id>
         <CustomerId>16</CustomerId>
         <DateOrdered>2013-01-11</DateOrdered>
         <DateShipped>2013-01-15</DateShipped>
         <SalesRepId>11</SalesRepId>
         <Total>2451.97</Total>
         <PaymentTypeId>2</PaymentTypeId>
         <PaymentOptionId>1009</PaymentOptionId>
         <OrderFilled>Y</OrderFilled>
      </OrdersViewRow>
   </OrdersView>
</CustomersViewRow>
```

After applying the changes from the XML document using `readXML()` to the row and printing its XML again using `writeXML()` you see that:

- The `City` attribute is now Houston.
- A new orders row for order `9999` got created.
- The date shipped for orders row `1018` has been set to 2013-03-13, and
- The orders row for order `1008` is removed

```
<CustomersViewRow>
   <Id>16</Id>
   <Name>The Sports Emporium</Name>
   <Address>222 E Nepessing St</Address>
   <City>Houston</City>
   <State>MI</State>
   <CountryId>4</CountryId>
   <ZipCode>48446</ZipCode>
   <CreditRatingId>1</CreditRatingId>
   <SalesRepId>13</SalesRepId>
   <OrdersView>
      <OrdersViewRow>
         <Id>9999</Id>
         <CustomerId>16</CustomerId>
         <Total>9999.00</Total>
      </OrdersViewRow>
      <OrdersViewRow>
         <Id>1018</Id>
         <CustomerId>16</CustomerId>
         <DateOrdered>2013-02-25</DateOrdered>
         <DateShipped>2013-03-13</DateShipped>
         <SalesRepId>11</SalesRepId>
         <Total>195.99</Total>
         <PaymentTypeId>2</PaymentTypeId>
         <PaymentOptionId>1009</PaymentOptionId>
         <OrderFilled>Y</OrderFilled>
      </OrdersViewRow>
      <OrdersViewRow>
         <Id>1023</Id>
         <CustomerId>16</CustomerId>
         <DateOrdered>2013-01-11</DateOrdered>
         <DateShipped>2013-01-15</DateShipped>
         <SalesRepId>11</SalesRepId>
         <Total>2451.97</Total>
         <PaymentTypeId>2</PaymentTypeId>
         <PaymentOptionId>1009</PaymentOptionId>
         <OrderFilled>Y</OrderFilled>
      </OrdersViewRow>
   </OrdersView>
</CustomersViewRow>
```

> **Note:**
>
> The example illustrated using `readXML()` to apply changes to a single row. If the XML document contained a wrapping `CustomersView` row, including the primary key attribute in each of its one or more nested `CustomersViewRow` elements, then that document could be processed using the `readXML()` method on the `CustomersView` view object for handling operations for multiple `CustomersView` rows.

Working Programmatically with Custom Data Sources and the Framework Base Class ProgrammaticViewObjectImpl

ADF Business Components supports programmatic view objects that you can create to interact with custom data sources.

The framework base classes `oracle.jbo.server.ProgrammaticViewObjectImpl` and `oracle.jbo.serverProgrammaticViewRowImpl` let you take control of interacting with a custom data source and returning the collection of data. ADF will internally take care of converting the data object into a `ViewRow`.

These framework base implementation classes provide specific hook points for the application developer to interact with a custom data source and perform operations. Using the framework base class, ADF supports features like activation/passivation for the given collection. Unlike earlier, developers do not need to code a wide variety of methods that require understanding of the various stages in the view object lifecycle to populate the row programmatically.

> **Note:**
>
> Prior to the `ProgrammaticViewObjectImpl` base class, applications extended from the base class `oracle.jbo.server.ViewObjectImpl` and overrode a number of lifecycle methods for custom behavior. Using programmatic view objects means integration with a custom data source is accomplished by the application developer without needing to understand the various stages of the view object lifecycle.

To work with programmatic view objects in the ADF Model project, you select the Programmatic option in the Create View Object wizard. Then View Object java classes that you generate in the wizard will by default extend from the framework base classes `oracle.jbo.server.ProgrammaticViewObjectImpl` and `oracle.jbo.server.ProgrammaticViewRowImpl` instead of extending from the classic style framework classes `oracle.jbo.server.ViewObjectImpl` and `oracle.jbo.server.ViewRowImpl`.

> **Note:**
>
> In order to ensure this behavior when creating a programmatic view object, you must de-select the option in the ADF Business Components Preferences dialog that enables extending from the classic style base class `oracle.jbo.server.ViewObjectImpl`. The option in the ADF Business Components-View Objects page of the Tools-Preferences dialog is **Classic Programmatic View** {de-select to enable extending from `ProgrammaticViewObjectImpl`).

How to Create a View Object Class Extending ProgrammaticViewObjectImpl

To create a programmatic view object that extends `oracle.jbo.server.ProgrammaticViewObjectImpl` or `oracle.jbo.server.ProgrammaticViewRowImp`, you use the Create View Object wizard and select the **Programmatic** data source option.

Before you begin:

You must disable classic style programmatic view object generation. In the Tools-Preferences dialog, de-select the option **Classic Programmatic View** on the ADF Business Components-View Objects page. If you leave this option selected (default), JDeveloper will generate view object Java classes that extend `oracle.jbo.server.ViewObjectImpl` and `oracle.jbo.server.ViewRowImpl`.

For details about classic mode, see Using Classic Style Programmatic View Objects for Alternative Data Sources.

To create programmatic view objects extending ProgrammaticViewObjectImpl:

1. In the Applications window, right-click the project in which you want to create the view object and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **View Object**, and click **OK**.
3. In the Create View Object wizard, in the Name page, provide a name and package for the view object. For the data source, select **Programmatic**.
4. In the Attributes page, click **New** one or more times to define the view object attributes your programmatic view object requires.
5. In the Attribute Settings page, adjust any setting you may need to for the attributes you defined.
6. In the Java page, select **Generate View Object Class** to enable a custom view object class (`ProgrammaticViewObjectImpl`) to contain your code.
7. Click **Finish** to create the view object.

   In your view object's custom Java class, override the methods described in section Key Framework Methods to Override for ProgrammaticViewObjectImpl Based View Objects to implement your custom data retrieval strategy.

Key Framework Methods to Override for ProgrammaticViewObjectImpl Based View Objects

You will override one of two methods, depending on the how the view object's **Access Mode** property has been set.

The property **Access Mode** determines how many rows will be returned by the view object query. The property’s default setting `SCROLLABLE` will cache the view object rows as you read them in. The `RANGEPAGING` setting fetches the number of rows specified by a range size. For more details about access mode, see section Using Range Paging to Efficiently Scroll Through Large Result Sets.

SCROLLABLE

If access mode is `SCROLLABLE`, then the `getScrollableData()` API needs to be overridden to provide a concrete implementation.

- `protected Collection<Object> getScrollableData(ScrollableDataFilter dataFilter)`

  For a scrollable programmatic view object the framework expects the extender to provide the complete `dataset` as the result of the following API call. The framework will internally manage the API calls when the client asks for next or previous rows in the collection.

RANGEPAGING

If access mode is `RANGEPAGING`, then the application need to override following two API methods together.

- `/Apps should return the collection within a current Range.`

  `protected Collection<Object> getRangePagingData(RangePagingDataFilter dataFilter)`

- `protected Collection<Object> retrieveDataByKey(Key key , int size).`

For a range paging view object the framework expects the extender to only provide the collection of rows with a current range. When the framework needs a different range of rows, a followup API call will be made. The current Range's start index and size information can be obtained from `RangePagingDataFilter` object passed as an argument.

What You May Need to Know About Programmatic View Object Triggers

You can use triggers defined in the Groovy scripting language in place of overridden methods of `ProgrammaticViewObjectImpl.java` to perform data retrieval operations on the custom datasource. Triggers can be called from the various programmatic view object lifecycle points.

The application allows you to call triggers that are defined in Groovy script in place of Java hook points. These triggers interact with a custom data source and perform data retrieval operations. They can be called from the various programmatic view object lifecycle points. Although the option of subclassing the framework class, namely `ProgrammaticViewObjectImpl` and overriding certain methods to define implementations specific to a custom datasource remains, in order for the trigger to execute, the Java hook points should not be defined. Alternatively, if Java hook points are defined, then the triggers shouldn't exist for the Java hook points to execute. Note that if Java hook points as well as triggers are defined, then the triggers will not execute. The application allows you to utilize Groovy scripts in the overridden methods to interact with the custom data source. These triggers can be called from various programmatic view object lifecycle points.

Specifically, the programmatic view object triggers are:

`FetchData`

This trigger is used to retrieve a data collection from the custom datasource. This trigger is invoked in place of the `getScrollableData()` and `getRangePagingData()` methods of `ProgrammaticViewObjectImpl.java` depending on whether the access mode of the view object is scroll or range paging. The `returnList` data collection is populated with the records (objects/maps) retrieved from the custom data source.

The following sample code illustrates usage of this trigger. The following context specific keywords is used in the sample code.

- `dataFilter` – Returns the DataFilter object which is a ScrollableDataFilter or RangePagingDataFilter depending on the mode of the view object.
- `dataFilter.fetchSize` – Returns the range size of the data to be fetched.
- `dataFilter.fetchStart` — Returns the range start value of the data to be fetched.
- `dataFilter.searchCriteria` - Returns a list of ViewCriteria applied on the view object.
- `dataFilter.sortCriteria` - Returns a list of SortCriteria applied on the view object.

- `dataFilter.bindParameterValues` - Returns a map containing the bind parameter names and values corresponding to the rowset that is currently being executed.
- `dataFilter.masterData` - When used in the context of a detail view object, it returns the dataprovider object of the master row.
- `returnList` - The collection that is to be populated with the records (objects/maps) from the custom data source.

```
@TriggerExpression(triggerType="FetchData", name="FetchData_Rule_0")
def FetchData_Rule_0_ValidationRuleScript_Trigger()
{
   def empData = model.data.DataCenter.getInstance().getEmpData()
   def empFilteredData = new ArrayList()
   model.data.DeptObject master = (model.data.DeptObject)dataFilter.masterData

   for (emp in empData)
   {
      if (master == null || emp.deptno.equals(master.deptno))
      {
         empFilteredData.add(emp)
      }
   }

   def fetchStart = dataFilter.fetchStart
   def fetchSize = dataFilter.fetchSize
   if(fetchStart == -1)
   {
     fetchStart = 0;
   }
   for(int i = fetchStart; i < fetchSize + fetchStart && i <
empFilteredData.size() ; i++)
   {
     returnList.add(empFilteredData.get(i))
@TriggerExpression(triggerType="RetrieveDataByKey",
name="RetrieveDataByKey_Rule_0")
def RetrieveDataByKey_Rule_0_ValidationRuleScript_Trigger()
{
   def empData = model.data.DataCenter.getInstance().getEmpData()

   def keyValue = dataFilter.key.keyValues[0]

   def iter = empData.iterator()
   while (iter.hasNext())
   {
      def emp = iter.next();
      if (emp.empno.equals(keyValue))
      {
         returnList.add(emp);
      }
   }
   }
}
```

`RetrieveDataByKey Trigger`

This trigger is used to retrieve a data collection matching a key value from the custom datasource. It is invoked in place of the `retrieveDataByKey` method of `ProgrammaticViewObjectImpl.java`. This trigger is invoked when the required data matching the key is not present in the current range of rows retrieved by the view object. This trigger retrieves the collection of objects/maps matching the key value.

The following sample code illustrate the usage of this trigger. The following context specific keywords is used in the sample code.

- `dmlFilter.key` - Returns an oracle.jbo.Key containing the key values of the data/object to be retrieved.
- `dmlFilter.fetchSize` - Returns the fetch size.
- `returnList` - The collection that is to be populated with the records (objects/maps) from the custom data source that match the key value.

```
@TriggerExpression(triggerType="RetrieveDataByKey",
name="RetrieveDataByKey_Rule_0")
def RetrieveDataByKey_Rule_0_ValidationRuleScript_Trigger()
{
   def empData = model.data.DataCenter.getInstance().getEmpData()

   def keyValue = dataFilter.key.keyValues[0]

   def iter = empData.iterator()
   while (iter.hasNext())
   {
      def emp = iter.next();
      if (emp.empno.equals(keyValue))
      {
         returnList.add(emp);
      }
   }
}
```

Key Framework Methods to Override for ProgrammaticViewRowImpl Based View Objects

The framework base class `oracle.jbo.server.ProgrammaticViewRowImpl` is an implementation class for programmatic `ViewRow`.

Oracle ADF provides multiple hookpoints to interact with programmatic view row during various lifecycle phases. Not all of the following API methods are mandatory to override.

- `createRowData(HashMap attrNameValueMap)`

  If the use case requires creation of new rows for a programmatic view object, then override this API. This hookpoint allows applications to create a `DataProvider` for this newly created row and return it to the framework for further management.
- `updateDataProvider(Object rowDataProvider , ViewAttributeDefImpl attrDef , Object newValue)`

  If the programmatic view object is created without a backing entity object, then override this API to retain the modified values of attributes in the row. Applications should override this API and update `newvalue` into `DataProvider`.
- `convertToSourceType(ViewAttributeDefImpl vad, String sourceType , Object val)`

  If required, the application should override this API to provide custom implementation for conversion of value from JavaType to sourceType. The framework calls this hookpoint prior to updating the `value` in `DataProvider`.

- `convertToAttributeType(AttributeDefImpl attrDef, Class javaTypeClass , Object val)`

  If required, applications should override this API to provide custom implementation for conversion of value from `sourceType` to `JavaType`. The framework calls this hookpoint as it fetches the value from `DataProvider`.

Using Classic Style Programmatic View Objects for Alternative Data Sources

You can override methods in a custom Java class of an ADF view object to programmatically retrieve data from data sources such as in-memory array, Java `*.properties file`, `REF CURSOR` etc.

By default view objects read their data from the database and automate the task of working with the Java Database Connectivity (JDBC) layer to process the database result sets. However, by overriding appropriate methods in its custom Java class, you can create a view object that programmatically retrieves data from alterative data sources like a `REF CURSOR`, an in-memory array, or a Java `*.properties` file, to name a few.

> **Note:**
>
> The sections describing alternative data sources are retained for legacy purposes. Starting in JDeveloper release 12.2.1.1.0, ADF Business Components provides improved support for programmatic view objects. New framework base classes for programmatic view objects implements common methods for custom data sources and provides hook points to interact with the view row during various phases of the view object lifecycle. This feature must be enabled in the View Objects page of the Tools-Preferences dialog. For more details, see How to Create a View Object Class Extending ProgrammaticViewObjectImpl.

The general process for enabling a programmatic view object to work with an non-database, data source involves overriding the default lifecycle methods of the view object. For a complete description of the lifecycle methods, see Key Framework Methods to Override for Programmatic View Objects.

To enable programmatic view objects for alternative data sources, follow this general process:

1. Create the view object in the view object wizard and select **Programmatic** for the data source.
2. In view object overview editor, generate the custom view object implementation class (`ViewObjImpl.java`).
3. In the custom view object implementation class, override `create()` to initialize any state required by the programmatic view object. At a minimum, remove all traces of a SQL query for this view object.
4. Override `executeQueryForCollection()` and call `setUserDataForCollection()` to associate the result of your custom query with a `UserData` object.

5. Override `hasNextForCollection()` and iterate over the `UserData` object to test for more records to retrieve. While `hasNextForCollection()` returns `true`:
   a. Override `createRowFromResultSet()` to create the row on the view object query collection.
   b. In your overridden `createRowFromResultSet()` method call the `getUserDataForCollection()` method to get an instance of the stored `UserData` object and `createNewRowForCollection()` to create a new blank row.
   c. If necessary, convert each record to an attribute data type supported by ADF Business Components view object attributes and call `populateAttributeForRow()` to store attribute values on the query collection.
   d. When `hasNextForCollection()` returns `false`, inform the view object that the query collection is done being populated by calling `setFetechCompleteForCollection()`.
6. Override `releaseUserDataForCollection()` to release the result set.

Because the view object component can be related to several active row sets at runtime, many of these lifecycle methods receive an `Object` parameter (a query collection) in which the ADF Business Components framework passes the collection of rows that your custom code fills, as well as the array of bind variable values that might affect which rows get populated into the specific collection.

You can store a `UserData` object with each collection of rows so that your custom data source implementation can associate any needed data source context information. The framework provides the `setUserDataForCollection()` and `getUserDataForCollection()` methods to get and set this context information for each collection. Each time one of the overridden framework methods is called, you can use the `getUserDataForCollection()` method to retrieve the correct `ResultSet` object associated with the collection of rows the framework populates.

How to Create a Read-Only Programmatic View Object

To create a read-only programmatic view object, you use the Create View Object wizard.

To create the read-only programmatic view object:

1. In the Applications window, right-click the project in which you want to create the view object and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **View Object**, and click **OK**.
3. In the Create View Object wizard, in the Name page, provide a name and package for the view object. For the data source, select **Programmatic**.
4. In the Attributes page, click **New** one or more times to define the view object attributes your programmatic view object requires.
5. In the Attribute Settings page, adjust any setting you may need to for the attributes you defined.
6. In the Java page, select **Generate View Object Class** to enable a custom view object class (`ViewObjImpl`) to contain your code.
7. Click **Finish** to create the view object.

In your view object's custom Java class, override the methods described in Key Framework Methods to Override for Programmatic View Objects to implement your custom data retrieval strategy.

How to Create an Entity-Based Programmatic View Object

To create a entity-based view object with programmatic data retrieval, create the view object in the normal way, enable a custom Java class for it, and override the methods described in the next section to implement your custom data retrieval strategy.

Key Framework Methods to Override for Programmatic View Objects

A programmatic view object typically overrides all of the following methods of the base `ViewObjectImpl` class to implement its custom strategy for retrieving data:

- `create()`

  This method is called when the view object instance is created and can be used to initialize any state required by the programmatic view object. At a minimum, this overridden method will contain the following lines to ensure the programmatic view object has no trace of a SQL query related to it:

  ```
  // Wipe out all traces of a query for this VO
  getViewDef().setQuery(null);
  getViewDef().setSelectClause(null);
  setQuery(null);
  ```

- `executeQueryForCollection()`

  This method is called whenever the view object's query needs to be executed (or reexecuted). Your implementation must not override this method and completely change the query or change the list of parameters. For implementation best practices, see The Overridden executeQueryForCollection() Method.

- `hasNextForCollection()`

  This method is called to support the `hasNext()` method on the **row set iterator** for a row set created from this view object. Your implementation returns `true` if you have not yet exhausted the rows to retrieve from your programmatic data source.

- `createRowFromResultSet()`

  This method is called to populate each row of retrieved data. Your implementation will call `createNewRowForCollection()` to create a new blank row and then `populateAttributeForRow()` to populate each attribute of data for the row. Note that calls to `populateAttributeForRow()` require that you populate each attribute with the correctly typed value, as allowed by ADF Business Components view objects. The method does not handle data type conversion, and therefore your program is responsible for ensuring that the data type of each value matches an allowed view object attribute type.

- `getQueryHitCount()`

  This method is called to support the `getEstimatedRowCount()` method. Your implementation returns a count, or estimated count, of the number of rows that will be retrieved by the programmatic view object's query.

- `getCappedQueryHitCount()`

The row count query is optimized to determine whether the query would return more rows than the capped value specified by a global row fetch limit. If the number of potential rows is greater, the method returns a negative number. Although the scroll bar in the user interface may not be able to use the row count query to show an accurate scroll position, your row count query will perform well even with large tables. Your implementation can check the `Cap` value and return the actual row count. The framework obtains the `Cap` value from the row fetch limit specified in the `adf-config.xml` file. Note that `oldCap` is not used

The method returns a row count when the value is less than or equal to the `Cap`; otherwise, returns a negative number. Your implementation can use this information to build a performing row count query. If performance is not important, you may just return the same value as `getQueryHitCount()`, but the `getCappedQueryHitCount()` now provides additional information about the number of rows it is looking for. For example, assume the `DEPT` table has one million rows. When `getQueryHitCount()` is called, the framework will execute `SELECT COUNT(*) FROM DEPT` against the database and return all one million rows. However, when you intend to show at most 500 rows, you can set a global row fetch limit and call `getCappedQueryHitCount()`. In this case, the framework will execute `SELECT COUNT(*) FROM DEPT WHERE ROWNUM <= 500`. The query will complete much faster and also provides a performance improvements. The method wraps the view object query in a nested clause like `SELECT COUNT(*) FROM (SELECT DEPTNO, LOC FROM DEPT) WHERE ROWNUM <= :cap` (assuming that `SELECT DEPTNO, LOC FROM DEPT` is the view object query statement).

- `protected void releaseUserDataForCollection()`

  Your code can store and retrieve a user data context object with each row set. This method is called to allow you to release any resources that may be associated with a row set that is being closed.

The examples in the following sections each override these methods to implement different kinds of programmatic view objects.

How to Create a View Object on a REF CURSOR

Sometimes your application might need to work with the results of a query that is encapsulated within a stored procedure. PL/SQL allows you to open a cursor to iterate through the results of a query, and then return a reference to this cursor to the client. This so-called `REF CURSOR` is a handle with which the client can then iterate the results of the query. This is possible even though the client never actually issued the original SQL `SELECT` statement.

> **Note:**
>
> The example in this section refers to the `oracle.summit.model.viewobjectonrefcursor` package in the `SummitADF_Examples` application workspace.

Declaring a PL/SQL package with a function that returns a `REF CURSOR` is straightforward. The following example shows how your package might look.

```
CREATE OR REPLACE PACKAGE RefCursorExample IS
  TYPE ref_cursor IS REF CURSOR;
  FUNCTION get_orders_for_customer(p_custId NUMBER) RETURN ref_cursor;
  FUNCTION count_orders_for_customer(p_custId NUMBER) RETURN NUMBER;
END RefCursorExample;
.
/
show errors
CREATE OR REPLACE PACKAGE BODY RefCursorExample IS
  FUNCTION get_orders_for_customer(p_custIdl NUMBER) RETURN ref_cursor IS
    the_cursor ref_cursor;
  BEGIN
    OPEN the_cursor FOR
      SELECT o.id, o.date_ordered, o.total
        FROM s_ord o, s_customer c
        WHERE o.customer_id = c.id
        AND c.id = p_custId;
      RETURN the_cursor;
  END get_orders_for_customer;

  FUNCTION count_orders_for_customer(p_custId NUMBER) RETURN NUMBER IS
    the_count NUMBER;
  BEGIN
    SELECT COUNT(*)
      INTO the_count
      FROM s_ord o, s_customer c
      WHERE o.customer_id = c.id
      AND c.id = p_cust_id;
    RETURN the_count;
  END count_orders_for_customer;
END RefCursorExample;
.
/
show errors
```

After defining an entity-based `OrdersForCustomer` view object with an entity usage for an `Order` **entity object**, go to its custom Java class `OrdersForCustomerImpl.java`. Then, override the methods of the view object as described in the following sections.

The Overridden create() Method

The `create()` method removes all traces of a SQL query for this view object. The following example shows how to override the `create()` method for this purpose.

```
protected void create() {
  getViewDef().setQuery(null);
  getViewDef().setSelectClause(null);
  setQuery(null);
}
```

The Overridden executeQueryForCollection() Method

The `executeQueryForCollection()` method is executed when the framework needs to issue the database query for the query collection based on this view object. One view object can produce many related result sets, each potentially the result of different bind variable values. If the row set in query is involved in a framework-coordinated master/detail view link, then the `params` array will contain one or more framework-supplied name-value pairs of bind parameters from the source view object. If there are any user-supplied bind parameter values, they will *precede* the framework-supplied bind variable values in the params array, and the number of user parameters will be indicated by the value of the numUserParams argument.

The method calls a helper method retrieveRefCursor() to execute the stored function and return the REF CURSOR return value, cast as a JDBC ResultSet. The following example shows how to override the executeQueryForCollection() method for this purpose.

```
protected void executeQueryForCollection(Object qc,Object[] params,
                                         int numUserParams) {
  storeNewResultSet(qc,retrieveRefCursor(qc,params));
  super.executeQueryForCollection(qc, params, numUserParams);
}
```

Then, it calls the helper method storeNewResultSet() that uses the setUserDataForCollection() method to store this ResultSet with the collection of rows for which the framework is asking to execute the query. The following example shows how to define the storeNewResultSet() method for this purpose.

```
private void storeNewResultSet(Object qc, ResultSet rs) {
  ResultSet existingRs = getResultSet(qc);
  // If this query collection is getting reused, close out any previous rowset
  if (existingRs != null) {
     try {existingRs.close();} catch (SQLException s) {}
  }
  setUserDataForCollection(qc,rs);
  hasNextForCollection(qc); // Prime the pump with the first row.
}
```

The retrieveRefCursor() method uses the helper method described in Invoking Stored Procedures and Functions to invoke the stored function and return the REF CURSOR. The following example shows how to define the retrieveRefCursor() method for this purpose.

```
private ResultSet retrieveRefCursor(Object qc, Object[] params) {
  ResultSet rs = (ResultSet)callStoredFunction(OracleTypes.CURSOR,
                  "RefCursorExample.get_orders_for_customer(?)",
                  new Object[]{getNamedBindParamValue("bv_custId",params)});
  return rs ;
}
```

The Overridden createRowFromResultSet() Method

For each row that the framework needs fetched from the data source, it will invoke your overridden createRowFromResultSet() method. The implementation retrieves the collection-specific ResultSet object from the user-data context. It uses the getResultSet() method to retrieve the result set wrapper from the query-collection user data, and the createNewRowForCollection() method to create a new blank row in the collection, and then uses the populateAttributeForRow() method to populate the attribute values for each attribute defined at design time in the view object overview editor.

Note:

Calls to `populateAttributeForRow()` assume that attribute values that you populate on the view object already conform to the data types expected for ADF Business Components view object attributes. The method will not handle data type conversion, and therefore your program is responsible for converting the data type of the populated value to match an allowed view object attribute type.

The following example shows how to override the `createRowFromResultSet()` method for this purpose.

```
protected ViewRowImpl createRowFromResultSet(Object qc, ResultSet rs) {
  /*
   * We ignore the JDBC ResultSet passed by the framework (null anyway) and
   * use the resultset that we've stored in the query-collection-private
   * user data storage
   */
  rs = getResultSet(qc);

  /*
   * Create a new row to populate
   */
  ViewRowImpl r = createNewRowForCollection(qc);
  try {
    /*
     * Populate new row by type correct attribute slot number for current row
     * in Result Set
     */
    populateAttributeForRow(r,0, rs.getLong(1));
    populateAttributeForRow(r,1, rs.getString(2));
    populateAttributeForRow(r,2, rs.getString(3));
  }
  catch (SQLException s) {
    throw new JboException(s);
  }
  return r;
}
```

The Overridden hasNextForCollectionMethod()

The overridden implementation of the framework method `hasNextForCollection()` has the responsibility to return `true` or `false` based on whether there are more rows to fetch. When you've hit the end, you call the `setFetchCompleteForCollection()` to tell the view object that this collection is done being populated. The following example shows how to override the `hasNextForCollection()` method for this purpose.

```
protected boolean hasNextForCollection(Object qc) {
  ResultSet rs = getResultSet(qc);
  boolean nextOne = false;
  try {
    nextOne = rs.next();
    /*
     * When were at the end of the result set, mark the query collection
     * as "FetchComplete".
     */
    if (!nextOne) {
      setFetchCompleteForCollection(qc, true);
      /*
       * Close the result set, we're done with it
       */
      rs.close();
    }
  }
  catch (SQLException s) {
   throw new JboException(s);
  }
  return nextOne;
}
```

The Overridden releaseUserDataForCollection() Method

Once the collection is done with its fetch-processing, the overridden `releaseUserDataForCollection()` method gets invoked and closes the `ResultSet` cleanly so no database cursors are left open. The following example shows how to override the `releaseUserDataForCollection()` method for this purpose.

```
  protected void releaseUserDataForCollection(Object qc, Object rs) {
     ResultSet userDataRS = getResultSet(qc);
     if (userDataRS != null) {
      try {
        userDataRS.close();
      }
      catch (SQLException s) {
        /* Ignore */
      }
    }
    super.releaseUserDataForCollection(qc, rs);
  }
```

The Overridden getQueryHitCount() Method

Lastly, in order to properly support the view object's `getEstimatedRowCount()` method, the overridden `getQueryHitCount()` method returns a count of the rows that would be retrieved if all rows were fetched from the row set. Here the code uses a stored function to get the job done. Since the query is completely encapsulated behind the stored function API, the code also relies on the PL/SQL package to provide an implementation of the count logic as well to support this functionality. The following example shows how to override the `getQueryHitCount()` method for this purpose.

```
public long getQueryHitCount(ViewRowSetImpl viewRowSet) {
  Long result = (Long)callStoredFunction(NUMBER,
                   "RefCursorExample.count_orders_for_customer(?)",
                   viewRowSet.getParameters(true));
  return result.longValue();
}
```

Creating a View Object with Multiple Updatable Entities

When adding a secondary entity usage to an ADF view object with multiple entity usages, the secondary entity usage is non-updateable by default. You can override this default behavior and make it updateable.

By default, when you create a view object with multiple entity usages, each secondary entity usage that you add to a view object in the overview editor is configured with these settings:

- The **Updatable** checkbox is deselected
- The **Reference** checkbox is selected

You can change the default behavior to enable a secondary entity usage to be updatable by selecting the usage in the **Selected** list of the **Entity Objects** page of the view object overview editor and selecting the **Updatable** checkbox.

Additionally, for each secondary entity usage, you can decide whether to leave **Reference** select to control whether or not to refresh the attributes of the secondary entity when the entity lookup information changes. By default, **Reference** is selected to ensure attributes of each secondary entity objects will be refreshed. For details about this setting when you allow row inserts with multiple entity usages, see What Happens at Runtime: View Row Creation.

Table 11-4 summarizes the combinations you can select when you define secondary entity usages for a view object.

Table 11-4 View Object Properties to Control View Row Creation Behavior

Updatable	Reference	View Row Behavior
`true`	true	This combination allows the entity usage's attributes to be updated and keeps its attributes synchronized with the value of the primary key. Since this combination works fine with the view link consistency feature, you can use it to make sure your view object only has one entity object usage that will participate in inserts.
`true`	false	This combination allows the entity usage's attributes to be updated but prevents its attributes from being changed by the a primary key lookup. This is a rather rare combination, and works best in situations where you only plan to use the view object to update or delete existing data. With this combination, the user can update attributes related to any of the nonreference, updatable entity usages and the view row will delegate the changes to the appropriate underlying entity rows. **Note:** The combination of the view link consistency feature with a view object having some of its secondary entity usages set as `Updatable=true`, `Reference=false` can end up creating unwanted extra new entities in your application.

Table 11-4 (Cont.) View Object Properties to Control View Row Creation Behavior

Updatable	Reference	View Row Behavior
false	true	This is the default behavior, described in How to Create Joins for Entity-Based View Objects. This combination assumes you do not want the entity usage to be updatable.

If you need a view object with multiple updatable entities to support creating new rows (`Updatable=true`, `Reference=false`) and the association between the entity objects is not a composition, then you need to write a bit of code, as described in How to Programmatically Create New Rows With Multiple Updatable Entity Usages.

How to Programmatically Create New Rows With Multiple Updatable Entity Usages

If you need a view object with multiple updatable entities to support creating new rows (`Updatable=true`, `Reference=false`) and the association between the entity objects is not a composition, then you need to override the `create()` method of the view object's custom view row class to enable that to work correctly.

> **Note:**
>
> You only need to write code to handle creating new rows when the association between the updatable entities is not a composition. If the association is a composition, then ADF Business Components handles this automatically.

When you call `createRow()` on a view object with multiple update entities, it creates new entity row parts for each updatable entity usage. Since the multiple entities in this scenario are related by an association, there are three pieces of code you might need to implement to ensure the new, associated entity rows can be saved without errors:

1. You may need to override the `postChanges()` method on entity objects involved to control the correct posting order.
2. If the primary key of the associated entity is populated by a database sequence using `DBSequence`, and if the multiple entity objects are associated but not composed, then you need to override the `postChanges()` and `refreshFKInNewContainees()` method to handle cascading the refreshed primary key value to the associated rows that were referencing the temporary value.
3. You need to override the `create()` method of the view object's custom view row class to modify the default row creation behavior to pass the context of the parent entity object to the newly created child entity.

To understand the code for steps 1 and 2, see the example with associated entity objects described in How to Control Entity Posting Order to Prevent Constraint Violations. The last thing you need to understand is how to override `create()` method on the view row. Consider a ProductInventoryVO view object with a primary entity usage of Product and secondary entity usage of Inventory. Assume the Product entity usage is marked as updatable and nonreference, while the Inventory entity usage is a reference entity usage.

> **Note:**
>
> The example in this section refers to the oracle.summit.model.multieoupdate package in the SummitADF_Examples application workspace.

The following example shows the commented code required to correctly sequence the creation of the multiple, updatable entity row parts during a view row create operation.

```
/**
 * By default, the framework will automatically create the new
 * underlying entity object instances that make up this
 * view object row being created.
 *
 * We override this default view object row creation to explicitly
 * pre-populate the new (detail) InventoryImpl instance using
 * the new (master) ProductImpl instance. Since all entity objects
 * implement the AttributeList interface, we can directly pass the
 * new ProductImpl instance to the InventoryImpl create()
 * method that accepts an AttributeList.
 */
protected void create(AttributeList attributeList) {
  // The view row will already have created "blank" entity instances
  // so be sure to use the respective names of the entity instance.
  ProductImpl newProduct = getProduct();
  InventoryImpl newInventory = getInventory();
   try {
      // Let inventory "blank" entity instance to do programmatic defaulting
      newProduct.create(attributeList);
      // Let inventory "blank" entity instance to do programmatic
      // defaulting passing in new ProductImpl instance so its attributes
      // are available to the ProductInventoryVORowImpl's create method.
      newInventory.create(newProduct);
   }
   catch (JboException ex) {
     newProduct.revert();
     newInventory.revert();
     throw ex;
   }
   catch (Exception otherEx) {
     newProduct.revert();
     newInventory.revert();
     throw new RowCreateException(true      /* EO Row? */,
                                 "Inventory" /* EO Name */,
                                 otherEx   /* Details */);
   }
}
```

In order for this ProductInventoryVO view object's view row class (ProductInventoryVORowImpl class) to be able to invoke the protected create()

method on the Product and Inventory entity objects, the entity object classes need to override their create() methods for method accessibility:

```
/**
 * Overridding this method in this class allows friendly access
 * to the create() method by other classes in this same package, like the
 * ProductInventoryVO view object implementation class, whose overridden
 * create() method needs to call this.
 * @param nameValuePair
 */
  protected void create(AttributeList nameValuePair) {
    super.create(nameValuePair);
  }
```

When overriding the create() method, the declaration of the method will depend on the following conditions:

- If the view object and entity objects are in the same package, the overridden create() method can have protected access and the ProductInventoryVORowImpl class will have access to them.
- If either entity object is in a different package, then ProductImpl.create() and InventoryImpl.create() (whichever is in a different package) have to be declared public in order for the ProductInventoryVORowImpl class to be able to invoke them.

What Happens at Runtime: View Row Creation

If you need a view object with multiple updatable entities to support creating new rows, you will want to understand that the **Reference** flag controls behavior related to view row creation, as well as automatic association-driven lookup of information. If you disable the **Reference** flag for a given entity usage, then:

- Each time a new view row is created, a new entity instance will be created for that entity usage.
- The entity row to which the view row points for its storage of view row attributes related to that entity usage is never changed automatically by the framework.

Conversely, if you leave the **Reference** flag enabled (default) for an entity usage then:

- No new entity instance will be created for that entity usage when a new view row is created.
- The entity row to which the view row points for storage of view row attributes related to that entity usage will automatically be kept in sync with changes made to attributes in the view row that participate in an association with said entity.

Consider a ProductInventoryVO view object that joins information from the PRODUCT and INVENTORY tables to show ProductId, PName, ProductInventoryId (a name chosen in the view object editor to identify this as an attribute of ProductInventoryVO), InventoryInventoryId (a name chosen in the view object editor to identify this as an attribute of ProductInventoryVO) and AmountInStock attributes.

Now, consider what happens at runtime for the default case where you set up the secondary entity object marked as both updatable and reference:

- The Product entity object is the primary entity usage.

- The Inventory entity object is a secondary entity usage and is marked as a Reference.

When the user creates a new row in the ProductInventoryVO, ADF Business Components only creates a new Product entity instance (since the Reference flag for the Inventory entity usage is enabled). If the user changes the product's InventoryInventoryId attribute to 10, then ADF Business Components will automatically look up the Inventory entity with primary key 10 in the entity cache (reading it in from the database if not already in the cache) and make this new view row's Inventory entity usage point to this inventory 10 entity. That has the result of automatically reflecting the right AmountInStock value for inventory 10.

In the default scenario, the reference lookup occurs both because the entity usage for Inventory is marked as a reference, as well as the fact that an association exists between the Product entity and the Inventory entity. Through the association definition, ADF Business Components knows which attributes are involved on each side of this association. When any of the attributes on the Product side of the ProductToInventory association are modified, if the Inventory entity usage is marked as a Reference, ADF Business Components will perform that automatic reference lookup. If the user changes value of the AmountInStock to 20 in this new view row, after committing the change, the database will have a new product for inventory 10 and have updated the amount of inventory 10 to 20.

Now, consider what happens at runtime where you set up the secondary entity object marked as updatable and reference is disabled:

- The Product entity object is the primary entity usage.
- The Inventory entity object is a secondary entity usage, but this usage is not marked as a Reference.

In this scenario, when the user creates a new row in the ProductInventoryVO, ADF Business Components will create both a new Product entity instance and a new Inventory entity instance (since the Reference flag for the Inventory entity usage is disabled). If the user changes the product's InventoryId attribute to 10, it will have no effect on the value of the AmountInStock attribute being displayed in the row. Additionally, if the user sets InventoryInventoryId to 99 and AmountInStock to 20 in this new view row, after committing the changes, the database will have both a new product for inventory 10 and a new inventory number 99.

Programmatically Creating View Definitions and View Objects

When you create an ADF view object, the application creates a view definition object utilizing the XML file. Alternatively, you can create the view definition object programmatically using a framework class.

The oracle.jbo.server.ViewDefImpl class lets you dynamically define the view definition meta-object for view object instances. The view definition describes the view object's structure.

Typically, the application creates the view definition object by loading an XML file that you create using JDeveloper overview editors. When the application needs to create a view object instance, it queries the MetaObjectManager for the view object's view definition by the view definition name, it then finds the XML file, opens it, parses it, and constructs a view definition object in memory.

Alternatively, you can create the view definition programmatically using methods of the ViewDefImpl class. When you create a programmatic view definition, your application code begins with code like:

```
ViewDefImpl viewDef = new ViewDefImpl("MyViewDef");
viewDef.setFullName("sessiondef.mypackage.MyViewDef");
```

A view definition that you create must be uniquely identified by its full name, where the full name is a package-qualified name. Thus, you call setFullName() to pass in the package-qualified name of your view definition object (for example, sessiondef.mypackage.MyViewDef).

The MyViewDef name that you initially pass in is the short name of the view definition you create. Your application may pass the short name when an API requires a view definition name. For example, your application might request the defName parameter when invoking ApplicationModule.createViewObject(String, String).

To create a view definition and then create a view object instance based on that definition, follow these basic steps (as illustrated in the following example):

1. Create the view definition object and set the full name.
2. Define the view object SQL statement.
3. Resolve the view definition and save it into the MDS repository.
4. With the view definition, construct instance of view objects based on it.

Note:

To save the view definition into the MDS repository, the adf-config.xml file must be appropriately configured for the saved view definition. For details about configuring the adf-config.xml file, see What You May Need to Know About MDS Repository Configuration..

```
/*
  * 1. Create the view definition object.
  */
ViewDefImpl v = new ViewDefImpl("DefNameForTheObject");

v.setFullName("sessiondef.some.unique.DefNameForTheObject");

/*
* 2. Then, define the view object's SQL statement by using a fully-
* specified custom SQL query.
*/
v.setQuery("select e.empno,e.ename,e.sal,e.deptno,d.dname,d.loc,"+
               "d.deptno,trunc(sysdate)+1 tomorrow_date, "+
               "e.sal + nvl(e.comm,0) total_compensation, "+
               "to_char(e.hiredate,'dd-mon-yyyy') formated_hiredate"+
               "  from emp e, dept d "+
               " where e.deptno = d.deptno (+)"+
               " order by e.ename");
v.setFullSql(true);

/*
* 3. Then resolve and save the view definition.
*/
```

```
v.resolveDefObject();
v.writeXMLContents();
v.saveXMLContents();

/*
* 4. Finally, use the dynamically-created view definition to construct
* instances of view objects based on it.  myAM is an instance of
* oracle.jbo.ApplicationModule that will parent this VO instance.
*/
ViewObject vo = myAM.createViewObject("SomeInstanceName", v.getFullName());
```

What You May Need to Know About MDS Repository Configuration

After defining a view definition, it is important to write and save the view definition into the MDS repository. If it is not properly saved, you may encounter issues when the request is redirected to a different node in a cluster because the definition cannot be loaded and accessed from the other node.

In order to save the definition, you need to define the `mds-config` element of `adf-config.xml`. For example, your `adf-config.xml` file should contain definitions similar to those shown in the following example.

```
<mds-config version="11.1.1.000">
   <persistence-config>
<!-- metadata-namespaces must define /sessiondef and /persdef namespaces -->
     <metadata-namespaces>
       <namespace path="/sessiondef" metadata-store-usage="mymdsstore">
       <namespace path="/persdef" metadata-store-usage="mymdsstore">
     </metadata-namespaces>

     <metadata-store-usages>
       <metadata-store-usage id="mymdsstore" default-cust-store="true">
         <metadata-store name="fs1"
               class-name="oracle.mds.persistence.stores.file.FileMetadataStore">
<!-- metadata-path value should be the absolute dir path where you want
     the metadata documents to be written -->
           <property name="metadata-path" value="/tmp">
         </metadata-store>
       </metadata-store-usage>
     </metadata-store-usages>
   </persistence-config>

   <cust-config>
     <match path="/">
       <customization-class name="oracle.adf.share.config.UserCC">
     </match>
   </cust-config>
</mds-config>
```

If your `adf-config.xml` file already defines the `metadata-store-usage` element, then you may be able to define the two namespaces `/sessiondef` and `/persdef` so that they use that `metadata-store-usage` definition. For more information about MDS configuration entries in the `adf-config.xml` file, see adfc-config.xml. For more information about configuring MDS repositories, see the "Managing the Metadata Repository" chapter in *Administering Oracle Fusion Middleware*.

What You May Need to Know About Creating View Objects at Runtime

It's important to understand the overhead associated with creating view objects at runtime, as described in Programmatically Creating View Definitions and View Objects. Avoid the temptation to do this without a compelling business requirement. For example, if your application issues a query against a table whose name you know at design time and if the list of columns to retrieve is also fixed, then create a view object at design time. When you do this, your SQL statements are neatly encapsulated, can be easily explained and tuned during development, and incur no runtime overhead to discover the structure and data types of the resulting rows.

In contrast, when you use the `createViewObjectFromQueryStmt()` API on the `ApplicationModule` interface at runtime, your query is buried in code, it's more complicated to proactively tune your SQL, and you pay a performance penalty each time the view object is created. Since the SQL query statement for a dynamically created view object could theoretically be different each time a new instance is created using this API, an extra database round trip is required to discover the "shape" of the query results on-the-fly. Only create queries dynamically if you cannot know the name of the table to query until runtime. Most other needs can be addressed using a design-time created view object in combination with runtime API's to set bind variables in a fixed where clause, or to add an additional WHERE clause (with optional bind variables) at runtime.

Declaratively Preventing Insert, Update, and Delete

ADF Business Components provides an extension class that allows you to control insert, update and delete on a view object.

Some 4GL tools like Oracle Forms provide declarative properties that control whether a given data collection allows inserts, updates, or deletes. While the view object does not yet support this as a built-in feature in the current release, it's easy to add this facility using a framework extension class that exploits custom metadata properties as the developer-supplied flags to control insert, update, or delete on a view object.

Note:

The example in this section refers to the `oracle.summit.model.declblock` package in the `SummitADF_Examples` application workspace.

To allow developers to have control over individual view object instances, you could adopt the convention of using application module custom properties by the same name as the view object instance. For example, if an application module has view object instances named `ProductsInsertOnly`, `ProductsUpdateOnly`, `ProductsNoDelete`, and `Products`, your generic code might look for application module custom properties by these same names. If the property value contains `Insert`, then insert is enabled for that view object instance. If the property contains `Update`, then update allowed. And, similarly, if the property value contains `Delete`, then delete is allowed. You could use helper methods like this to test for these application module properties and determine whether insert, update, and delete are allowed for a given view object:

```
private boolean isInsertAllowed() {
  return isStringInAppModulePropertyNamedAfterVOInstance("Insert");
}
private boolean isUpdateAllowed() {
  return isStringInAppModulePropertyNamedAfterVOInstance("Update");
}
private boolean isDeleteAllowed() {
  return isStringInAppModulePropertyNamedAfterVOInstance("Delete");
}
private boolean isStringInAppModulePropertyNamedAfterVOInstance(String s) {
  String voInstName = getViewObject().getName();
  String propVal = (String)getApplicationModule().getProperty(voInstName);
  return propVal != null ? propVal.indexOf(s) >= 0 : true;
}
```

The following example shows the other code required in a custom framework extension class for view rows to complete the implementation. It overrides the following methods:

- `isAttributeUpdateable()`

  To enable the user interface to disable fields in a new row if insert is not allowed or to disable fields in an existing row if update is not allowed.

- `setAttributeInternal()`

  To prevent setting attribute values in a new row if insert is not allowed or to prevent setting attributes in an existing row if update is not allowed.

- `remove()`

  To prevent remove if delete is not allowed.

- `create()`

  To prevent create if insert is not allowed.

```
public class CustomViewRowImpl extends ViewRowImpl {
  public boolean isAttributeUpdateable(int index) {
    if (hasEntities() &&
        ((isNewOrInitialized() && !isInsertAllowed()) ||
         (isModifiedOrUnmodified() && !isUpdateAllowed()))) {
      return false;
    }
    return super.isAttributeUpdateable(index);
  }
  protected void setAttributeInternal(int index, Object val) {
    if (hasEntities()) {
      if (isNewOrInitialized() && !isInsertAllowed())
        throw new JboException("No inserts allowed in this view");
      else if (isModifiedOrUnmodified() && !isUpdateAllowed())
        throw new JboException("No updates allowed in this view");
    }
    super.setAttributeInternal(index, val);
  }
  public void remove() {
    if (!hasEntities() || isDeleteAllowed() || isNewOrInitialized())
      super.remove();
    else
        throw new JboException("Delete not allowed in this view");
  }
  protected void create(AttributeList nvp) {
    if (isInsertAllowed()) {
      super.create(nvp);
    } else {
      throw new JboException("Insert not allowed in this view");
    }
  }
  // private helper methods omitted from this example
}
```

What You May Need to Know About Programmatic View Object Triggers

You can use triggers defined in the Groovy scripting language in place of overridden methods of `ProgrammaticViewObjectImpl.java` to perform data retrieval operations on the custom datasource. Triggers can be called from the various programmatic view object lifecycle points.

The application allows you to call triggers that are defined in Groovy script in place of Java hook points. These triggers interact with a custom data source and perform data retrieval operations. They can be called from the various programmatic view object lifecycle points. Although the option of subclassing the framework class, namely `ProgrammaticViewObjectImpl` and overriding certain methods to define implementations specific to a custom datasource remains, in order for the trigger to execute, the Java hook points should not be defined. Alternatively, if Java hook points are defined, then the triggers shouldn’t exist for the Java hook points to execute. Note that if Java hook points as well as triggers are defined, then the triggers will not execute. The application allows you to utilize Groovy scripts in the overridden methods to interact with the custom data source. These triggers can be called from various programmatic view object lifecycle points.

Specifically, the programmatic view object triggers are:

`FetchData`

This trigger is used to retrieve a data collection from the custom datasource. This trigger is invoked in place of the `getScrollableData()` and `getRangePagingData()` methods of `ProgrammaticViewObjectImpl.java` depending on whether the access mode of the view object is scroll or range paging. The `returnList` data collection is populated with the records (objects/maps) retrieved from the custom data source.

The following sample code illustrates usage of this trigger. The following context specific keywords is used in the sample code.

- `dataFilter` – Returns the DataFilter object which is a ScrollableDataFilter or RangePagingDataFilter depending on the mode of the view object.
- `dataFilter.fetchSize` – Returns the range size of the data to be fetched.
- `dataFilter.fetchStart` — Returns the range start value of the data to be fetched.
- `dataFilter.searchCriteria` - Returns a list of ViewCriteria applied on the view object.
- `dataFilter.sortCriteria` - Returns a list of SortCriteria applied on the view object.
- `dataFilter.bindParameterValues` - Returns a map containing the bind parameter names and values corresponding to the rowset that is currently being executed.

- `dataFilter.masterData` - When used in the context of a detail view object, it returns the dataprovider object of the master row.
- `returnList` - The collection that is to be populated with the records (objects/maps) from the custom data source.

```
@TriggerExpression(triggerType="FetchData", name="FetchData_Rule_0")
def FetchData_Rule_0_ValidationRuleScript_Trigger()
{
   def empData = model.data.DataCenter.getInstance().getEmpData()
   def empFilteredData = new ArrayList()
   model.data.DeptObject master = (model.data.DeptObject)dataFilter.masterData

   for (emp in empData)
   {
      if (master == null || emp.deptno.equals(master.deptno))
      {
         empFilteredData.add(emp)
      }
   }

   def fetchStart = dataFilter.fetchStart
   def fetchSize = dataFilter.fetchSize
   if(fetchStart == -1)
   {
     fetchStart = 0;
   }
   for(int i = fetchStart; i < fetchSize + fetchStart && i <
empFilteredData.size() ; i++)
   {
     returnList.add(empFilteredData.get(i))
@TriggerExpression(triggerType="RetrieveDataByKey",
name="RetrieveDataByKey_Rule_0")
def RetrieveDataByKey_Rule_0_ValidationRuleScript_Trigger()
{
   def empData = model.data.DataCenter.getInstance().getEmpData()

   def keyValue = dataFilter.key.keyValues[0]

   def iter = empData.iterator()
   while (iter.hasNext())
   {
      def emp = iter.next();
      if (emp.empno.equals(keyValue))
      {
         returnList.add(emp);
      }
   }
   }
}
```

`RetrieveDataByKey Trigger`

This trigger is used to retrieve a data collection matching a key value from the custom datasource. It is invoked in place of the `retrieveDataByKey` method of `ProgrammaticViewObjectImpl.java`. This trigger is invoked when the required data matching the key is not present in the current range of rows retrieved by the view object. This trigger retrieves the collection of objects/maps matching the key value.

The following sample code illustrate the usage of this trigger. The following context specific keywords is used in the sample code.

- `dmlFilter.key` - Returns an oracle.jbo.Key containing the key values of the data/ object to be retrieved.
- `dmlFilter.fetchSize` - Returns the fetch size.
- `returnList` - The collection that is to be populated with the records (objects/maps) from the custom data source that match the key value.

```
@TriggerExpression(triggerType="RetrieveDataByKey",
name="RetrieveDataByKey_Rule_0")
def RetrieveDataByKey_Rule_0_ValidationRuleScript_Trigger()
{
   def empData = model.data.DataCenter.getInstance().getEmpData()

   def keyValue = dataFilter.key.keyValues[0]

   def iter = empData.iterator()
   while (iter.hasNext())
   {
      def emp = iter.next();
      if (emp.empno.equals(keyValue))
      {
         returnList.add(emp);
      }
   }
}
```

Defining Triggers for Programmatic View Objects

ADF Business Components allows you to apply triggers in a programmatic view object's lifecycle. Triggers execute at these set lifecycle events. You can use Groovy script to implement business rules that are executed in response to these programmatic view object triggers.

To add a trigger to a programmatic view object.

1. In the Applications Navigator, double-click the view object you want to add a trigger.
2. In the overview editor, click the **Business Rules** navigation tab.
3. On the Business Rules page, select the view-level Triggers node, and click the **Create New Trigger** icon.
4. From the Add Trigger dialog box, select the appropriate trigger point from the Type dropdown list.
5. Enter a Groovy expression in the Trigger Definition tab.

The application creates a `<trigger>` tag in the view object's XML file and also populates the `.bcs` file associated with the view object. When a Groovy expression is evaluated at runtime, it is assumed to be untrusted unless explicitly identified as a trusted expression. To avoid the runtime exception, use the Properties window to identify the expression as a trusted expression..

12 Implementing Validation and Business Rules Programmatically

This chapter describes how to use ADF entity object events and features to programmatically implement business rules in an Oracle ADF application. It also describes how to invoke custom validation code, for example, using setter methods to populate entity rows.
This chapter includes the following sections:

About Programmatic Business Rules

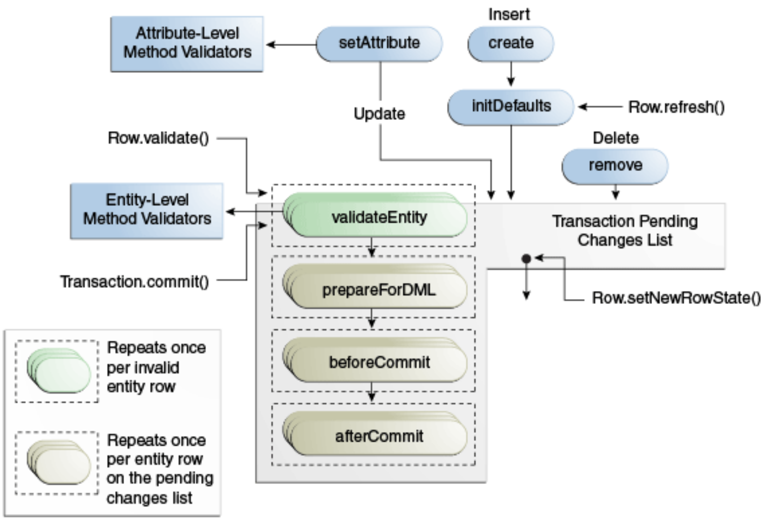
ADF Business Components provide method validators and events to programmatically define business logic in addition to using built-in declarative validation features.

Complementing the built-in *declarative* validation features, **entity objects** and **view objects** contain method validators and several events you can handle that allow you to *programmatically* implement encapsulated business logic using Java code. These concepts are illustrated in Figure 12-1.

- Attribute-level method validators trigger validation code when an attribute value changes.
- Entity-level method validators trigger validation code when an entity row is validated.
- You can override the following key methods in a custom Java class for an entity:
  - `create()`, to assign default values when a row is created

- `initDefaultExpressionAttributes()`, to assign defaults either when a row is created or when a new row is refreshed
- `remove()`, to conditionally disallow deleting
- `isAttributeUpdateable()`, to make attributes conditionally updatable
- `setAttribute()`, to trigger attribute-level method validators
- `validateEntity()`, to trigger entity-level method validators
- `prepareForDML()`, to assign attribute values before an entity row is saved
- `beforeCommit()`, to enforce rules that must consider all entity rows of a given type
- `afterCommit()`, to send notifications about a change to an entity object's state

Figure 12-1 Key Entity Objects Features and Events for Programmatic Business Logic



Attribute-Level Method Validators
setAttribute
Insert
create
Update
initDefaults
Row.refresh()
Row.validate()
Delete
remove
Entity-Level Method Validators
validateEntity
Transaction Pending Changes List
Transaction.commit()
prepareForDML
Row.setNewRowState()
beforeCommit
afterCommit
Repeats once per invalid entity row
Repeats once per entity row on the pending changes list

Note:

Only new and modified rows participate in transaction validation. Although deleted rows are part of the transaction, they are not included in the validation.

When coding programmatic business rules, it's important to have a firm grasp of the validation cycle. See Understanding the Validation Cycle.

Programmatic Business Rules Use Cases and Examples

While much of your validation can be implemented using basic declarative behavior, you can implement more complex business rules for your business domain layer when needed, using the Method validator to invoke custom validation code.

Some examples of when you might want to use programmatic business rules include:

- Eagerly defaulting an attribute value from a database sequence
- Assigning values derived from complex calculations
- Undoing pending changes to an entity object
- Accessing and storing information about the current user session
- Determining conditional updatability for attributes

Additional Functionality for Programmatic Business Rules

You may find it helpful to understand other **Oracle ADF** features before you start using programmatic validation. Following are links to other functionality that may be of interest.

- Before implementing business rules programmatically, you should see if the declarative validation can handle the needs of your application. For more information, see Defining Validation and Business Rules Declaratively.
- You can use resource bundles to provide localizable validation error messages, as described in Working with Resource Bundles.
- How to Synchronize with Trigger-Assigned Values, explains how to use the `DBSequence` type for primary key attributes whose values need to be populated by a database sequence at *commit* time.
- For information about security features in Oracle Fusion Web Applications, including how to access information about the authenticated user, see Enabling ADF Security in a Fusion Web Application.
- For information about using Groovy script in your entity object business logic, see Using Groovy Scripting Language with Business Components.

Using Method Validators

You can define custom Java code that is triggered by method validators. ADF Method validators allow you to supplement declarative validation rules. You can define attribute or entity level method validators.

Method validators are the primary way of supplementing declarative validation rules and Groovy-scripted expressions using your own Java code. Method validators trigger Java code that you write in your own validation methods at the appropriate time during the entity object validation cycle. There are many types of validation you can code with a method validator, either on an attribute or on an entity as a whole.

You can add any number of attribute-level or entity-level method validators, provided they each trigger a distinct method name in your code. All validation method names must begin with the word `validate`; however, following that rule you are free to name them in any way that most clearly identifies the functionality. For an attribute-level validator, the method must take a single argument of the same type as the entity attribute. For an entity-level validator, the method takes no arguments. The method must also be public, and must return a boolean value. Validation will fail if the method returns `false`.

> **Note:**
>
> Although it is important to be aware of these rules, when you use JDeveloper to create method validators, JDeveloper creates the correct interface for the class.

At runtime, the Method validator passes an entity attribute to a method implemented in your entity object class.

In the following example, the method accepts strings that start with a capital letter and throws an exception on null values, empty strings, and strings that do not start with a capital letter.

```
public boolean validateIsCapped(String text)
{
  if (text != null &&
      text.length() != 0 &&
      text[0] >= 'A' &&
      text[0] <= 'Z')
  {
    return true;
  }
}
```

How to Create an Attribute-Level Method Validator

The use of method validators is a programmatic approach that supplements your declarative validation rules.

Before you begin:

It may be helpful to have an understanding of what method validators are. For more information, see Using Method Validators.

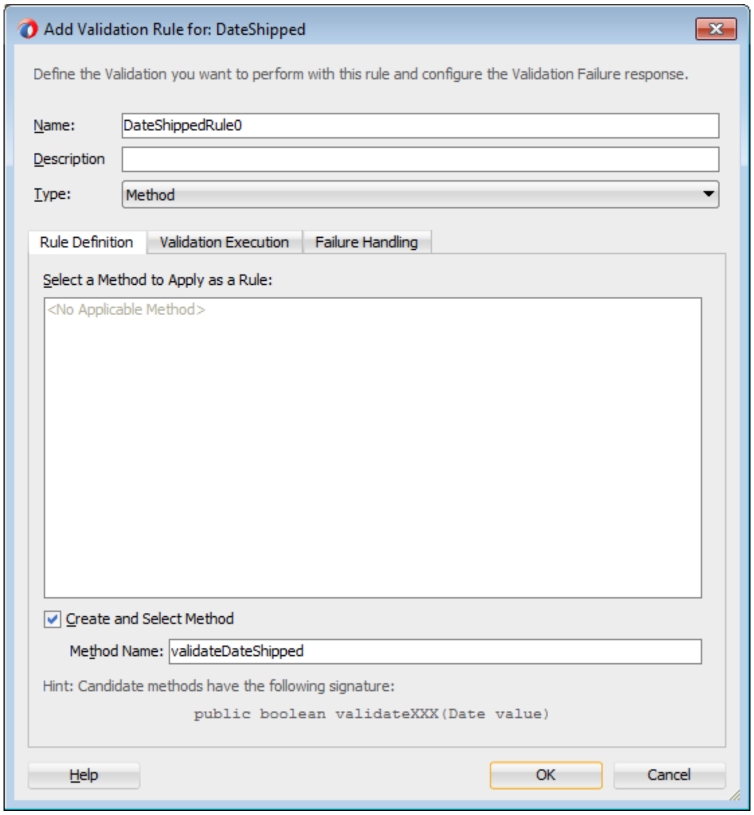
You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Programmatic Business Rules.

To create an attribute-level Method validator:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Java** navigation tab.

   The Java page shows the Java generation options that are currently enabled for the entity object. If your entity object does not yet have a custom entity object class, then you must generate one before you can add a Method validator. To generate the custom Java class, click the **Edit** icon, then select **Generate Entity Object Class**, and click **OK** to generate the `*.java` file.
3. Click the **Business Rules** navigation tab, and then expand the **Attributes** section and select the attribute that you want to validate.
4. Click the **New** icon to add a validation rule.
5. In the Add Validation Rule dialog, select **Method** from the **Rule Type** dropdown list.

Figure 12-2 Adding an Attribute-Level Method Validator



Add Validation Rule for: DateShipped

Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: DateShippedRule0

Description:

Type: Method

Select a Method to Apply as a Rule:

<No Applicable Method>

☑ Create and Select Method

Method Name: validateDateShipped

Hint: Candidate methods have the following signature:

```
public boolean validateXXX(Date value)
```

The Add Validation Rule dialog displays the expected method signature for an attribute-level validation method. You have two choices:

- If you already have a method in your entity object's custom Java class of the appropriate signature, it will appear in the list and you can select it after deselecting the **Create and Select Method** checkbox.
- If you leave the **Create and Select Method** checkbox selected (see Figure 12-2), you can enter any method name in the **Method Name** box that begins with the word `validate`. When you click **OK,** JDeveloper adds the method to your entity object's custom Java class with the appropriate signature.

6. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression. For more information, see Triggering Validation Execution.
7. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails.

   For more information, see Creating Validation Error Messages.

What Happens When You Create an Attribute-Level Method Validator

When you add a new method validator, JDeveloper updates the XML document to reflect the new validation rule. If you asked to have the method created, the method is added to the entity object's custom Java class. The following example illustrates a simple attribute-level validation rule that ensures that the `OrderShippedDate` of an order is a date in the current month. Notice that the method accepts an argument of the same type as the corresponding attribute, and that its conditional logic is based on the value of this incoming parameter. When the attribute validator fires, the attribute value has not yet been set to the new value in question, so calling the `getOrderShippedDate()` method inside the attribute validator for the `OrderShippedDate` attribute would return the attribute's *current* value, rather than the *candidate* value that the client is attempting to set.

> **Note:**
>
> The return value of the `compareTo()` method is zero (`0`) if the two dates are equal, negative one (`-1`) if the first date is less than the second, or positive one (`1`) if the first date is greater than the second.

```
public boolean validateOrderShippedDate(Date  data) {
  if (data != null && data.compareTo(getFirstDayOfCurrentMonth()) <= 0) {
    return false;
  }
  return true;
}
```

How to Create an Entity-Level Method Validator

Entity-level method validators are similar to attribute-level method validators, except that they have a broader scope: the entire entity rather than a single attribute.

In addition, you can defer execution of the validator to time of the transaction when using an entity-level method validator.

Before you begin:

It may be helpful to have an understanding of what method validators are. For more information, see Using Method Validators.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Programmatic Business Rules.

To create an entity-level method validator:

1. In the Applications window, double-click the desired entity object.
2. In the overview editor, click the **Java** navigation tab.

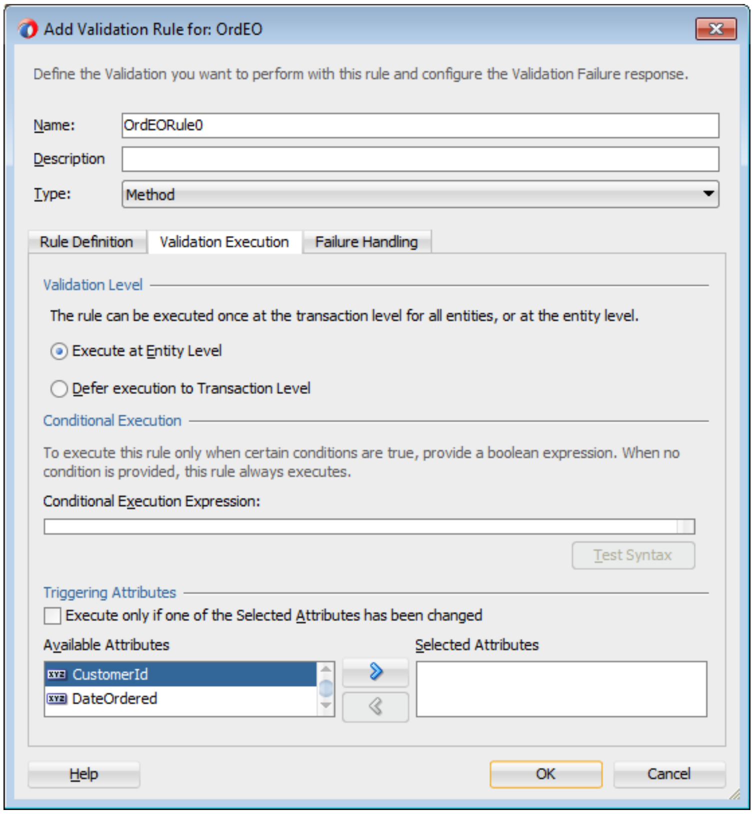
   The Java page shows the Java generation options that are currently enabled for the entity object. If your entity object does not yet have a custom entity object class, then you must generate one before you can add a Method validator. To generate the custom Java class, click the **Edit** icon, then select **Generate Entity Object Class**, and click **OK** to generate the `*.java` file.
3. Click the **Business Rules** navigation tab, and then select the **Entity** node and click the **New** icon to add a validation rule.
4. In the Add Validation Rule dialog, select **Method** from the **Rule Type** dropdown list.

The Add Validation Rule dialog displays the expected method signature for an entity-level validation method. You have two choices:

- If you already have a method in your entity object's custom Java class of the appropriate signature, it will appear in the list and you can select it after deselecting the **Create and Select Method** checkbox.
- If you leave the **Create and Select Method** checkbox selected (see Figure 12-3), you can enter any method name in the **Method Name** box that begins with the word `validate`. When you click **OK,** JDeveloper adds the method to your entity object's custom Java class with the appropriate signature.

5. Optionally, click the **Validation Execution** tab to enter criteria for the execution of the rule, such as dependent attributes and a precondition expression. For more information, see Triggering Validation Execution.

Figure 12-3 Adding an Entity-Level Method Validator



Add Validation Rule for: OrdEO

Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: OrdEORule0

Description

Type: Method

Validation Level

The rule can be executed once at the transaction level for all entities, or at the entity level.

● Execute at Entity Level

○ Defer execution to Transaction Level

Conditional Execution

To execute this rule only when certain conditions are true, provide a boolean expression. When no condition is provided, this rule always executes.

Conditional Execution Expression:

Triggering Attributes

□ Execute only if one of the Selected Attributes has been changed

Available Attributes: CustomerId, DateOrdered

Selected Attributes

For Method entity validators, you can also use the **Validation Execution** tab to specify the validation level. If you select **Defer Execution to Transaction Level**, the validator will fire when the entity is committed. This is useful when multiple rows are displayed for editing in a table.

6. Click the **Failure Handling** tab and enter or select the error message that will be shown to the user if the validation rule fails.

   For more information, see Creating Validation Error Messages.

What Happens When You Create an Entity-Level Method Validator

When you add a new method validator, JDeveloper updates the XML document to reflect the new validation rule. If you asked to have the method created, the method is added to the entity object's custom Java class. The following example illustrates a simple entity-level validation rule that ensures that the `DateShipped` of an order comes after the `DateOrdered`.

```
public boolean validateDateShippedAfterDateOrdered() {
  Date DateShipped = getDateShipped();
  Date DateOrdered  = getDateOrdered();
  if (DateShipped != null && DateShipped.compareTo(DateOrdered) < 0) {
    return false;
  }
  return true;
}
```

If you select **Defer Execution to Transaction Level** on the Validation Execution tab of the Add Validation Rule dialog and set `SkipValidation="skipDataControls"` on the page that displays the entity object, you can postpone the validation until transaction time. This allows the user to modify multiple rows in a table and then validate them as a group when the user commits. The following example shows a method validator that verifies that the department name is not null for a collection of entity rows.

```
// Validation method for Departments.
public boolean validateDepartments(ArrayList ctxList) {
   Iterator iter = ctxList.iterator();
   while (iter.hasNext()) {
      JboValidatorContext entValContext = (JboValidatorContext)iter.next();
      DepartmentsImpl deptEO = (DepartmentsImpl)entValContext.getSource();
      if (deptEO.getDepartmentName() == null) {
         // if Dept is null, throw error
         return false;
      }
   }
   return true;
}
```

What You May Need to Know About Translating Validation Rule Error Messages

Like the locale-specific UI **control hints** for entity object attributes, the validation rule error messages are added to the entity object's component message bundle file. These entries in the message bundle represent the strings for the default locale for your application. To provide translated versions of the validation error messages, follow the same steps as for translating the UI control hints, as described in Working with Resource Bundles.

Assigning Programmatically Derived Attribute Values

ADF Business Components allows you to perform programmatic defaulting when declarative defaulting is insufficient.

When declarative defaulting falls short of your needs, you can perform programmatic defaulting in your entity object:

- When an entity row is first created
- When the entity row is first created or when refreshed to null values
- When the entity row is saved to the database
- When an entity attribute value is set

How to Provide Default Values for New Rows at Create Time

The `create()` method provides the entity object event you can handle to initialize default values the first time an entity row is created. The following example shows the overridden create method of an entity object. It calls an attribute setter method to populate the `DateOrdered` attribute in a new order entity row.

You can also define default values using a Groovy expression. For more information, see How to Define a Static Default Value.

> **Note:**
>
> Calling the `setAttribute()` method inside the overridden `create()` method does not mark the new row as being changed by the user. These programmatically assigned defaults behave like declaratively assigned defaults. Also note that any changes you make to the `create()` method must occur after the call to `super.create()`.

```
// In entity object implementation class
protected void create(AttributeList nameValuePair) {
   super.create(nameValuePair);
   this.setDateOrdered(new Date());
}
```

Choosing Between create() and initDefaultExpressionAttributes() Methods

You should override the `initDefaultExpressionAttributes()` method for programmatic defaulting logic that you want to fire both when the row is first created, and when it might be refreshed back to initialized status.

If an entity row has `New` status and you call the `refresh()` method on it, then the entity row is returned to an `Initialized` status if you do not supply either the `REFRESH_REMOVE_NEW_ROWS` or `REFRESH_FORGET_NEW_ROWS` flag. As part of this process, the entity object's `initDefaultExpressionAttributes()` method is invoked, but not its `create()` method again.

Eagerly Defaulting an Attribute Value from a Database Sequence

How to Synchronize with Trigger-Assigned Values, explains how to use the `DBSequence` type for primary key attributes whose values need to be populated by a database sequence at *commit* time. Sometimes you may want to eagerly allocate a sequence number at entity row creation time so that the user can see its value and so that this value does not change when the data is saved. To accomplish this, use the `SequenceImpl` helper class in the `oracle.jbo.server` package in an overridden `create()` method as shown in the following example. It shows code from the custom Java class for an entity object. After calling `super.create()`, it creates a new instance of the SequenceImpl object, passing the sequence name and the current transaction object. Then it calls the setWarehouseId() attribute setter method with the return value from SequenceImpl's getSequenceNumber() method.

> **Note:**
>
> For a metadata-driven alternative to this approach, see Assigning the Primary Key Value Using an Oracle Sequence.

```
// In entity object implementation class
import oracle.jbo.server.SequenceImpl;
// Default WarehouseId value from WAREHOUSE_SEQ sequence at entity row create
time
protected void create(AttributeList attributeList) {
    super.create(attributeList);
    SequenceImpl sequence = new SequenceImpl("WAREHOUSE_SEQ",getDBTransaction());
    setWarehouseId(sequence.getSequenceNumber());
}
```

How to Assign Derived Values Before Saving

If you want to assign programmatic defaults for entity object attribute values before a row is saved, override the prepareForDML() method and call the appropriate attribute setter methods to populate the derived attribute values. To perform the assignment only during INSERT, UPDATE, or DELETE, you can compare the value of the operation parameter passed to this method against the integer constants DML_INSERT, DML_UPDATE, DML_DELETE respectively.

The following example shows an overridden prepareForDML() method that assigns derived values.

```
protected void prepareForDML(int operation, TransactionEvent e) {
  super.prepareForDML(operation, e);
  //Populate GL Date
  if (operation == DML_INSERT) {
    if (this.getGlDate() == null) {
      String glDateDefaultOption =
        (String)this.getInvoiceOption().getAttribute("DefaultGlDateBasis");
      if ("I".equals(glDateDefaultOption)) {
        setAttribute(GLDATE, this.getInvoiceDate());
      } else {
        setAttribute(GLDATE, this.getCurrentDBDate());
      }
    }
  }

  //Populate Exchange Rate and Base Amount if null
  if ((operation == DML_INSERT) || (operation == DML_UPDATE)) {
    BigDecimal defaultExchangeRate = new BigDecimal(1.5);
    if ("Y".equals(this.getInvoiceOption().getAttribute("UseForeignCurTrx"))) {
      if (!(this.getInvoiceCurrencyCode().equals(
                          this.getLedger().getAttribute("CurrencyCode")))) {
        if (this.getExchangeDate() == null) {
          setAttribute(EXCHANGEDATE, this.getInvoiceDate());
        }
        if (this.getExchangeRateType() == null) {
          String defaultConvRateType =
            (String)this.getInvoiceOption().getAttribute("DefaultConvRateType");
          if (defaultConvRateType != null) {
            setAttribute(EXCHANGERATETYPE, defaultConvRateType);
          } else {
            setAttribute(EXCHANGERATETYPE, "User");
          }
        }
        if (this.getExchangeRate() == null) {
          setAttribute(EXCHANGERATE, defaultExchangeRate);
        }
        if ((this.getExchangeRate() != null) &&
            (this.getInvoiceAmount() != null)) {
          setAttribute(INVAMOUNTFUNCCURR,
                     (this.getExchangeRate().multiply(this.getInvoiceAmount())));
        }
      } else {
        setAttribute(EXCHANGEDATE, null);
        setAttribute(EXCHANGERATETYPE, null);
        setAttribute(EXCHANGERATE, null);
        setAttribute(INVAMOUNTFUNCCURR, null);
      }
    }
  }
}
```

How to Assign Derived Values When an Attribute Value Is Set

To assign derived attribute values whenever another attribute's value is set, add code to the latter attribute's setter method. The following example shows the setter method for an AssignedTo attribute in an entity object.

After the call to setAttributeInternal() to set the value of the AssignedTo attribute, it uses the setter method for the AssignedDate attribute to set its value to the current date and time.

> **Note:**
>
> It is safe to add custom code to the generated attribute getter and setter methods as shown here. When JDeveloper modifies code in your class, it intelligently leaves your custom code in place.

```
public void setAssignedTo(Number value) {
  setAttributeInternal(ASSIGNEDTO, value);
  setAssignedDate(getCurrentDateWithTime());
}
```

Undoing Pending Changes to an Entity Using the Refresh Method

Use the refresh(int flag) method on an ADF Business Components row to refresh pending row-changes. The int flag argument allows different values that control the behavior of this method.

You can use the `refresh(int flag)` method on a row to refresh any pending changes it might have. The behavior of the `refresh()` method depends on the flag that you pass as a parameter. The three key flag values that control its behavior are the following constants in the `Row` interface:

- `REFRESH_WITH_DB_FORGET_CHANGES` forgets modifications made to the row in the current transaction, and the row's data is refreshed from the database. The latest data from the database replaces data in the row regardless of whether the row was modified or not.
- `REFRESH_WITH_DB_ONLY_IF_UNCHANGED` works just like `REFRESH_WITH_DB_FORGET_CHANGES`, but for *unmodified* rows. If a row was already modified by this transaction, the row is not refreshed.
- `REFRESH_UNDO_CHANGES` works the same as `REFRESH_WITH_DB_FORGET_CHANGES` for *unmodified* rows. For a modified row, this mode refreshes the row with attribute values at the beginning of this transaction. The row remains in a modified state if it had been previously posted but not committed in the current transaction prior to performing the refresh operation.

How to Control What Happens to New Rows During a Refresh

By default, any entity rows with `New` status that you `refresh()` are reverted back to blank rows in the `Initialized` state. Declarative defaults are reset, as well as programmatic defaults coded in the `initDefaultExpressionAttributes()` method, but the entity object's `create()` method is not invoked during this blanking-out process.

You can change this default behavior by combining one of the flags in Undoing Pending Changes to an Entity Using the Refresh Method with one of the following two flags (using the bitwise-`OR` operator):

- `REFRESH_REMOVE_NEW_ROWS`, new rows are removed during refresh.
- `REFRESH_FORGET_NEW_ROWS`, new rows are marked `Dead`.

How to Cascade Refresh to Composed Children Entity Rows

You can cause a `refresh()` operation to cascade to composed child entity rows by combining the `REFRESH_CONTAINEES` flag (using the bitwise-`OR` operator) with any of the valid flag combinations described in Undoing Pending Changes to an Entity Using the Refresh Method and How to Control What Happens to New Rows During a Refresh. This causes the entity to invoke `refresh()` using the same mode on any composed child entities it contains.

Using View Objects for Validation

You can manage pending changes for ADF entity-based view objects in the entity cache, while read-only view objects only retrieve data.

When your business logic requires performing SQL queries, the natural choice is to use a view object to perform that task. Keep in mind that the SQL statements you execute for validation will "see" pending changes in the entity cache only if they are entity-based view objects. Read-only view objects will only retrieve data that has been posted to the database.

How to Use View Accessors for Validation Against View Objects

Since entity objects are designed to be reused in any application scenario, they should not depend *directly* on a view object instance in the data model of any specific **application module**. Doing so would prevent them from being reused in other application modules, which is highly undesirable.

Instead, you should use a **view accessor** to validate against a view object. For more information, see How to Create a View Accessor for an Entity Object or View Object.

Using a view accessor, your validation code can access the view object and set bind variables, as shown in the following example.

```
// Sample entity-level validation method
public boolean validateSomethingUsingViewAccessor() {
  RowSet rs = getMyValidationVO();
  rs.setNamedBindParameter("Name1", value1);
  rs.setNamedBindParameter("Name2", value2);
  rs.executeQuery();
  if ( /* some condition */) {
  /*
   * code here returns true if the validation succeeds
   */
  }
  return false;
}
```

Best Practice:

Any time you access a row set programmatically, you should consider creating a secondary iterator for the row set. This ensures that you will not disturb the current row set of the default **row set iterator** that may be utilized when your expose your view objects as **data controls** to the user interface project. You can call `createRowSetIterator()` on the row set you are working with to create a secondary named row set iterator. When you are through with programmatic iteration, your code should call `closeRowSetIterator()` on the row set to remove the secondary iterator from memory.

As the sample code suggests, view objects used for validation typically have one or more named bind variables in them. In this example, the bind variables are set using the `setNamedBindParameter()` method. However, you can also set these variables declaratively in JDeveloper using Groovy expressions in the view accessor definition page.

Depending on the kind of data your view object retrieves, the "`/* some condition */`" expression in the example will look different. For example, if your view object's SQL query is selecting a `COUNT()` or some other aggregate, the condition will typically use the `rs.first()` method to access the first row, then use the `getAttribute()` method to access the attribute value to see what the database returned for the count.

If the validation succeeds or fails based on whether the query has returned zero or one row, the condition might simply test whether `rs.first()` returns `null` or not. If `rs.first()` returns `null`, there is no "first" row. In other words, the query retrieved no rows. In other cases, you may be iterating over one or more query results retrieved by the view object to determine whether the validation succeeds or fails.

How to Validate Conditions Related to All Entities of a Given Type

The `beforeCommit()` method is invoked on *each* entity row in the pending changes list after the changes have been posted to the database, but before they are committed. This can be a useful method in which to execute view object-based validations that must assert some rule over all entity rows of a given type.

> **Note:**
>
> You can also do this declaratively using a transaction-level validator (see How to Set Transaction-Level Validation).

If your `beforeCommit()` logic can throw a `ValidationException`, you must set the `jbo.txn.handleafterpostexc` property to `true` in your configuration to have the framework automatically handle rolling back the in-memory state of the other entity objects that may have already successfully posted to the database (but not yet been committed) during the current commit cycle.

For example, consider the overridden `beforeCommit()` shown in the following example. In this example, there are three view objects based on polymorphic entity objects (`Persons`, `Staff`, and `Supplier`), with the `PersonTypeCode` attribute as the discriminator. The `PersonsImpl.java` file has an overridden `beforeCommit()` method that calls a validation method. The validation method uses the fourth view object, `PersonsValidator`, to make sure that the principal name is unique across each person type. For example, there is a `PrincipalName` of `SKING` for the `Staff` view object, but there cannot be another `SKING` in this or the other person types.

```
// In entity object implementation class
. . .
@Override
public void beforeCommit(TransactionEvent transactionEvent) throws
ValidationException {
  String principalName = getPrincipalName();
  if (!validatePrincipalNameIsUniqueUsingViewAccessor(principalName)) {
    throw new ValidationException("Principal Name must be unique across person
types");
  }
    super.beforeCommit(transactionEvent);
}

public boolean validatePrincipalNameIsUniqueUsingViewAccessor(String
principalName) {
RowSet rs = getPersonsValidatorVO();
rs.setNamedWhereClauseParam("principalName", principalName);
rs.setRangeSize(-1);
rs.executeQuery();
Row[] validatorRows = rs.getAllRowsInRange();
if (validatorRows.length > 1)
  // more than one row has the same princpalName
{
    return false;
}
rs.closeRowSetIterator();
return true;
}
```

What You May Need to Know About Row Set Access with View Accessors

If your entity object or view object business logic iterates over its own view accessor row set, and that view accessor is not also used by a model-defined List of Values, then there is no need to use a secondary row set iterator. For example, if an entity object has a view accessor named `AirportValidationVA` for a view object that takes one named bind parameter, it can iterate its own view accessor row set using either Groovy script or Java. The following example shows Groovy script that iterates over a view accessor row set.

```
AirportValidationVA.setNamedWhereClauseParam("VarTla",newValue)
AirportValidationVA.executeQuery();
return AirportValidationVA.first() != null;
```

The following example shows a Java method validator that iterates over a view accessor row set.

```
public boolean validateJob(String job) {
   getAirportValidationVA().setNamedWhereClauseParam("VarTla",job);
   getAirportValidationVA().executeQuery();
   return getAirportValidationVA().first() != null;
}
```

Accessing Related Entity Rows Using Association Accessors

Use an ADF entity object’s custom Java class’s association accessor method to access information from related entity objects.

To access information from related entity objects, you use an association accessor method in your entity object's custom Java class. By calling the accessor method, you can easily access any related entity row — or set of entity rows — depending on the cardinality of the association.

How to Access Related Entity Rows

You can use an association accessor to access related entity rows. The following example shows code from the `controlpostorder` module in the `SummitADF` application workspace that shows the overridden `postChanges()` method in the `EmpEO` entity object's custom Java class. It uses the `getDeptEO()` association accessor to retrieve the related department for the employee.

```
// In EmpEOImpl.java
public void postChanges(TransactionEvent transactionEvent) {
   /* If current entity is new or modified */
   if (getPostState() == STATUS_NEW ||
      getPostState() == STATUS_MODIFIED) {
      /* Get the associated dept for the employee */
      DeptEOImpl dept = getDeptEO();
      /* If there is an associated dept */
```

```
        if (dept != null) {
           /* And if it's post-status is NEW */
           if (dept.getPostState() == STATUS_NEW) {
              /*
     * Post the department first, before posting this
     * entity by calling super below
     */
              dept.postChanges(transactionEvent);
           }
        }
     }
     super.postChanges(transactionEvent);
  }
```

How to Access Related Entity Row Sets

If the cardinality of the association is such that multiple rows are returned, you can use the association accessor to return sets of entity rows.

The following example illustrates the code for the overridden `postChanges()` method in the `DeptEO` entity object's custom Java class. It shows the use of the `getEmpEO()` association accessor to retrieve the `RowSet` object of `EmpEO` rows in order to update the `DeptId` attribute in each row using the `setDeptId()` association accessor.

```
// In DeptEOImpl.java in the controlpostorder module
// of the SummitADF application workspace
RowSet newEmployeesBeforePost = null;
@Override
public void postChanges(TransactionEvent transactionEvent) {
      /* Update references only if Department is a NEW one */
   if (getPostState() == STATUS_NEW) {
      /*
      * Get a rowset of employees related
      * to this new department before calling super
      */
   newEmployeesBeforePost = (RowSet)getEmpEO();
   }
   super.postChanges(transactionEvent);
    }
@Override
protected void refreshFKInNewContainees() {
   if (newEmployeesBeforePost != null) {
      Number newDeptId = getId().getSequenceNumber();
         /*
         * Process the rowset of employees that referenced
         * the new department prior to posting, and update their
         * Id attribute to reflect the refreshed Id value
         * that was assigned by a database sequence during posting.
         */
      while (newEmployeesBeforePost.hasNext()){
         EmpEOImpl emp = (EmpEOImpl)newEmployeesBeforePost.next();
         emp.setDeptId(newDeptId);
      }
      closeNewProductRowSet();
   }
}
```

Referencing Information About the Authenticated User

Use the Configure ADF Security wizard to enable the ADF authentication servlet to trigger user login and logout by the web application container. You can also retrieve authenticated user credentials.

If you have run the Configure ADF Security wizard on your application to enable the ADF authentication servlet to support user login and logout, the `oracle.jbo.server.SessionImpl` object provides methods you can use to get information about the name of the authenticated user and about the roles of which they are a member. This is the implementation class for the `oracle.jbo.Session` interface that clients can access.

For information about how to access information about the authenticated user, see How to Determine Membership of a Java EE Security Role.

For more information about security features in Oracle Fusion Web Applications, read Enabling ADF Security in a Fusion Web Application.

Accessing Original Attribute Values

Use the `getPostedAttribute()` method to retrieve an ADF entity object attribute's original value before it was changed in entity row in the current transaction.

If an entity attribute's value has been changed in the current transaction, when you call the attribute getter method for it you will get the pending changed value. Sometimes you want to get the original value before it was changed. Using the `getPostedAttribute()` method, your entity object business logic can consult the original value for any attribute as it was read from the database before the entity row was modified. This method takes the attribute *index* as an argument, so pass the appropriate generated attribute index enums that JDeveloper maintains for you.

Storing Information About the Current User Session

Use the user data hash table provided the Session object to store current user session information that the ADF entity object business logic can utilize.

If you need to store information related to the current user session in a way that entity object business logic can reference, you can use the user data hash table provided by the `Session` object.

How to Store Information About the Current User Session

When a new user accesses an application module for the first time, the `prepareSession()` method is called. As shown in the following example, the application module overrides `prepareSession()` to retrieve information about the authenticated user by calling a `retrieveUserInfoForAuthenticatedUser()` method on the view object instance. Then, it calls the `setUserIdIntoUserDataHashtable()` helper method to save the user's numerical ID into the user data hash table.

```
// In the application module
protected void prepareSession(Session session) {
  super.prepareSession(session);
  /*
   * Query the correct row in the VO based on the currently logged-in
   * user, using a custom method on the view object component
   */
  getLoggedInUser().retrieveUserInfoForAuthenticatedUser();
  setUserIdIntoUserDataHashtable();
}
```

The following example shows the code for the view object's `retrieveUserInfoForAuthenticatedUser()` method. It sets its own `EmailAddress` bind variable to the name of the authenticated user from the session and then calls `executeQuery()` to retrieve the additional user information from the `USERS` table.

```
// In the view object's custom Java class
public void retrieveUserInfoForAuthenticatedUser() {
  SessionImpl session = (SessionImpl)getDBTransaction().getSession();
  setEmailAddress(session.getUserPrincipalName());
  executeQuery();
  first();
}
```

One of the pieces of information about the authenticated user that the view object retrieves is the user's numerical ID number, which that method returns as its result. For example, the user `sking` has the numeric `UserId` of `300`.

The next example shows the `setUserIdIntoUserDataHashtable()` helper method — used by the `prepareSession()` code in the sample above— that stores this numerical user ID in the user data hash table, using the key provided by the string constant `CURRENT_USER_ID`.

```
// In the application module
private void setUserIdIntoUserDataHashtable() {
  Integer userid = getUserIdForLoggedInUser();
  Hashtable userdata = getDBTransaction().getSession().getUserData();
  userdata.put(CURRENT_USER_ID, userid);
}
```

The corresponding entity objects in this example can have an overridden `create()` method that references this numerical user ID using a helper method like the one in the following example to set the `CreatedBy` attribute programmatically to the value of the currently authenticated user's numerical user ID.

```
protected Number getCurrentUserId() {
  Hashtable userdata = getDBTransaction().getSession().getUserData();
  Integer userId = (Integer)userdata.get(CURRENT_USER_ID);
  return userdata != null ? Utils.intToNumber(userId):null;
}

// In the application module
protected void prepareSession(Session session) {
  super.prepareSession(session);
  /*
   * Query the correct row in the VO based on the currently logged-in
   * user, using a custom method on the view object component
   */
  getLoggedInUser().retrieveUserInfoForAuthenticatedUser();
  setUserIdIntoUserDataHashtable();
}
```

How to Use Groovy to Access Information About the Current User Session

The top-level `adf` object allows you access to objects that the framework makes available to Groovy script. The `adf.userSession` object returns a reference to the ADF Business Components user session, which you can use to reference values in the `userData` hash map that is part of the session.

The following example shows the Groovy script you would use to reference a `userData` hash map key named `MyKey`.

```
adf.userSession.userData.MyKey
```

Accessing the Current Date and Time

ADF Business Components includes pre-defined Groovy expressions that you can use in entity object business logic to retrieve current date and time.

You might find it useful to reference the current date and time in your entity object business logic. You can reference the current date or current date and time using the following Groovy script expressions:

- `adf.currentDate` — returns the current date (time truncated)
- `adf.currentDateTime` — returns the current date and time

For information about using Groovy script in your entity object business logic, see Using Groovy Scripting Language with Business Components.

Sending Notifications Upon a Successful Commit

Upon successful commit of pending row changes, the `afterCommit()` method is called on such ADF Business Components entity rows. Use this method to send a notification as well.

The `afterCommit()` method is invoked on *each* entity row that was in the pending changes list and got successfully saved to the database. You can use this method to send a notification on a commit.

A better way to send notifications upon a successful commit is by declaring a business event. For information on how to create a business event, see Creating Business Events.

Conditionally Preventing an Entity Row from Being Removed

Use the `remove()` method to control removal of an ADF entity row.

Before an entity row is removed, the `remove()` method is invoked on an entity row. You can throw a `JboException` in the `remove()` method to prevent a row from being removed if the appropriate conditions are not met.

For example, you can add a test in the `remove()` method that determines the state of the entity object and allows the removal only if it is a new record. The following example illustrates this technique.

Note:

The entity object offers declarative prevention of deleting a master entity row that has existing, composed children rows. You configure this option on the Relationship page of the overview editor for the association.

```
// In entity object custom Java class
private boolean isDeleteAllowed() {
    byte s = this.getEntityState();
  return s==STATUS_NEW;
}

/**
 * Add entity remove logic in this method.
 */
public void remove() {
  if (isDeleteAllowed())
    super.remove();
  else
      throw new JboException("Delete not allowed in this view");
}
```

Determining Conditional Updatability for Attributes

Check if a given ADF entity object attribute is `updateable` or not at runtime by overriding the `isAttributeUpdateable()` method in the entity object class.

You can override the `isAttributeUpdateable()` method in your entity object class to programmatically determine whether a given attribute is updatable or not at runtime based on appropriate conditions.

The following example shows how an entity object can override the `isAttributeUpdateable()` method to enforce that its `PersonTypeCode` attribute is updatable only if the current authenticated user is a staff member. Notice that when the entity object fires this method, it passes in the integer attribute index whose updatability is being considered.

You can implement conditional updatability logic for a particular attribute inside an `if` or `switch` statement based on the attribute index. Here `PERSONTYPECODE` is referencing the integer attribute index enums that JDeveloper maintains in your entity object custom Java class.

> **Note:**
>
> Entity-based view objects inherit this conditional updatability as they do everything else encapsulated in your entity objects. Should you need to implement this type of conditional updatability logic in a way that is specific to a transient view object attribute, or to enforce some condition that involves data from multiple entity objects participating in the view object, you can override this same method in a view object's view row class to achieve the desired result.

```
// In the entity object custom Java class
public boolean isAttributeUpdateable(int index) {
  if (index == PERSONTYPECODE) {
    if (!currentUserIsStaffMember()) {
      return super.isAttributeUpdateable(index);
    }
    return CUSTOMER_TYPE.equals(getPersonTypeCode()) ? false : true;
  }
  return super.isAttributeUpdateable(index);
}
```

Implementing Custom Validation Rules

ADF Business Components allows you to create custom validation rule classes that capture common validation code and use it along with built-in declarative validation rules.

ADF Business Components comes with a base set of built-in declarative validation rules that you can use. However, a powerful feature of the validator architecture for entity objects is that you can create your own custom validation rules. When you notice that you or your team are writing the same kind of validation code over and over, you can build a custom validation rule class that captures this common validation "pattern" in a parameterized way.

After you've defined a custom validation rule class, you can register it in JDeveloper so that it is as simple to use as any of the built-in rules. In fact, you can even bundle your custom validation rule with a custom UI panel that JDeveloper leverages to facilitate developers' using and configuring the parameters your validation rule might require.

How to Create a Custom Validation Rule

To write a custom validation rule for entity objects, you need a Java class that implements the `JboValidatorInterface` in the `oracle.jbo.rules` package. You can create a skeleton class from the New Gallery.

Before you begin:

It may be helpful to have an understanding of custom validation rules. For more information, see Implementing Custom Validation Rules.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Programmatic Business Rules.

To create a custom validator:

1. In the Applications window, right-click the project in which you want to create the validator and choose **New > From Gallery**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Validation Rule**, and click **OK**.
3. In the Create Validation Rule Class dialog, enter a name and package for the rule.
4. Enter a display name and a description, and click **OK**.

As shown in the following example, `JBOValidatorInterface` contains one main `validate()` method, and a getter and setter method for a `Description` property.

```
package oracle.jbo.rules;
public interface JboValidatorInterface {
  void validate(JboValidatorContext valCtx) { }
  java.lang.String getDescription() { }
  void setDescription(String description) { }
}
```

If the behavior of your validation rule will be parameterized to make it more flexible, then add additional bean properties to your validator class for each parameter. For example, the code in the following example implements a custom validation rule called `DateMustComeAfterRule` which validates that one date attribute must come after another date attribute. To allow the developer using the rule to configure the names of the date attributes to use as the initial and later dates for validation, this class defines two properties `initialDateAttrName` and `laterDateAttrName`.

The following example shows the code that implements the custom validation rule. It extends the `AbstractValidator` to inherit support for working with the entity object's custom message bundle, where JDeveloper saves the validation error message when a developer uses the rule in an entity object.

The `validate()` method of the validation rule gets invoked at runtime whenever the rule class should perform its functionality. The code performs the following basic steps:

1. Ensures validator is correctly attached at the entity level.
2. Gets the entity row being validated.
3. Gets the values of the initial and later date attributes.
4. Validate that initial date is before later date.
5. Throws an exception if the validation fails.

For easier reuse of your custom validation rules, you would typically package them into a JAR file for reference by applications that make use of the rules.

```
// package and imports omitted
public class DateMustComeAfterRule extends AbstractValidator
       implements JboValidatorInterface {
  /**
   * This method is invoked by the framework when the validator should do its job
   */
  public void validate(JboValidatorContext valCtx) {
    // 1. If validator is correctly attached at the entity level...
    if (validatorAttachedAtEntityLevel(valCtx)) {
      // 2. Get the entity row being validated
      EntityImpl eo = (EntityImpl)valCtx.getSource();
      // 3. Get the values of the initial and later date attributes
      Date initialDate = (Date) eo.getAttribute(getInitialDateAttrName());
      Date laterDate = (Date) eo.getAttribute(getLaterDateAttrName());
      // 4. Validate that initial date is before later date
      if (!validateValue(initialDate,laterDate)) {
        // 5. Throw the validation exception
        RulesBeanUtils.raiseException(getErrorMessageClass(),
                                      getErrorMsgId(),
                                      valCtx.getSource(),
                                      valCtx.getSourceType(),
                                      valCtx.getSourceFullName(),
                                      valCtx.getAttributeDef(),
                                      valCtx.getNewValue(),
                                      null, null);
      }
    }
    else {
      throw new RuntimeException("Rule must be at entity level");
    }
  }
  /**
   * Validate that the initialDate comes before the laterDate.
   */
  private boolean validateValue(Date initialDate, Date laterDate) {
    return (initialDate == null) || (laterDate == null) ||
    (initialDate.compareTo(laterDate) < 0);
  }
  /**
   * Return true if validator is attached to entity object
   * level at runtime.
   */
  private boolean validatorAttachedAtEntityLevel(JboValidatorContext ctx) {
    return ctx.getOldValue() instanceof EntityImpl;
  }
  // NOTE: Getter and Setter Methods omitted

How to Register and Use a Custom Rule in JDeveloper

After you've created a custom validation rule, you can add it to the project or application level in the JDeveloper IDE so that other developers can use the rule declaratively.

Registering a Custom Validator at the Project Level

When you register a custom validation rule at the project level, you can use it within the project.

Before you begin:

It may be helpful to have an understanding of custom validation rules. For more information, see Implementing Custom Validation Rules.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Programmatic Business Rules.

To register a custom validation rule, you must have already created it, as described in How to Create a Custom Validation Rule.

To register a custom validation rule in a project containing entity objects:

1. In the Applications window, right-click the project containing the entity objects and choose **Project Properties**.
2. In the Project Properties dialog, expand **ADF Business Components** and select **Registered Rules**.
3. On the Registered Rules page, click **Add**.
4. In the Register Validation Rule dialog, browse to find the validation rule you have created and click **OK**.

Registering a Custom Validator at the IDE Level

When you register a custom validation rule at the IDE level for JDeveloper, you can use it in other projects as well as your current project.

Before you begin:

It may be helpful to have an understanding of custom validation rules. For more information, see Implementing Custom Validation Rules.

You may also find it helpful to understand additional functionality that can be added using other validation features. For more information, see Additional Functionality for Programmatic Business Rules.

To register a custom validation rule, you must have already created it, as described in How to Create a Custom Validation Rule.

To register a custom validator at the IDE level:

1. From the main menu, choose **Tools > Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and select **Register Rules**.
3. From the Register Rules page, you can add a one or more validation rules.

   When adding a validation rule, provide the fully qualified name of the validation rule class, and supply a validation rule name that will appear in JDeveloper's list of available validators.

13
Implementing Business Services with Application Modules

This chapter describes how to create ADF application modules that encapsulate the data model of an Oracle ADF application derived from a JDBC data source. This chapter also describes how to combine business service methods with that data model to implement a complete business service.

This chapter includes the following sections:

About Application Modules

An ADF application module encapsulates end-user tasks as logical units of work. User interface clients use the application module to manage application data.

An **application module** is the transactional component that UI clients use to work with application data. The application module is an ADF business component that encapsulates the business service methods and data model for a logical unit of work related to an end-user task.

In the early phases of application development, architects and designers often use UML use case techniques, as well as **ADF task flows**, to create a high-level description of the application's planned end-user functionalities. Each high-level, end-user use case identified during the design phase typically depends on:

- The domain business objects involved. To answer the question, "What core business data is relevant to the use case?"
- The user-oriented view of business data required. To answer the questions, "What subset of columns, what filtered set of rows, sorted in what way, grouped in what way, is needed to support the use case?"

The identified domain objects involved in each use case help you identify the required **entity objects** from your business domain layer. The user-oriented view of the required business data helps to define the right SQL queries captured as view objects and to retrieve the data in the exact way needed by the end user. For best performance, this includes retrieving the minimum required details necessary to support the use case. In addition to leveraging **view object** queries and **view criteria** to shape the data, you've learned how to use a **view link** to set up a master-detail hierarchy in your data model to match exactly the kind of end-user experience you want to offer the user to accomplish the use case.

The application module is the "work unit" container that includes instances of the reusable view objects required for the use case in question. These view object instances are related through metadata to the underlying entity objects in your reusable business domain layer where the end-user use cases determine the information being presented or modified.

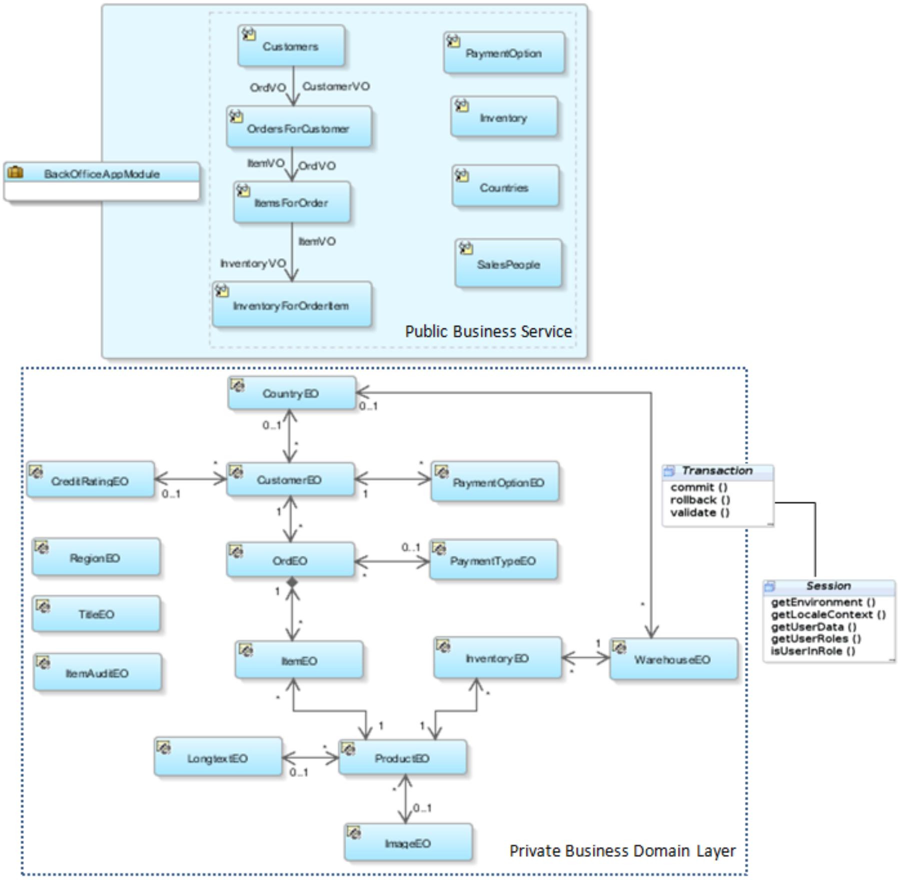
Application Module Use Cases and Examples

This chapter illustrates the following concepts illustrated in Figure 13-1, and more:

- You expose instances of view objects in an application module to define its data model.
- You write service methods to encapsulate task-level business logic.
- You expose selected methods on the client interface for UI clients to call.
- You expose selected methods on the service interface for programmatic use in application integration scenarios.

  Note that starting in release 12c, support for EJB Session Bean-enabled application modules in an **ADF Business Components** model project has been deprecated in Oracle JDeveloper. It is no longer possible to create or run EJB Session Bean-enabled application modules in JDeveloper. As an alternative for existing EJB Session Bean-enabled application modules, you may want to migrate application modules services to Web Service-enabled application modules, as described in Creating SOAP Web Services with Application Modules. This approach is consistent with the best practice for exposing service methods using external services.
- You use the **application module instance** from a pool during a logical transaction that can span multiple web pages or views.
- Your application module works with a `Transaction` object that acquires a database connection and coordinates saving or rolling back changes made to entity objects.
- The related `Session` object provides runtime information about the current application user.

Figure 13-1 Application Module Is a Business Service Component Encapsulating a Unit of Work



Additional Functionality for Application Modules

You may find it helpful to understand other **Oracle ADF** features before you start working with application modules. Following are links to other functionality that may be of interest.

- For details about creating **shared application module**s, see Sharing Application Module View Instances.
- For details about exposing ADF Business Components service methods using external services, see Creating SOAP Web Services with Application Modules.
- For details about how the **Data Controls panel** exposes the application module to UI developers, see Using ADF Model in a Fusion Web Application.
- For details about configuring application module instances to improve runtime performance, see Using State Management in a Fusion Web Application and Tuning Application Module Pools.
- For details about how to maximize the performance and scalability in the production environment, see the "Tuning Oracle Application Development Framework (ADF)" chapter in *Tuning Performance*.

- For a quick reference to the most common code that you will typically write, use, and override in your custom application module classes, see Most Commonly Used ADF Business Components Methods.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Creating and Modifying an Application Module

You create a single or multiple ADF application modules depending on the size of the application in terms of user tasks.

In a large application, you typically create one application module to support each coarse-grained end-user task. In a smaller-sized application, you may decide that creating a single application module is adequate to handle the needs of the complete set of application functionality. Defining Nested Application Modules provides additional guidance on this subject.

How to Create an Application Module

Any view object you create is a reusable component that can be used in the context of one or more application modules. Each view object performs the query it encapsulates in the context of that application module's transaction. The set of view object instances used by an application module defines its **data model**, in other words, the set of data that a client can display and manipulate through a user interface.

To add an application module to your existing ADF Business Components project, use the Create Application Module wizard, which is available in the New Gallery.

Before you begin:

It may be helpful to have an understanding of application modules. For more information, see Creating and Modifying an Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

> Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

To manually create an application module:

1. In the Applications window, right-click the project in which you want to create the application module and choose **New** and **Application Module**.
2. In the Create Application Module wizard, on the Name page, provide a package name and an application module name. Click **Next**.

> **Note:**
>
> In Fusion web applications, the reserved words `data`, `bindings`, `security`, and `adfContext` must not be used to name your application module. Also, avoid using the "_" (underscore) at the beginning of the name. For more information, see How to Edit an Existing Application Module.

3. On the Data Model page, include instances of the view objects you have previously defined and edit the view object instance names to be exactly what you want clients to see in the Data Controls panel. Then click **Next**.
4. On the Java page, you can optionally generate the Java files that allow you to programmatically customize the behavior of the application module or to expose methods on the application module's client interface that can be called by clients. To generate an XML-only application module component, leave the fields unselected and click **Finish**.

   Initially, you may want to generate only the application module XML definition component. After you complete the wizard, you can subsequently use the overview editor to generate the application module class files when you require programmatic access. For details about the programmatic use of the application module, see Customizing an Application Module with Service Methods.

For more step by step details, see Adding Master-Detail View Object Instances to an Application Module.

What Happens When You Create an Application Module

When you create an application module, JDeveloper creates the XML document file that represents its declarative settings and saves it in the directory that corresponds to the name of its package. For example, in the Summit ADF sample application the application module named `BackOfficeAppModule` in the `summit.model` package has the XML file `./summit/model/BackOfficeAppModule.xml` under the project's source path. This XML file contains the information needed at runtime to re-create the view object instances in the application module's data model.

If you are curious to view its contents, you can see the XML file for the application module by double-clicking the application module node in the Applications window to open the overview editor. In the editor window, click the **Source** tab to view the XML so that you can inspect it. The Structure window shows the structure of the XML file.

When you create business components, JDeveloper automatically creates a data control that contains all the functionality of the application module. **Data controls** are an ADF Model abstraction layer that provides supplemental metadata to describe the application module's operations and data collections (row sets of view object instances), including information about the attributes, methods, and types involved. Developers can then use the representation of the data control displayed in JDeveloper's **Data Controls panel** to create UI components that are automatically bound to the application module. At runtime, the **ADF Model** layer reads the metadata describing the data controls and bindings from appropriate XML files and implements the two-way connection between the user interface and the business service.

For example, the `BackOfficeAppModule` application module implements the business service layer of the `SummitADF` application workspace. Its data model contains numerous view object instances, including several master-detail hierarchies. The view layer of the core Summit ADF sample application consists of JSF pages whose UI components are bound to data from the view object instances in the `BackOfficeAppModule`'s data model, and to built-in operations and service methods on its client interface. For details about how the Data Controls panel exposes the application module to UI developers, see Exposing Application Modules with ADF Data Controls.

How to Add a View Object Instance to an Application Module

You can add a view object instance to an application module as you create the application module with the Create Application Module wizard, or you can add it later to an already created application module.

For information about using the Create Application Module wizard, see How to Create an Application Module.

Adding a View Object Instance to an Existing Application Module

You can add a view object instance to an application module that you have already created. To add a view object instance to an existing application module, and optionally, customize the view object instance, use the Data Model page of the overview editor for the application module.

Before you begin:

It may be helpful to have an understanding of application modules. For more information, see Creating and Modifying an Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.

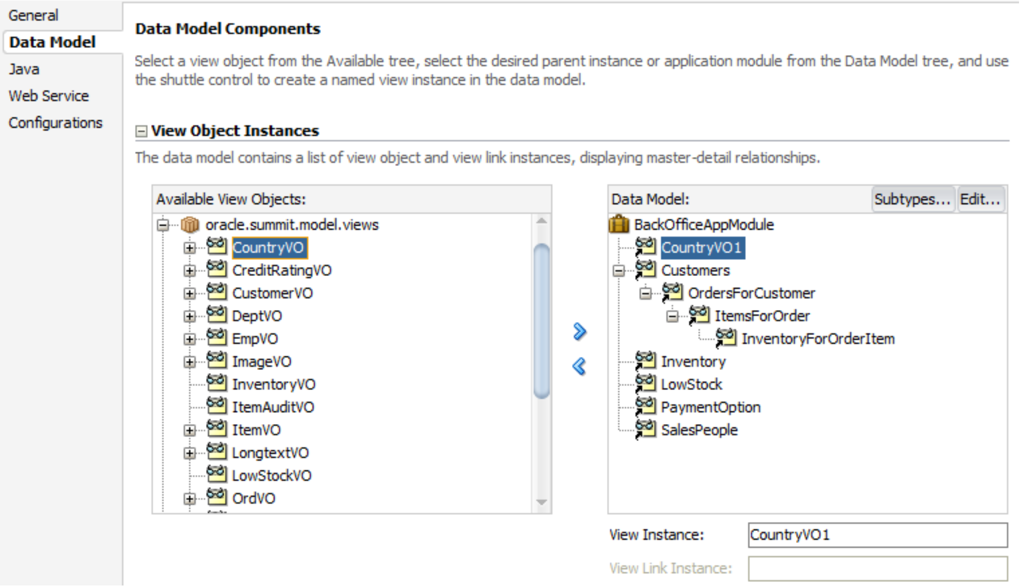
To add a view object instance to an existing application module:

1. In the Applications window, double-click the application module for which you want to define a new view instance.
2. In the overview editor, click the **Data Model** navigation tab.
3. On the Data Model Components page, expand the **View Object Instances** section and, in the **Available View Objects** list, select the view object you want to add.

   The **New View Instance** field below the list shows the name that will be used to identify the next instance of that view object that you add to the data model.
4. With the desired view object selected, shuttle the view object to the **Data Model** list.

   For example, Figure 13-2 shows the `CountryVO` view object in the `SummitADF` workspace shuttled to the data model, where it appears as `CountryVO1`.

Figure 13-2   Data Model Displays Added View Instances



Data Model Components

Select a view object from the Available tree, select the desired parent instance or application module from the Data Model tree, and use the shuttle control to create a named view instance in the data model.

View Object Instances

The data model contains a list of view object and view link instances, displaying master-detail relationships.

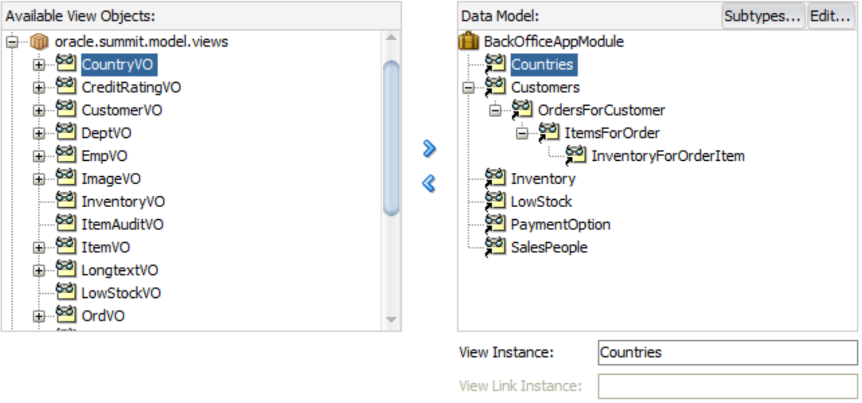
View Instance: CountryVO1

View Link Instance:

5. To change the name of the newly created view instance, enter a different name in the **New View Instance** field.

   For example, you might change the view instance name `CountryVO1` to `Countries`, as shown in Figure 13-3.

Figure 13-3   Overview Editor Displays View Instance Renamed



View Instance: Countries

View Link Instance:

Adding Master-Detail View Object Instances to an Application Module

You can use the data model that the application module overview editor displays to create a hierarchy of view instances, based on existing view links that your project defines. If you have defined view links that establish more than one level of master-detail hierarchy, then you can proceed to create as many levels of master-detail view instances as your application supports.

Before you begin:

It may be helpful to have an understanding of application modules. For more information, see Creating and Modifying an Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

> Create hierarchical relationships between view objects, as described in Working with Multiple Tables in a Master-Detail Hierarchy.

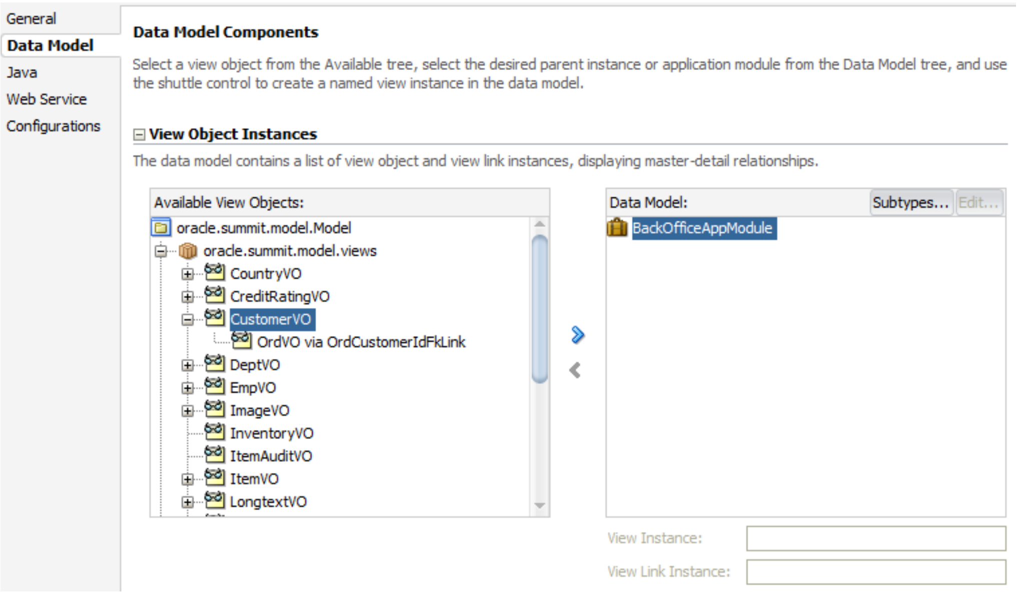
To add master-detail view object instances to a data model:

1. In the Applications window, double-click the application module for which you want to define a new master-detail view instances.
2. In the overview editor, click the **Data Model** navigation tab.
3. On the Data Model Components page, expand the **View Object Instances** section and, in the **Available View Objects** list, select the instance of the view object that you want to be the actively coordinating master.

   The master view object will appear with a plus sign in the list indicating the available view links for this view object. The view link must exist to define a master-detail hierarchy.

   For example, the `SummitADF` workspace of the Summit ADF sample application contains the master view object `CustomerVO` and detail view object `OrdVO` related by the view link `OrdCustomerIdFkLink`. To view the master-detail hierarchy in the **Available View Objects** list, you would expand `CountryVO`, as shown in Figure 13-4.

   Figure 13-4 Master View Object Selected



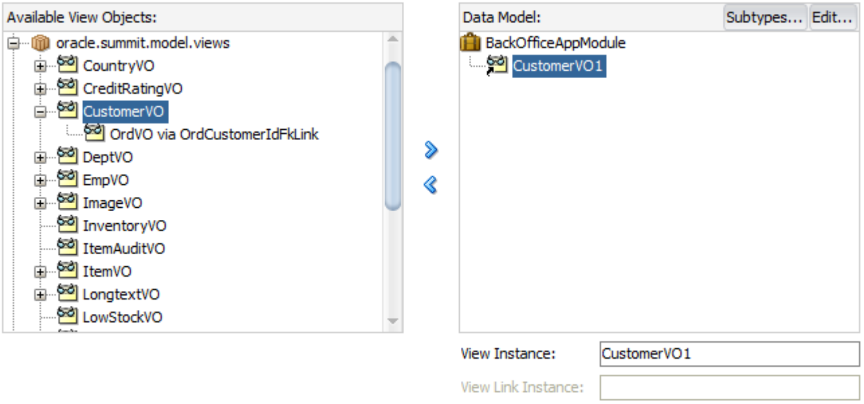
Select a view object from the Available tree, select the desired parent instance or application module from the Data Model tree, and use the shuttle control to create a named view instance in the data model.

The data model contains a list of view object and view link instances, displaying master-detail relationships.

4. Shuttle the selected master view object to the **Data Model** list.

   For example, you might shuttle the master view object `CustomerVO` to the data model, where it receives the view instance name `CustomerVO1`, as shown in Figure 13-5.

Figure 13-5 Master View Instance Created

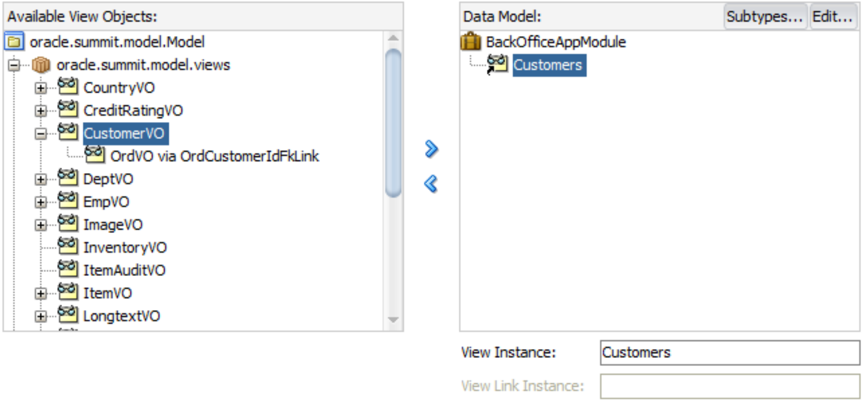


View Instance: CustomerVO1

5. To change the name of the newly created master view instance, enter a different name in the **View Instance** field.

   For example, you might change the view instance name `CustomerVO1` to `Customers`, as shown in Figure 13-6.

Figure 13-6 Overview Editor Displays View Instance Renamed

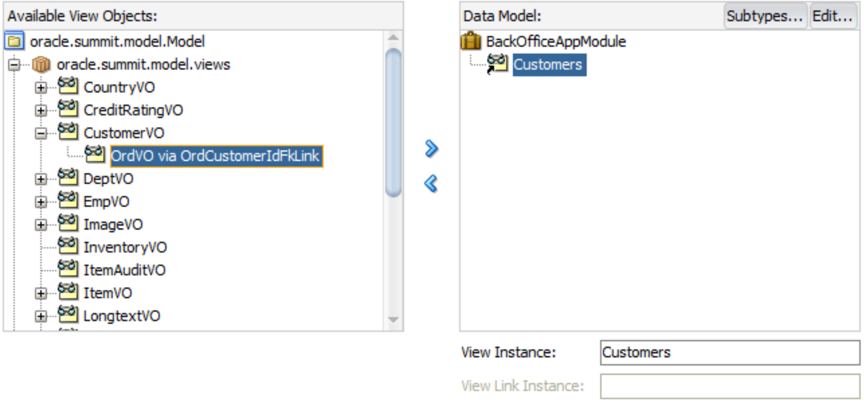


View Instance: Customers

6. In the **Data Model** list, leave the newly created master view instance selected so that it appears highlighted. This will be the target of the detail view instance you will add. Then locate and select the detail view object beneath the master view object in the **Available View Objects** list.

   For example, Figure 13-7 shows the detail `OrdVO` indented beneath master `CustomerVO` with the name `OrdVO via OrdCustomerIdFkLink`. The name identifies the view link `OrdCustomerIdFkLink`, which defines the master-detail hierarchy between `CustomerVO` and `OrdVO`. Notice also that `OrdVO` will have the view instance name `OrdersForCustomers` when added to the data model.

Figure 13-7   Detail View Object Selected



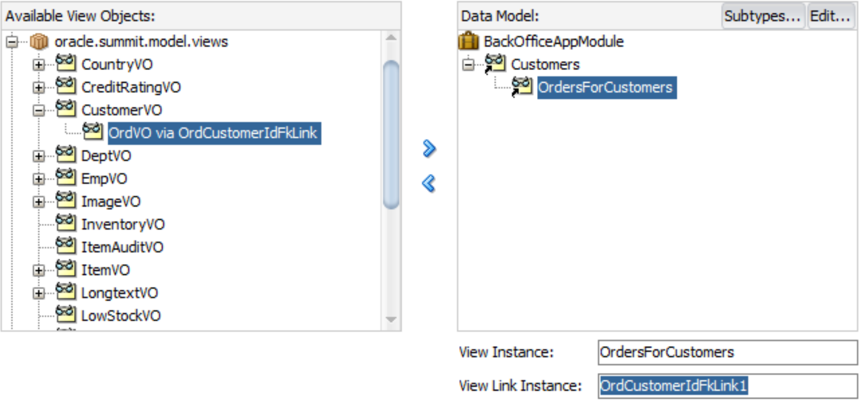
View Instance: Customers

View Link Instance:

7. To add the detail instance to the previously added master instance, shuttle the detail view object to the **Data Model** list below the selected master view instance and rename the view instance.

   For example, you might shuttle `OrdVO via OrdCustomerIdFkLink` to the data model beneath the selected master view instance `Customers`, as shown in Figure 13-8.

Figure 13-8   Detail View Instance Created and Renamed



View Instance: OrdersForCustomers

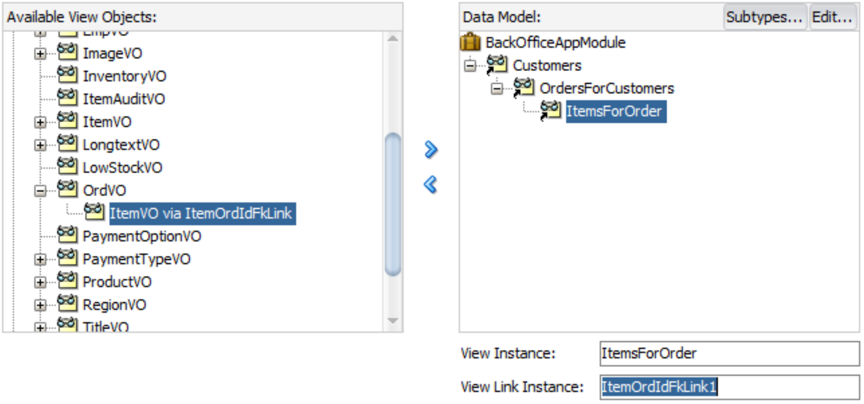
View Link Instance: OrdCustomerIdFkLink1

8. To add another level of hierarchy, repeat Step 3 through Step 6, but select the newly added detail in the **Data Model** list, then shuttle over the new detail, which itself has a master-detail relationship with the previously added detail instance.

   For example, the `SummitADF` workspace contains the view object `ItemVO via ItemOrdIdFkLink` which is a detail of the `OrdVO` view object, which is itself a detail of the master view object `CustomerVO`.

   To create the master-detail-detail data model hierarchy, you might shuttle the detail view object `ItemVO via ItemOrdIdFkLink` to the data model beneath the view instance `OrdersForCustomers` (renamed from `OrdVO1`) and rename the new detail view instance `ItemsForOrder`, as shown in Figure 13-9. In the **Data Model** list the view instance `Customers` (renamed from `CustomerVO1`) is the master of `OrdersForCustomer` (renamed from `OrdVO1`), which is, in turn, a master of `ItemsForOrder` (renamed from `ItemVO1`).

Figure 13-9   Master-Detail-Detail Hierarchy Created



View Instance: ItemsForOrder

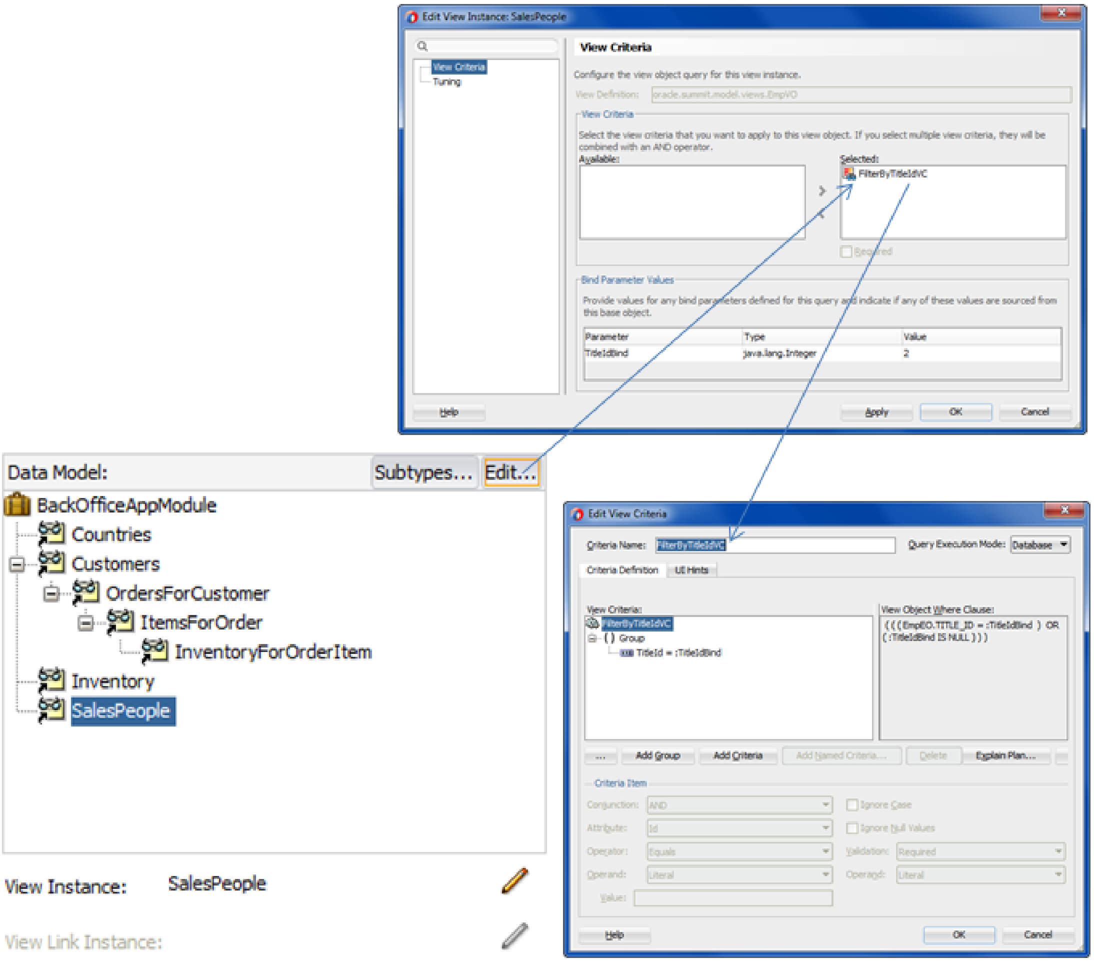
View Link Instance: ItemOrdIdFkLink1

Customizing a View Object Instance that You Add to an Application Module

You can optionally customize the view object instance by using the Data Model Components page of the overview editor for the application module. For example, you might want to apply a filter to set the controlling attribute for a master-detail view object relationship.

For example, in the `SummitADF` workspace of the Summit ADF sample application, the view instance `SalesPeople` has been defined for the `BackOfficeAppModule` application module and a view criteria `FilterByTitleIdVC` has been defined for this view instance that filters the sales staff by a title. Figure 13-10 shows the Edit View Instance dialog opened for the `SalesPeople` view instance with the `FilterByTitleIdVC` selected. The bind variable `TitleIdBind` defines a default value of 2, which sets the value of the `TitleId` attribute, as the controlling attribute for the `SalesPeople` view instance. The controlling attribute, when set by the view criteria filter, provides a way to retrieve only the view rows for the matching ID.

Figure 13-10 Customized View Object Instance Using a View Criteria FIlter



Edit View Instance: SalesPeople

View Criteria

Configure the view object query for this view instance.

View Definition: oracle.summit.model.views.EmpVO

Select the view criteria that you want to apply to this view object. If you select multiple view criteria, they will be combined with an AND operator.

Selected: FilterByTitleIdVC

□ Required

Provide values for any bind parameters defined for this query and indicate if any of these values are sourced from this base object.

Parameter	Type	Value
TitleIdBind	java.lang.Integer	2

Data Model:

View Instance: SalesPeople

View Link Instance:

Edit View Criteria

Criteria Name: FilterByTitleIdVC

Query Execution Mode: Database

View Criteria:

```
FilterByTitleIdVC
  ( ) Group
      TitleId = :TitleIdBind
```

View Object Where Clause:

```
( ( ( EmpEO.TITLE_ID = :TitleIdBind ) OR
( :TitleIdBind IS NULL ) ) )
```

Conjunction: AND

Attribute: Id

Operator: Equals

Operand: Literal

Value:

□ Ignore Case

□ Ignore Null Values

Validation: Required

Operand: Literal

Before you begin:

It may be helpful to have an understanding of application modules. For more information, see Creating and Modifying an Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

To customize a view object instance that you add to an existing application module:

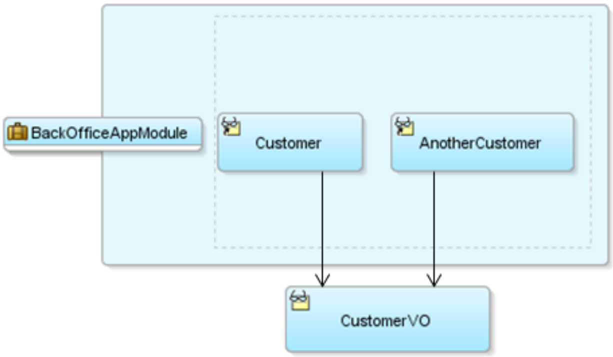
1. In the Applications window, double-click the application module for which you want to customize an existing view instance.
2. In the overview editor, click the **Data Model** navigation tab.
3. On the Data Model Components page, expand the **View Object Instances** section and, in the **Data Model** list, select the view object instance you want to customize and click the **Edit** button.
4. In the Edit View Instance dialog, perform any of the following steps, and then click **OK**.

- In the **View Criteria** group box, select one or more view criteria that you want to apply to the view object instance. The view criteria will be appended as a `WHERE` clause to the instance query. For details about defining view criteria, see Working with Named View Criteria.
- In the **View Criteria** group box, for each view criteria that you add to the **Selected** list, you may define one or more view criteria as mandatory filters on the view instance. Select the **Required** checkbox for the currently selected view criteria when it should remain applied on the view instance at all times. Normally, when multiple view criteria are applied to a view instance, one will be the default view criteria and should remain applied at all times. Mandatory view criteria, will remain applied on the view criteria list even when the application programmatically applies view criteria (using `applyViewCriteria()` for example).
- In the **Bind Parameters Values** group box, enter any values that you wish the instance to use when applying the defined view criteria. For more information about defining bind variables, see Working with Bind Variables.

What Happens When You Add a View Object Instance to an Application Module

You add instances of view object components to define the data model of an application module. Figure 13-11 shows a JDeveloper business components diagram of a `BackOfficeAppModule` application module that appears in the SummitADF workspace of the Summit sample application.

Figure 13-11 Application Module Containing Two Instances of a View Object Component



The sample application module contains two instances of the `CustomerVO` view object component, with member names of `Customer` and `AnotherCustomer` to distinguish them. At runtime, both instances share the same `CustomerVO` view object component definition—this ensures that they have the same attribute structure and view object behavior—however, each might be used independently to retrieve data about different users. For example, some of the runtime properties, like an additional filtering `WHERE` clause or the value of a bind variable, might be different on the two distinct instances.

The following example shows how the `BackOfficeAppModule` application module defines its member view object instances in its XML document file.

```
<AppModule
   Name="BackOfficeAppModule"
   ...>
   <ViewUsage
      Name="Customer"
      ViewObjectName="oracle.summit.model.appmodule.CustomerVO"/>
   <ViewUsage
      Name="AnotherCustomer"
      ViewObjectName="oracle.summit.model.appmodule.CustomerVO"/>
</AppModule>
```

How to Edit an Existing Application Module

After you've created a new application module, you can edit any of its settings by using the Edit Application Module dialog. To launch the editor, in the Applications window, right-click the application module node and choose **Open**, or double-click the application module. By visiting the different pages of the editor, you can adjust the data model to determine whether or not to reference nested application modules, specify Java generation settings, client interface methods, runtime instantiation behavior, and custom properties.

If you edit the name of your application module, choose a name that is not among the reserved words that Oracle Application Development Framework (Oracle ADF) defines. In particular, reserved words are not valid for a data control usage name which JDeveloper automatically assigns based on your application module's name. In Fusion web applications, these reserved words consist of `data`, `bindings`, `security`, and `adfContext`. For example, you should not name an application module `data`. If JDeveloper creates a data control usage with an ID that collides with a reserved word, your application may not reliably access your data control objects at runtime and may fail with a runtime `ClassCastException`.

Do not name the application module with an initial underscore (_) character to prevent a potential name collision with a wider list of reserved words that begin with the underscore.

Application module names that incorporate a reserved word into their name (or that change the case of the reserved word) will not conflict. For example, `Product_Data`, `Product_data`, or just `Data` are all valid application module names since the whole name does not match the reserved word `data`.

How to Change the Data Control Name Before You Begin Building Pages

By default, an application module will appear in the Data Controls panel as an **application module data control** named *`AppModuleName`*`DataControl`. The user interface designer uses the Data Controls panel to bind data from the application module to the application's web pages. For example, if the application module is named `SummitAppModule`, the Data Controls panel will display the data control with the name `SummitAppModuleDataControl`. You can change the default data control name to make it shorter or to supply a more preferable name.

When the user interface designer works with the data control, they will see the data control name for your application module in the `DataBindings.cpx` file in the user interface project and in each data binding page definition XML file. In addition, you might refer to the data control name in code when needing to work programmatically with the application module service interface. For this reason, if you plan to change the name of your application module, do this change before you begin building your view layer.

For complete information about the application module data control, see Using ADF Model in a Fusion Web Application.

> **Note:**
>
> If you decide to change the application module's data control name after you have already referenced it in one or more pages, you will need to open the **page definition files** and `DataBindings.cpx` file where it is referenced and update the old name to the new name manually.

To change the application module data control name:

1. In the Applications window, double-click the application module for which you want to edit the data control name.
2. In the Properties window, expand the **Other** section, and enter your preferred data control name in the **Data Control Name** field.

What You May Need to Know About Application Module Granularity

A common question related to application modules is, "How big should my application module be?" In other words, "Should I build one big application module to contain the entire data model for my enterprise application, or many smaller application modules that allow me to compartmentalize the application according to functionality?" The answer depends on your situation.

In general, application modules should be as big as necessary to support the specific use case you have in mind for them to accomplish. They can be assembled from finer-grained application module components using a nesting feature, as described in Defining Nested Application Modules. Since a complex business application is not really a single use case, a complex business application implemented using Oracle ADF will typically not be just a single application module.

In actual practice, you may choose any granularity you wish to support the type of modularization you require. For example, the need to support disparate data sources or the need to configure separate tuning options are both legitimate cases for creating multiple application modules. Or, in a small application with one main use case and a "backend" supporting use case, you might create two application modules. However, for the sake of simplicity you can combine both use cases, rather than create a second application module that contains just a couple of view objects.

Other situations may dictate creating more than one **root application module**. For example, if you need to support more than one transaction per user session, you can create multiple application modules. Alternatively, you can work with data control scope and task flows to manage transactions, as described in Managing Transactions in Task Flows.

What You May Need to Know About View Object Components and View Object Instances

While designing an application module, you use instances of a view object component to define its data model. Just as the user interface may contain two instances of a `Button` component with member names of `myButton` and `anotherButton` to distinguish them, your application module contains two instances of the `CustomerVO` view object component, with member names of `CustomerList` and `AnotherCustomerList` to distinguish them.

Configuring Your Application Module Database Connection

JDeveloper allows you to modify JDBC data source definition for each ADF application module as an alternative to using the default runtime JDBC data source connection for all application modules.

When you initialize your data model project to use ADF Business Components, JDeveloper prompts you to supply database connection details. You must specify a database connection before you can run ADF Business Components wizards and work with the database's tables and views to create business components. After you specify the connection details, JDeveloper also creates a Java Database Connectivity (JDBC) data source that will be used as the default runtime connection for all application modules created in the current project.

You can use the overview editor for application module configurations (on the `bc4j.xcfg` file) to change the JDBC data source definition for each application module individually. To display the application module configuration overview editor, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink. In cases where you do not want to use a data source, you also use the overview editor to replace the connection type for individual application modules with a JDBC URL connection type.

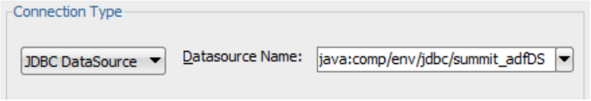
You can use either the JDBC data source or the JDBC URL connection type to run the application module in any context where Java can run. Your application is not restricted to running inside a Java Enterprise Edition (Java EE) application server. For example, although the Oracle ADF Model Tester is a standalone Java tool and does not run within the context of a Java EE application server, you can use either connection type to test your business components in the Oracle ADF Model Tester. You can use the application module configurations overview editor to select among both connection types for the existing application resource connections that appear in the Databases window.

JDeveloper configures the application module by default to use the data source connection type. A JDBC data source is a vendor-independent encapsulation of a database server connection. The JDBC data source offers advantages that the JDBC URL connection type does not. When you define a connection type based on a data source, you reconfigure the data source without changing the deployed application. The data source is also centrally defined at the application server level, whereas JDBC URL connections are not. In cases where a JDBC data source is not viable, at runtime, ADF Business Components will construct a default JDBC URL based on the data source connection information.

How to Use a JDBC Data Source Connection Type

The type of connection all default application module configurations use is a JDBC data source. You define a JDBC data source as part of your application server configuration information, and then the application module looks up the resource at runtime using a logical name. When you use the JDBC data source as the connection type, your application resource connection details may change, and you will not need to change the deployed application module configuration. For this reason the JDBC data source is the recommended choice for all application module configurations. Figure 13-12 shows how the default selection appears in the overview editor for application module configurations (on the `bc4j.xcfg` file). To display the application module configuration overview editor, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink.

Figure 13-12 JDBC DataSource Connection Type Setting



JDBC DataSource
Datasource Name: java:comp/env/jdbc/summit_adfDS

> **Note:**
>
> The other type of connection type displayed in the Connection Type dropdown is a JDBC URL connection. This connection type is supported for legacy applications and should not be used instead of the JDBC data source connection type.

The following example shows the `<resource-ref>` tags in the `web.xml` file of a Fusion web application. These define two logical data sources named `jdbc/Summit_adfDS` and `jdbc/Summit_adfCoreDS`. The application module configurations overview editor references this logical connection name after the prefix `java:comp/env` in the **Datasource Name** field. For example, the JDBC data source name for the same Fusion web application would display the value `java:comp/env/jdbc/summit_adfDS` that you can select. Therefore the **Datasource Name** field is prepopulated with the JNDI name for all available application resources connection names.

```
<!-- In web.xml -->
<resource-ref>
  <res-ref-name>jdbc/summit_adfDS</res-ref-name>
  <res-type>javax.sql.DataSource</res-type>
  <res-auth>Container</res-auth>
</resource-ref>
<resource-ref>
  <res-ref-name>jdbc/summit_adfCoreDS</res-ref-name>
  <res-type>javax.sql.DataSource</res-type>
  <res-auth>Container</res-auth>
</resource-ref>
```

You can directly edit the **Datasource Name** field when you want to specify a connection name for a global data source that is required to run the application on a target standalone application server. When you deploy to Oracle WebLogic Server, by default, the application-specific data source is not packaged with the application and Oracle WebLogic Server is configured to find a global data source named `jdbc/`*`applicationConnectName`*`DS` using the look up `java:comp/env/jdbc/`*`applicationConnectName`*`DS`. Therefore, by following this naming convention, you enable a single data source connection name to work correctly when running the application in JDeveloper using an application-specific data source or when running on the deployed standalone server using a global data source.

> **Note:**
>
> When configuring the ADF application module to access a highly available database system, such as redundant databases or Oracle Real Application Clusters (Oracle RAC) as the backend, the data source must be container-defined. In this scenario, the application module will use a multi data source; however, from the standpoint of the application module configuration, the naming convention for the multi data source is the same as it is for an non-multi data source. This ensures that the correct data source will be used at runtime. For details about configuring multi data sources for high availability applications, see Multi Data Sources in the *High Availability Guide*.

What Happens When You Create an Application Module Database Connection

When you select connection type in the Edit Configuration dialog, JDeveloper updates the application module configuration file, `bc4j.xcfg` in the `./common` subdirectory relative to the application module's XML document. The file defines configurations for all of the application modules in a single Java package. The `bc4j.xcfg` file does not appear in the Applications window. To view the `bc4j.xcfg` file in JDeveloper, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink.

For example, if you open the overview editor for application module configurations (on the `bc4j.xcfg` file) for the `SummitAppModule` application module in the `./classes/oracle/summit/model/services/common` directory of the core Summit ADF sample application's `Model` project, you will see the named configurations for this application module.

The configurations defined by the `bc4j.xcfg` file allow the Fusion web application to interact with specific, deployed application modules. In addition to the connection type for the application module, the `bc4j.xcfg` file contains metadata information about application module names and it contains the runtime parameters that are configured for the application module. The application resource database connection details for the named connection type are defined in the Connections node of the Applications window and saved in the application's `connections.xml` file.

The following example displays a sample `bc4j.xcfg` file from the core Summit ADF sample application. The configurations `SummitAppModuleLocal` and `SummitAppModule` both reference a data source (named `Summit_adfDS`) in the `JDBCDataSource` attribute.

The `JDBCDataSource` attribute in each configuration specifies the JNDI name for the application resources connection name in the form of `java:comp/env/jdbc/`*`applicationConnectName`*`DS`, where *`applicationConnectName`* is the name of the application resources database connection defined in JDeveloper (in this case, `Summit_adf`). This JNDI naming convention (with the application-specific name space `java:comp/env/jdbc/` and `DS` appended to the application resources database connection name) ensures that a deployed Fusion web application will run on Oracle WebLogic Server using the application's global data source and no changes will be required. The global data source is typically defined by the application server administrator using the Oracle WebLogic Server Administration Console.

```
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
   <AppModuleConfigBag 
ApplicationName="oracle.summit.model.services.SummitAppModule">
      <AppModuleConfig name="SummitAppModuleLocal"
                       DeployPlatform="LOCAL"
                       JDBCName="summit_adf"
                       jbo.project="oracle.summit.model.Model"

java.naming.factory.initial="oracle.jbo.common.JboInitialContextFactory"

ApplicationName="oracle.summit.model.services.SummitAppModule">
         <Database jbo.TypeMapEntries="Java"/>
         <Security 
AppModuleJndiName="oracle.summit.model.services.SummitAppModule"/>
         <Custom ns0:JDBCDataSource="java:comp/env/jdbc/summit_adfDS"
                                     xmlns:ns0="http://xmlns.oracle.com/bc4j/
configuration"/>
      </AppModuleConfig>
      ...
   </AppModuleConfigBag>
</BC4JConfig>
```

How to Change Your Application Module's Runtime Configuration

In addition to creating the application module XML definition, JDeveloper also adds a default configuration named *`appModuleName`*`Local` to the `bc4j.xcfg` file in the subdirectory named `common`, relative to the directory containing the application module XML definition file. The `bc4j.xcfg` file does not appear in the Applications window. To view the `bc4j.xcfg` file in JDeveloper, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink. To view the default settings or to change the application module's runtime configuration settings, select the **Database and Scalablity** tab in the overview editor and make the desired changes.

Before you begin:

It may be helpful to have an understanding of application module database connections. For more information, see Configuring Your Application Module Database Connection.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

To manage your application module's configuration:

1. In the Applications window, double-click the application module for which you want to edit the configuration.
2. In the overview editor, click the **Configurations** navigation tab.
3. In the Configurations page, click the configuration hyperlink that you want to edit.

   The Configuration page may display these three default configurations:

   - `*appModuleName*Local`: One local configuration is automatically defined when you create the application module. Create a new local configuration, for example, when you want to change the runtime properties for the application module for testing purposes.
   - `*appModuleName*Shared`: The shared application module configuration is present only when a named instance of a shared application module has been defined in the Project Properties dialog for the data model project. A shared application module is one that groups view instances when you want to reuse lists of static data across the application. For example, you can define a shared application module to group view instances that access lookup data, such as a list of countries.
   - `*appModuleName*Service` (type SI for service interface): The service interface configuration is present only when the service interface (web service implementation wrapper) has been defined in the Service Interface page of the overview editor for the application module. An application module exposed as a web service allows your application module to participate in a composite application to provide data access and method calls to web service clients. The same application module can support interactive web user interfaces using ADF data controls and web service clients.
4. In the overview editor for application module configurations (on the `bc4j.xcfg` file), click the **Database and Scalability** tab to customize the desired runtime properties and save the changes.

How to Change the Database Connection for Your Project

When you are developing applications, you may have a number of different users or schemas that you want to switch between. You can do this by changing the database connection properties of the project that contains the business components. The selection you make will automatically update the connection string for each configuration in your project's `bc4j.xcfg` file that specifies a JDBC URL type connection.

Before you begin:

It may be helpful to have an understanding of application module database connections. For more information, see Configuring Your Application Module Database Connection.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

To change the connection used by your application module's configuration:

1. In the Applications window, right-click the project that contains the application module and choose **Project Properties**.

2. In the Project Properties dialog, select **ADF Business Components** and from the **Connection** dropdown list, choose the desired connection and then click the **Edit** icon.
3. In the Edit Database Connection dialog, make the appropriate changes.
4. Click **OK**.

Defining Nested Application Modules

JDeveloper allows you to create composite ADF application modules by way of application module nesting. This allows a higher application module to use the inner application module’s function.

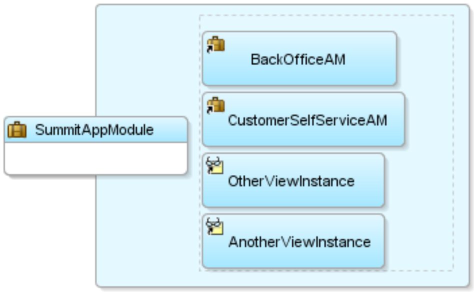
Application modules support the ability to create software components that mimic the modularity of your use cases, for which your higher-level functions might reuse a "subfunction" that is common to several business work flows. You can implement this modularity by defining composite application modules that you assemble using instances of other application modules. This task is referred to as **application module nesting**. That is, an application module can contain (logically) one or more other application module instances, as well as view object instances. The outermost containing application module is referred to as the **root application module**.

Declarative support for defining nested application modules is available through the overview editor for the application module, as shown in Figure 13-14. The API for application modules also supports nesting of application modules at runtime.

When you nest an instance of one application module inside another, you aggregate not only the view object instances in its data model, but also any custom service methods it defines. This feature of "nesting," or reusing, an instance of one application module inside of another is an important design aspect of ADF Business Components for implementing larger-scale, real-world application systems.

Considering that an application module represents an end-user use case or work flow, you can build application modules that cater to the data required by some shared, modular use case, and then reuse those application modules inside of other more complicated application modules that are designed to support a more complex use case. For example, imagine that after creating the application modules `BackOfficeAM` and `CustomerSelfServiceAM`, you later need to build an application that uses both of these services as an integral part of a new composite service application module. Figure 13-13 illustrates what this composite service would look like in a JDeveloper business components diagram. Notice that an application module like `SummitAppModule` can contain a combination of view object instances and application module instances.

Figure 13-13   Application Module Instances Can Be Reused to Assemble Composite Services



How to Define a Nested Application Module

To specify a composite root application module that nests an instance of an existing application module, use the overview editor for the application module. All of the nested component instances (contained by the application module instance) share the same transaction and entity object caches as the root application module that reuses an instance of them.

For example, in the `SummitADF` workspace of the Summit ADF sample application, the nested application module instances `BackOfficeAM` and `CustomerSelfServiceAM` share the same transaction and entity object caches as the root application module `SummitAppModule`.

> **Tip:**
>
> If you leverage nested application modules in your application, be sure to read How Nested Application Modules Appear in the Data Controls Panel to avoid common pitfalls when performing data binding involving them.

Before you begin:

It may be helpful to have an understanding of nested application modules. For more information, see Defining Nested Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

Create the desired application modules, as described in How to Create an Application Module.

To define a nested application module:

1. In the Applications window, double-click the root application module for which you want to define a nested application module.
2. In overview editor, click the **Data Model** navigation tab.

3. In the Data Model Components page, expand the **Application Module Instances** section and, in the **Available** list, select the application module that you want to add to the data model.

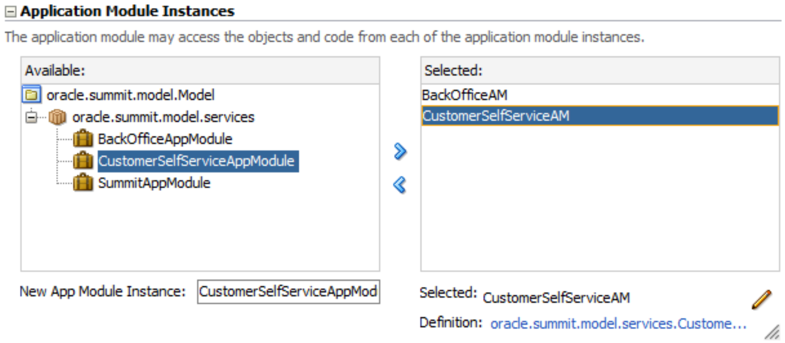
   The **New App Module Instance** field below the list shows the name that will be used to identify the nested application module that you add to the data model.

4. To change the name before adding it, type a different name in the **New App Module Instance** field.

5. With the desired application module selected, shuttle the application module to the **Selected** list.

   For example, in the `SummitADF` workspace of the Summit ADF sample application, the `SummitAppModule` application module defines two nested application module instances: `BackOfficeAM` and `CustomerSelfServiceAM`. Figure 13-14 shows the application module instances `BackOfficeAM` and `CustomerSelfServiceAM` have been added to the **Selected** list.

Figure 13-14 Data Model Displays Added Application Module Instances



⊟ Application Module Instances

The application module may access the objects and code from each of the application module instances.

Available:
- oracle.summit.model.Model
- oracle.summit.model.services
  - BackOfficeAppModule
  - CustomerSelfServiceAppModule
  - SummitAppModule

Selected:
- BackOfficeAM
- CustomerSelfServiceAM

New App Module Instance: CustomerSelfServiceAppMod

Selected: CustomerSelfServiceAM

Definition: oracle.summit.model.services.Custome...

What You May Need to Know About Root Application Modules Versus Nested Application Module Usages

At runtime, your application works with a *main* — or what's known as a *root* — application module. Any application module can be used as a root application module; however, in practice the application modules that are used as root application modules are the ones that map to more complex end-user use cases, assuming you're not just building a straightforward CRUD application. When a root application module contains other nested application modules, they all participate in the root application module's transaction and share the same database connection and a single set of entity caches. This sharing is handled for you automatically by the root application module and its `Transaction` object.

Additionally, when you construct an application using an **ADF bounded task flow**, to declaratively manage the transactional boundaries, Oracle ADF will automatically nest application modules used by the task flow at runtime. For details about bounded task flows and transactions, see Managing Transactions in Task Flows.

Creating an Application Module Diagram for Your Business Service

You can create an ADF Application Module UML diagram that can be referenced by other users. Use the diagram to modify Application Module details.

As you develop the business service's data model, it is often convenient to be able to visualize it using a UML model. JDeveloper supports easily creating a diagram for your application module that other developers can use for reference.

You can perform a number of tasks directly on the diagram, such as editing the application module, controlling display options, filtering methods names, showing related objects and files, publishing the application, and launching the Oracle ADF Model Tester.

How to Create an Application Module Diagram

To create an application module diagram, use the Create Business Components Diagram dialog, which is available in the New Gallery.

Before you begin:

It may be helpful to have an understanding of the UML model diagram For more information, see Creating an Application Module Diagram for Your Business Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

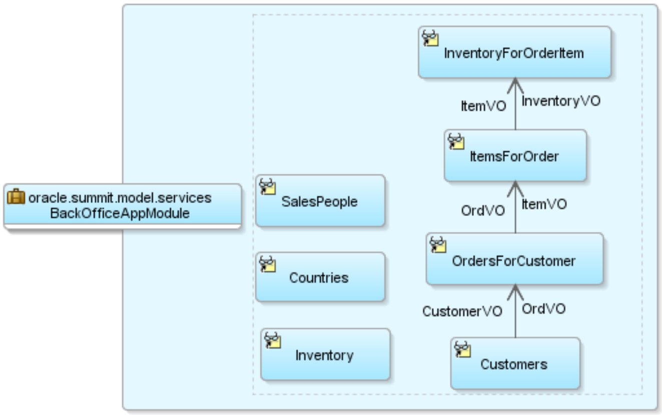
Create the desired application modules, as described in How to Create an Application Module.

To create a diagram of your application module:

1. In the Applications window, right-click the data model project in which you want to create the diagram and choose **New** and then **Business Components Diagram**.
2. In the Create Business Components dialog, enter a diagram name and a package name in which the diagram will be created.
3. Click **OK** to create the empty diagram and open the diagrammer.
4. In the Applications window, select the desired application module and drop it onto the diagram surface.
5. Inside the application module diagram, right-click the desired diagram node and choose **Visual Properties** and make the desired changes in the Edit Visual Properties dialog.
6. In the diagram editor, click anywhere outside of the application module diagram to display the Properties window for the diagram editor and make these changes:
   - Set the layout style
   - Change the font
   - Turn off the grid

After you complete these steps, the diagram looks similar to the diagram shown in Figure 13-15.

Figure 13-15 Partial UML Diagram of Application Module



What Happens When You Create an Application Module Diagram

When you create a business components diagram, JDeveloper creates a `.adfbc_diagram` file to represents the diagram in a subdirectory of the project's model path that matches the package name in which the diagram resides.

By default, the Applications window unifies the display of the project content's paths so that ADF components and Java files in the source path appear in the same package tree as the UML model artifacts in the project model path. You can use the **Applications Window Options > Directory View** toolbar option in the Applications window to switch between the unified directory view and a more distinct directory path view of the project content.

How to Use the Diagram to Edit the Application Module

The UML diagram of business components is not just a static picture that reflects the point in time when you dropped the application module onto the diagram. Rather, it is a UML-based rendering of the current component definitions, so it will always reflect the current state of affairs. The UML diagram is both a visualization aid and a visual navigation and editing tool.

You can bring up the overview editor for any application module in a diagram by choosing **Properties** from the context menu (or by double-clicking the application module).

You can also perform some application module editing tasks directly on the diagram, tasks such as renaming view object instances, dropping view object definitions from the Applications window onto the data model to create a new view object instance, and removing view object instances by pressing the Delete key.

Note:

Deleting components from the diagram only removes their visual representation on the diagram surface. The components and classes remain on the file system and in the Applications window.

How to Control Diagram Display Options

After you display the application module in the diagram, you can use the Edit Visual Properties dialog to control its display options. To display the dialog for the diagram, in the diagram, right-click the application module node and choose **Visual Properties**.

In the **Display** page, toggle properties like the following:

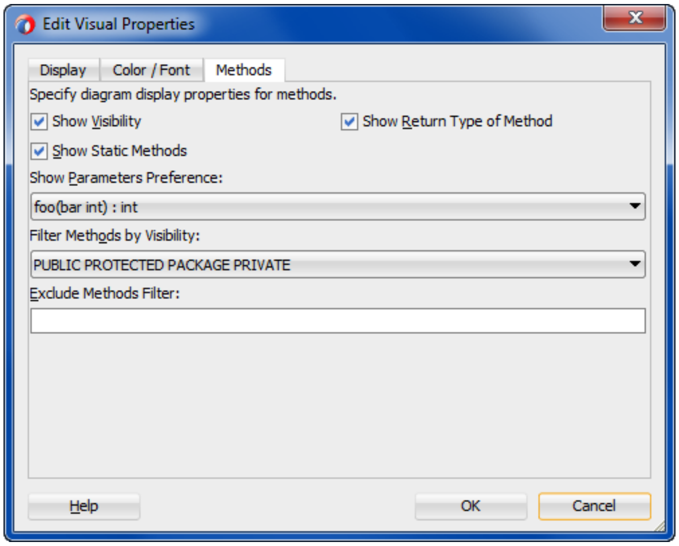
- **Show Package** — to display the package name
- **Show Methods** — to display service methods
- **Show Stereotype** — to display the type of object (for example "`<<application module>>`")
- **Show Usages** — to display all usages by other application modules in the current project

In the **Methods** page, consider changing the following settings depending on the amount of detail you want to provide in the diagram:

- **Show Visibility** (public, private, etc.)
- **Show Return Type of Method**
- **Show Static Methods**

By default, all operations of the application module are fully displayed, as shown by the Edit Visual Properties dialog settings in Figure 13-16.

Figure 13-16 Edit Visual Properties Dialog with Default Diagram Editor Options



Specify diagram display properties for methods.

☑ Show Visibility ☑ Show Return Type of Method

☑ Show Static Methods

Show Parameters Preference: foo(bar int) : int

Filter Methods by Visibility: PUBLIC PROTECTED PACKAGE PRIVATE

Exclude Methods Filter:

On the context menu of the diagram, you can also select to **View As**:

- **Compact** — to show only the icon and the name
- **Symbolic** — to show service operations
- **Expanded** — to show operations and data model (*default*)

How to Filter Method Names Displayed in the Diagram

Initially, if you show the methods for the application module, the diagram displays all the methods. Any method it recognizes as an overridden framework method displays in the **<<Framework>>** operations category. The rest display in the **<<Business>>** methods category.

The **Exclude Method Filters** setting in the **Methods** page of the Edit Visual Properties dialog is a regular expression that you can use to filter out methods you don't want to display on the diagram. For example, by setting **Exclude Method Filters** to:

```
findLoggedInUser.*|retrieveOrder.*|get.*
```

you can filter out all of the following application module methods:

- `findLoggedInUserByEmail`
- `retrieveOrderById`
- All the generated view object getter methods

How to Show Related Objects and Implementation Files in the Diagram

After selecting the application module on the diagram — or any set of individual view object instances in its data model — you can choose **Show > Related Elements** from the context menu to display related component definitions on the diagram. In a similar fashion, choosing **Show > Implementation Files** will include the files that implement the application module on the diagram. You can repeat these options on the additional diagram elements that appear until the diagram includes the level of detail you want to convey.

Figure 13-17 illustrates how the diagram displays the implementation files for an application module. You will see the related elements for the application module's implementation class (`AppModuleImpl`). The diagram also draws an additional dependency line between the application module and the implementation class. If you have cast the application module instance to a specific custom interface, the diagram will also show that.

Figure 13-17 Adding Detail to a Diagram Using Show Related Elements and Show Implementation Files

How to Publish the Application Module Diagram

To publish the diagram to `PNG`, `JPG`, `SVG`, or compressed `SVG` format, choose **Publish Diagram** from the context menu on the diagram surface.

How to Test the Application Module from the Diagram

To launch the Oracle ADF Model Tester for an application module in the diagram, choose **Run** from the context menu.

Supporting Multipage Units of Work

Use ADF application module pooling to implement scalable, fault-tolerant applications.

While interacting with your Fusion web application, end users might:

- Visit the same pages multiple times, expecting fast response times
- Perform a logical unit of work that requires visiting many different pages to complete
- Need to perform a partial "rollback" of a pending set of changes they've made but haven't saved yet.
- Unwittingly be the victim of an application server failure in a server farm before saving pending changes

The **application module pooling** and state management features simplify implementing scalable, well-performing applications to address these requirements.

> **Note:**
>
> ADF **bounded task flows** can represent a transactional unit of work. You can specify options on the task flow to determine how to handle the transaction. For details about the declarative capabilities of ADF bounded task flows, see Managing Transactions in Task Flows.

How to Simulate State Management in the Oracle ADF Model Tester

To simulate what the state management functionality does, you can launch two instances of Oracle ADF Model Tester on an application module.

Before you begin:

It may be helpful to have an understanding of state management. For more information, see Supporting Multipage Units of Work.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

To simulate transaction state passivation using the Oracle ADF Model Tester:

1. Run the Oracle ADF Model Tester and double-click a view object instance to query its data.
2. Make a note of the current values of several attributes for a few rows.
3. Update those rows to have a different value for those attributes, but do not commit the changes.
4. Choose **File > Save Transaction State** from the Oracle ADF Model Tester main menu.

   A Passivated Transaction State dialog appears, indicating a numerical transaction ID number. Make a note of this number.
5. Exit the Oracle ADF Model Tester completely.
6. Restart the Oracle ADF Model Tester and double-click the same view object instance to query its data.
7. Notice that the data is *not* changed. The queried data from the data reflects the current state of the database without your changes.
8. Choose **File > Restore Transaction State** from the Oracle ADF Model Tester main menu, and enter the transaction ID you noted in Step 4.

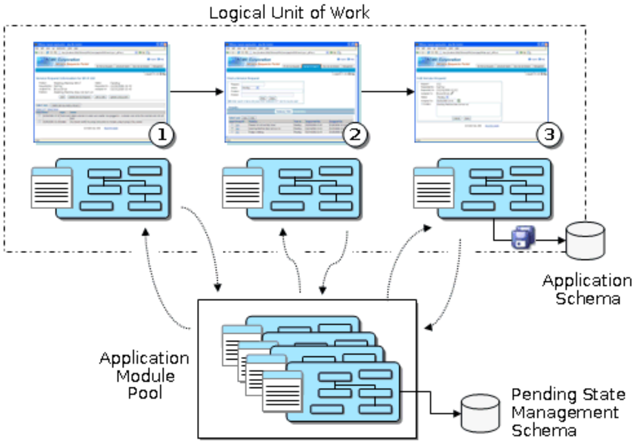
At this point, you'll see that your pending changes are reflected again in the rows you modified. If you commit the transaction now, your changes are permanently saved to the database.

What Happens at Runtime: How the Application Uses Application Module Pooling and State Management

Applications you build that leverage an application module as their business service take advantage of an automatic **application module pooling** feature. This facility manages a configurable set of application module instances that grows and shrinks as the end-user load on your application changes during the day. Due to the natural "think time" inherent in the end user's interaction with your application user interface, the number of application module instances in the pool can be smaller than the overall number of active users using the system.

As shown in Figure 13-18, as a given end user visits multiple pages in your application to accomplish a logical task, with each page request an application module instance in the pool is acquired automatically from the pool for the lifetime of that one request. At the end of the request, the instance is automatically returned to the pool for use by another user session. In order to protect the end user's work against application server failure, the application module supports the ability to freeze the set of pending changes in its entity caches to a persistent store by saving an XML snapshot describing the change set. For scalability reasons, this state snapshot is typically saved in a state management schema that is a different database schema than the one containing the application data.

Figure 13-18 Using Pooled Application Modules Throughout a Multipage, Logical Unit of Work



The pooling algorithm affords a tunable optimization whereby a certain number of application module instances will attempt to stay "sticky" to the last user session that returned them to the pool. The optimization is not a guarantee, but when a user can benefit from the optimization, they continue to work with the same application module instance from the pool as long as system load allows. When load is too high, the pooling algorithm uses any available instance in the pool to service the user's request and the frozen snapshot of their logical unit of work is reconstituted from the persistent store to allow the new instance of the application module to continue where the last one left off. The end user continues to work in this way until they commit or roll back their changes.

Using these facilities, the application module delivers the productivity of a stateful paradigm that can easily handle multipage work flows, in an architecture that delivers the runtime performance near that of a completely stateless application. You will learn more about these application module features in Using State Management in a Fusion Web Application and about how to tune them in Tuning Application Module Pools.

Customizing an Application Module with Service Methods

Any external client code which is a logical aspect of business functionality implementation can be accommodated in an ADF Application Module's custom Java class.

An application module can expose its data model of view object instances to clients without requiring any custom Java code. This allows client code to use the `ApplicationModule`, `ViewObject`, `RowSet`, and `Row` interfaces in the `oracle.jbo` package to work directly with any view object in the data model. However, just because you *can* programmatically manipulate view objects any way you want to in client code doesn't mean that doing so is always a best practice.

Whenever the programmatic code that manipulates view objects is a logical aspect of implementing your complete business service functionality, you should encapsulate the details by writing a custom method in your application module's Java class. This includes code that:

- Configures view object properties to query the correct data to display
- Iterates over view object rows to return an aggregate calculation
- Performs any kind of multistep procedural logic with one or more view objects

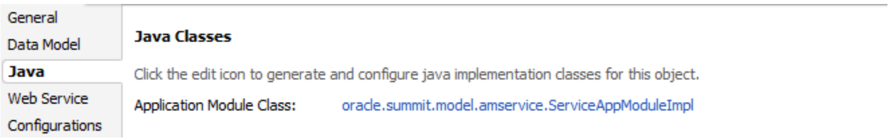
By centralizing these implementation details in your application module, you gain the following benefits:

- You make the intent of your code more clear to clients.
- You allow multiple client pages to easily call the same code if needed.
- You simplify regression-testing of your complete business service functionality.
- You keep the option open to improve your implementation without affecting clients.
- You enable *declarative* invocation of logical business functionality in your pages.

How to Generate a Custom Class for an Application Module

To add a custom service method to your application module, you must first enable a custom Java class for it. If you have configured your IDE-level Business Components Java generation preferences to automatically generate an application module class, a custom class will be present. As Figure 13-19 shows, if you're not sure whether your application module has a custom Java class, open the overview editor for the application module node in the Applications window. The Java Classes page of the editor displays the complete list of classes generated for the application module in the project. If the file exists because someone created it already, then the Java Classes page will display a linked file name identified as the **Application Module Class**. To open an existing file in the source editor, click the corresponding file name link.

Figure 13-19   Application Module's Custom Java Class in Overview Editor



Java Classes

Click the edit icon to generate and configure java implementation classes for this object.

Application Module Class: oracle.summit.model.amservice.ServiceAppModuleImpl

If no Java class exists in your project, you can generate one using the Java Classes page of the overview editor for the application module.

Before you begin:

It may be helpful to have an understanding of application module service methods. For more information, see Customizing an Application Module with Service Methods.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

Create the desired application modules, as described in How to Create an Application Module.

To generate a Java file for your application module class:

1. In the Applications window, double-click the application module.
2. In the overview editor, click the **Java** navigation tab and then click the **Edit java options** button.
3. In the Select Java Options dialog, select **Generate Application Module Class**.
4. Click **OK**.

   The new `.java` file will appear in the Java Classes page.

What Happens When You Generate a Custom Class for an Application Module

When you generate a custom class for an application module, JDeveloper creates the file in the same directory as the component's XML document file. The default name for its custom Java file will be *AppModuleName*`Impl.java`.

The Java generation option choices you made for the application module persist on the Java Classes page on subsequent visits to the overview editor for the application module. Just as with the XML definition file, JDeveloper keeps the generated code in your custom Java classes up to date with any changes you make in the editor. If later you decide you do not require a custom Java file, from the Java Classes page open the Select Java Options dialog and deselect **Generate Application Module Class** to remove the custom Java file from the project.

What You May Need to Know About Default Code Generation

By default, the application module Java class will look similar to what you see in the following example when you've first enabled it. Of interest, it contains Getter methods for each view object instance in the data model.

```
package oracle.summit.model.services;

import oracle.jbo.server.ApplicationModuleImpl;
// ---------------------------------------------------------------------
// ---    File generated by ADF Business Components Design Time.
// ---    Custom code may be added to this class.
// ---    Warning: Do not modify method signatures of generated methods.
// ---------------------------------------------------------------------
```

```
public class AppModuleImpl extends ApplicationModuleImpl {
  /** This is the default constructor (do not remove) */
  public AppModuleImpl() { }

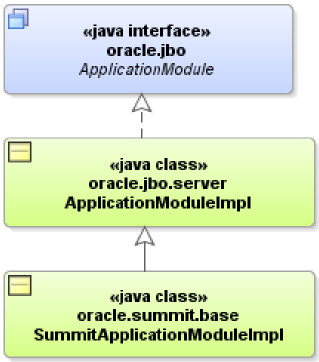
  /** Container's getter for YourViewObjectInstance1 */
  public YourViewObjectImpl getYourViewObjectInstance1() {
    return (YourViewObjectImpl)findViewObject("YourViewObjectInstance1");
  }

  // ... Additional ViewObjectImpl getters for each view object instance

  // ... ViewLink getters for view link instances here
}
```

As shown in Figure 13-20, your application module class extends the base ADF `ApplicationModuleImpl` class to inherit all the default behavior before adding your custom code.

Figure 13-20 Your Custom Application Module Class Extends ApplicationModuleImpl



How to Add a Custom Service Method to an Application Module

To add a custom service method to an application module, simply navigate to the application module's custom class and enter the Java code for a new method into the application module's Java implementation class. Use the following guidelines to decide on the appropriate visibility for the method:

- If you will use the method only inside this component's implementation as a helper method, make the method `private`.
- If you want to allow eventual subclasses of your application module to be able to invoke or override the method, make it `protected`.
- If you need clients to be able to invoke it, it must be `public`.

> **Note:**
>
> The application module examples in this chapter use strongly typed, custom entity object classes. For details about creating these entity classes, see Creating a Business Domain Layer Using Entity Objects.

The following example shows a `private retrieveOrderById()` helper method in the `AppModuleImpl.java` class for the `AppModule` application module. It uses the `static getDefinitionObject()` method of the `OrdEOImpl` entity object class to access its related entity definition, it uses the `createPrimaryKey()` method on the entity object class to create an appropriate Key object to look up the order, and then it uses the `findByPrimaryKey()` method on the entity definition to find the entity row in the entity cache. It returns an instance of the strongly typed `OrdersImpl` class, the custom Java class for the `Orders` entity object.

```
// In summit.model.appmodule.service.AppModuleImpl class
/*
 * Helper method to return a Order by Id
 */
private OrdersImpl retrieveOrderById(long orderId) {
  EntityDefImpl orderDef = OrdersImpl.getDefinitionObject();
  Key orderKey = OrdersImpl.createPrimaryKey(new DBSequence(orderId));
  return (OrdersImpl)orderDef.findByPrimaryKey(getDBTransaction(), orderKey);
}
```

The following example shows a `public findOrderAndCustomer()` method that allows the caller to pass in an ID of an order to be created. It uses the `getCustomer()` method of the `OrdersImpl` entity object class to access its related entity definition.

```
/*
 * Create a new Customer and Return its new id
 */
public String findOrderAndCustomer(long orderId) {
    OrdersImpl order = retrieveOrderById(orderId);
  if (order != null) {
        CustomerImpl cust = order.getCustomer();
    if (cust != null) {
      return "Customer: " + cust.getName() + ", Location: " + cust.getCity();
    }
    else {
      return "Unassigned";
    }
  }
  else {
    return null;
  }
}
```

How to Test the Custom Application Module Using a Static Main Method

When you are ready to test the methods of your custom application module, you can use JDeveloper to generate JUnit test cases. With JUnit, you can use any of the programmatic APIs available in the `oracle.jbo package` to work with the application module and invoke the custom methods. For details about using JUnit with ADF Business Components, see Regression Testing with JUnit.

As an alternative to JUnit test cases, a common technique to test your custom application module methods is to write a simple test case. For example, you could build the testing code into an object and include that code in a `static main()` method. The following example shows a sample `main()` method you could add to your custom application module class to test the sample methods you will write. You'll make use of a Configuration object (see How to Create a Command-Line Java Test Client) to instantiate and work with the application module for testing.

> **Note:**
>
> The fact that this Configuration object resides in the oracle.jbo.client package suggests that it is used for accessing an application module as an application *client*. Because a main() method is a kind of programmatic, command-line client, so this is an acceptable practice. Furthermore, even though you typically would not cast the return value of createRootApplicationModule() directly to an application module's implementation class, it is legal to do so in this one situation since despite being a client to the application module, the main() method's code resides right inside the application module implementation class itself.

A glance through the code in the following example shows that it exercises the methods created in the previous examples to:

1. Retrieve the total for order 101.
2. Retrieve the name of the customer for order 101.
3. Set the status of order 101 to the value "Y".

```
package oracle.summit.model.appmodule.service;

import oracle.jbo.ApplicationModule;
import oracle.jbo.JboException;
import oracle.jbo.client.Configuration;

public class TestAM {
    public TestAM() {
        super();
    }

    /*
     * Testing method
     */

    public static void main(String[] args) {
      String amDef = "oracle.summit.model.appmodule.service.AppModule";
      String config = "AppModuleLocal";
      ApplicationModule am =
                      Configuration.createRootApplicationModule(amDef,config);
        /*
         * NOTE: This cast to use the AppModuleImpl class is OK since this
         *       code is inside a business tier file and not in a
         *       client class that is accessing the business tier from "outside".
         */
        AppModuleImpl service = (AppModuleImpl)am;

        String customerName = service.findOrderAndCustomer(101);
        System.out.println("Customer for Order # 101 = " + customerName);
        try {
           service.updateOrderStatus(101,"Y");
        }
        catch (JboException ex) {
                System.out.println("ERROR: "+ex.getMessage());
            }
          Configuration.releaseRootApplicationModule(am,true);
        }
}
```

Running the custom application module class calls the `main()` method in the above example and produces the following output:

```
anonymous
Customer for Order # 101 = Customer: Kam's Sporting Goods, Location: Hong Kong
```

> **Note:**
>
> For an explanation of how you can use the client application to invoke the custom service methods that you create in your custom application module, see Publishing Custom Service Methods to UI Clients.

What You May Need to Know About Programmatic Row Set Iteration

Any time your application logic accesses a row set to perform programmatic iteration, you should use a secondary **row set iterator** when working with view object instances in an application module's data model, or view link accessor row sets of these view object instances, since they may be bound to user interface components. To create a secondary iterator, use the `createRowSetIterator()` method on the row set you are working with. When you are done using it, call the `closeRowSetIterator()` method on the row set to remove the secondary iterator from memory. The following example shows a typical application module custom method that correctly uses a secondary row set iterator for programmatic iteration, because the `CustomerView1` view object instance in its data model may be bound to a user interface (either now or at a later time).

```
// Custom method in an application module implementation class
public void doSomeCustomProcessing() {
    ViewObject vo = getCustomerView1();
    // create secondary row set iterator with system-assigned name
    RowSetIterator iter = vo.createRowSetIterator(null);
    while (iter.hasNext()) {
        Row r = iter.next();
        // Do something with the current row.
        Integer custId = (Integer)r.getAttribute("Id");
        String name  = (String)r.getAttribute("Name");
        System.out.println(custId + " " + name);
    }
    // close secondary row set iterator
    iter.closeRowSetIterator();
}
```

Note:

The same recommendation holds for custom code in a view object's implementation class that iterates its own default row set using that row set's default row set iterator.

There are two important reasons to follow this recommendation. Failing to do so can lead to confusion for the end user when the current row unexpectedly changes or it can introduce subtle business logic errors because the first or last row, or both rows get skipped.

- Confusing the end user by changing the current row unexpectedly

  The **iterator bindings** determine what row the end-user sees as the current row in the row set. If your own programmatic logic iterates through the row set using the same default row set iterator that the iterator binding uses, you may inadvertently change the current row the user has selected, leaving the user confused.

- Introducing subtle business logic errors by inadvertently skipping the first or last row

  Iterator bindings force their row set iterator to be on a valid row to guarantee that UI components display data when the row set is not empty. This has the side-effect of preventing your custom logic from navigating to the slot either before the first row or to the slot after the last row (when it is using the same row set iterator as an iterator binding). In concrete terms, this means that a typical `while (iter.hasNext())` row set iteration loop will either be skipped or start by processing the second row instead of the first as shown in the following example.

```
// Reset the default row set iterator (iter) to the slot before the first row
iter.reset();
// If an iterator binding is bound to the same default row set iterator,
// then it has already forced it to navigate to the first row here instead
// of being on the slot before the first row.
//
// If the row set iterator has only one row, the following will then return false
while (iter.hasNext()) {
  // If the row set has more than one row, the first time through the loop
  // this call to next() will return the second row rather than the first
  // row as expected.
  Row curRow = iter.next();
  // Do something with current row
}
```

Customizing Application Module Message Strings

You can add a resource bundle file for an ADF Application Module. You use this resource bundle file or .properties file to hold custom message strings.

The ADF application module does not normally require a resource bundle of its own. However, you can create a custom message string file (`.properties`) that you can use to add your custom message strings.

The `.properties` file you create can reference attribute properties by their fully qualified package name and custom method exception messages. For example, you might define message keys and strings as follows:

```
test.Order.Orderno_LABEL=Order Number
INVALID=You have called the method foo in an invalid way.
```

If your resource bundle defines a message for a method exception message, the custom method should appear in the application module client interface, as described in How to Publish a Custom Method on the Application Module's Client Interface.

For example, if you defined a message for the method `foo()` to replace the exception message `INVALID`, your interface might define this method to invoke the message from the resource bundle as:

```
public void foo() {
    ResourceBundleDef r = getResourceBundleDef();
    throw new JboException(r,"INVALID",null);
}
```

How to Add a Resource Bundle File for the Application Module

When you want to create a `.properties` file to contain custom message strings, you use the resource bundle option on the Resource Bundle page of the Project Properties dialog and select the option **One Bundle Per File**. By default JDeveloper sets the option to **One Bundle Per Project**, which produces a single `.properties` file for the project.

Before you begin:

It may be helpful to have an understanding of how projects use resource bundles. For more information, see Customizing Application Module Message Strings.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete these tasks:

1. Create the desired application module, as described in How to Create an Application Module.
2. Set the project properties for the data model project to generate one bundle per file, as described in Working with Resource Bundles.

To generate the resource bundle for the application module:

1. In the Applications window, double-click the application module for which you want to generate the resource bundle.
2. In the overview editor, click the **General** navigation tab and enter any display name.

   Adding a display name for the application module will generate the `.properties` file with a message key for the display name.
3. Save the file.

What Happens When You Add a Resource Bundle to an Application Module

When you generate a resource bundle for an application module, JDeveloper creates the `.properties` file in the same directory as the component's XML document file. The default name for its custom Java file will be *`AppModuleName`*`MsgBundle.properties`.

The following example shows the `ResourceBundle` element in the application module XML document that references the `.properties` file.

```
<AppModule
  ...
  <ResourceBundle>
    <PropertiesBundle
      PropertiesFile=
         "oracle.summit.model.services.common.BackOfficeAppModuleMsgBundle"/>
  </ResourceBundle>
</AppModule>
```

Publishing Custom Service Methods to UI Clients

For the user interface to invoke a public custom method in the ADF Application Module class, include this method on the Application Module’s UI client interface.

When you add a `public` custom method to your application module class, if you want your application's UI to be able to invoke it, you need to include the method on the application module's UI client interface.

How to Publish a Custom Method on the Application Module's Client Interface

To include a public method from your application module's custom Java class on the client interface, use the Java Classes page of the overview editor for the application module.

Before you begin:

It may be helpful to have an understanding of the purpose of the client interface. For more information, see Publishing Custom Service Methods to UI Clients.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

> Create the desired application modules, as described in How to Create an Application Module.

To publish a custom method on the client interface:

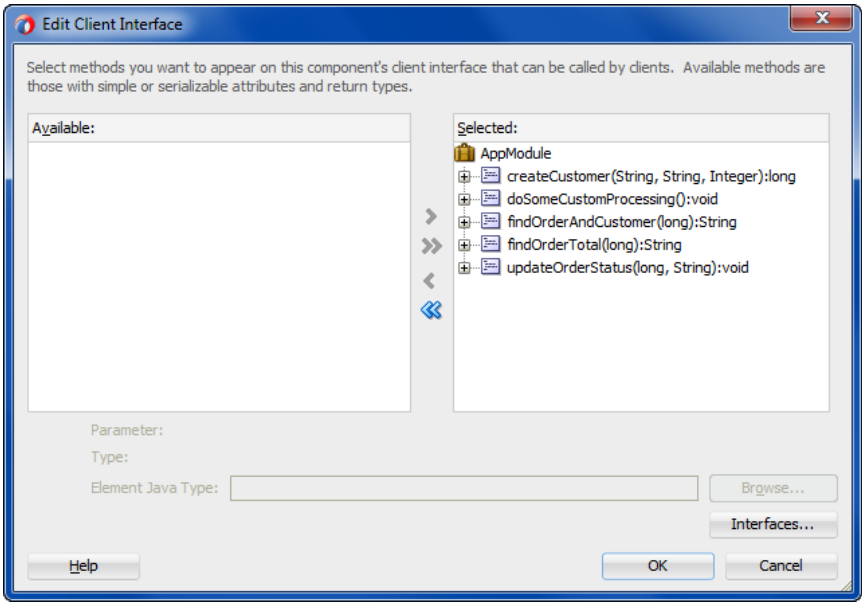
1. In the Applications window, double-click the application module for which you want to define the client interface.

2. In the overview editor, click the **Java** navigation tab and in the **Client Interface** section, click the **Edit application module client interface** button.
3. In the Edit Client Interface dialog, select one or more desired methods from the **Available** list and click the **Add** button to shuttle them into the **Selected** list.
4. Click **OK**.

   The new methods will appear in the **Client Interface** section of the Java Classes page.

Figure 13-21 shows multiple public methods added to the client interface.

Figure 13-21 Public Methods Added to an Application Module's Client Interface



Select methods you want to appear on this component's client interface that can be called by clients. Available methods are those with simple or serializable attributes and return types.

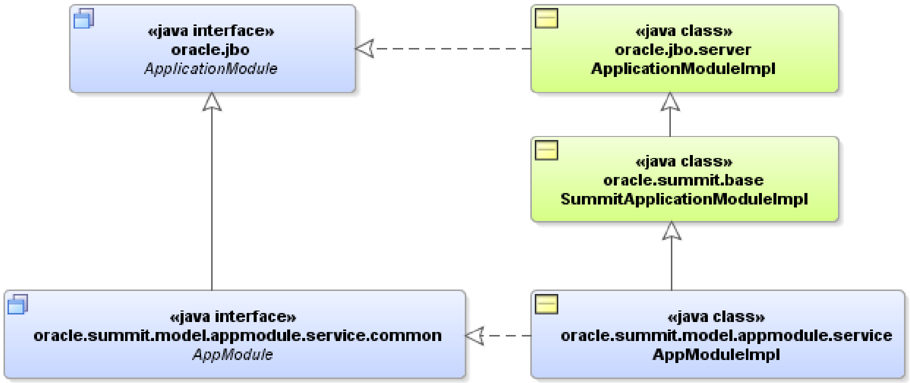
Selected:

- AppModule
  - createCustomer(String, String, Integer):long
  - doSomeCustomProcessing():void
  - findOrderAndCustomer(long):String
  - findOrderTotal(long):String
  - updateOrderStatus(long, String):void

What Happens When You Publish Custom Service Methods

When you publish custom service methods on the client interface, as shown in Figure 13-22, JDeveloper creates a Java interface with the same name as the application module in the `common` subpackage of the package in which your application module resides. For an application module named `AppModule` in the `summit.model` package, this interface will be named `AppModule` and reside in the `summit.model.common` package. The interface extends the base `ApplicationModule` interface in the `oracle.jbo` package, reflecting that a client can access all of the base functionality that your application module inherits from the `ApplicationModuleImpl` class.

Figure 13-22 Custom Client Interface Extends the Base ApplicationModule Interface



As shown in the following example, the `AppModule` interface includes the method signatures of all of the methods you've selected to be on the client interface of your application module.

```
package summit.model.appmodule.service.common;
import oracle.jbo.ApplicationModule;
// ---------------------------------------------------------------------
// ---    File generated by ADF Business Components Design Time.
// ---------------------------------------------------------------------
public interface AppModule extends ApplicationModule {
    String findOrderAndCustomer(long orderId);
    void updateOrderStatus(long orderId, String newStatus);
    String findOrderTotal (long orderId);
    long createCustomer(String name, String city, Integer countryId);
}
```

> **Note:**
>
> After adding new custom methods to the client interface, if your new custom methods do not appear to be available when you use JDeveloper's code insight context-sensitive statement completion, try recompiling the generated client interface. To do this, select the application module in the Applications window, select the source file for the interface of the same name in the Structure window, and choose **Rebuild** from the context menu. Consider this tip for new custom methods added to view objects and view rows as well.

How to Generate Client Interfaces for View Objects and View Rows

In addition to generating a client interface for your application module, it is also possible to generate strongly typed client interfaces for working with the other key client objects that you can customize. For example, you can add custom methods to the view object client interface and the view row client interface, respectively.

Before you begin:

It may be helpful to have an understanding of the purpose of the client interface. For more information, see Publishing Custom Service Methods to UI Clients.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

Create the desired view object, as described in Populating View Object Rows from a Single Database Table.

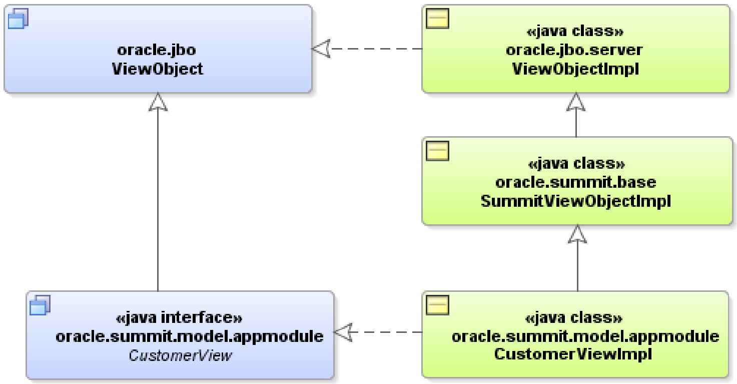
To publish a custom method on the client interface for view objects:

1. In the Applications window, double-click the view object for which you want to define the client interface.
2. In the overview editor, click the **Java** navigation tab and in the **Client Interface** section, click the **Edit java options** button.
3. In the Select Java Options dialog, click the **Generate View Object Class** and click the **Generate View Row Class**. Click **OK**.
4. In the overview editor, expand the **Client Interface** section and then click the **Edit view object client interface** button.
5. In the Edit Client Interface dialog, select one or more desired methods from the **Available** list and click the **Add** button to shuttle them into the **Selected** list.
6. In the overview editor, expand the **Client Row Interface** section and then click the **Edit view object client row interface** button.
7. In the Edit Client Interface dialog, select one or more desired methods from the **Available** list and click the **Add** button to shuttle them into the **Selected** list.
8. Click **OK**.

   The new methods will appear in the Java Classes page.

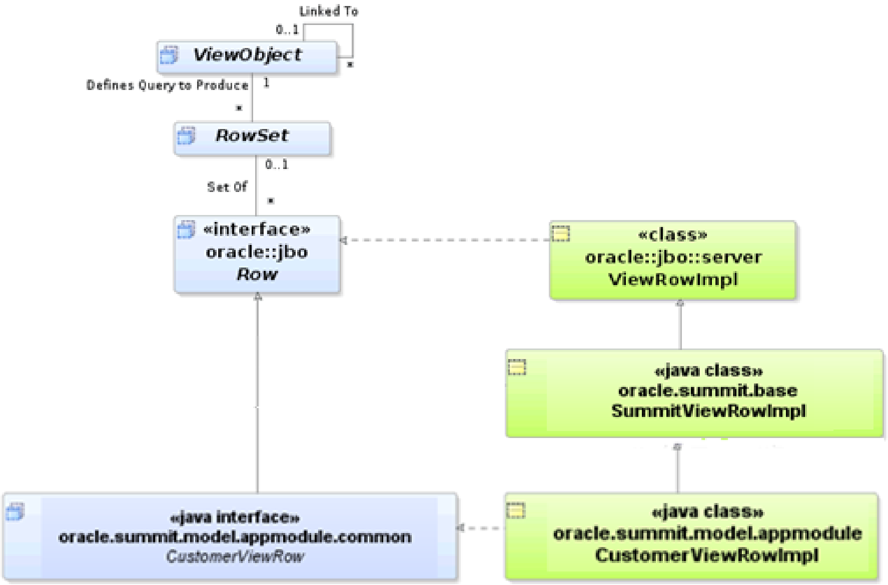
For example, if for the `CustomerView` view object in the `summit.model.views` package you were to enable the generation of a custom view object Java class and add one or more custom methods to the view object client interface, JDeveloper would generate the `CustomerViewImpl` class and `CustomerView` interface, as shown in Figure 13-23. As with the application module custom interface, notice that it gets generated in the `common` subpackage.

Figure 13-23 Custom View Object Interface Extends the Base ViewObject Interface



Likewise, if for the same view object you were to enable the generation of a custom view row Java class and add one or more custom methods to the view row client interface, JDeveloper would generate the `CustomerViewRowImpl` class and `CustomerViewRow` interface, as shown in Figure 13-24.

Figure 13-24 Custom View Row Interface Extends the Base Row Interface



How to Test Custom Service Methods Using the Oracle ADF Model Tester

You can test the methods of your custom application module in the Oracle ADF Model Tester after you have published them on the client interface, as described in Publishing Custom Service Methods to UI Clients.

Before you begin:

It may be helpful to have an understanding of the purpose of the client interface. For more information, see Publishing Custom Service Methods to UI Clients.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

Create the desired application modules, as described in How to Create an Application Module.

To test the service methods that you have published:

1. In the Applications window, right-click the application module and choose **Run**.

   Alternatively, choose **Debug** when you want to run the application in the Oracle ADF Model Tester with debugging enabled. The debugger process panel opens in the Log window and the various debugger windows. When debugging using the

Oracle ADF Model Tester, you can use these windows to view status message and exceptions, step in and out of source code, and manage breakpoints.

For information about receiving diagnostic messages specific to ADF Business Component debugging, see How to Enable ADF Business Components Debug Diagnostics.

2. To open the method testing panel for a method defined by a client interface, do one of the following:

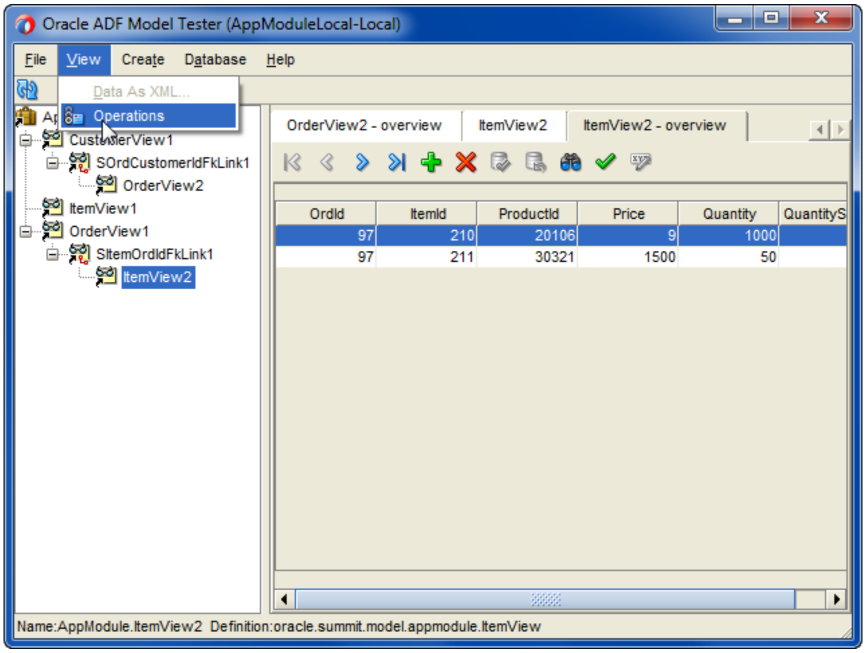
   - In the data model tree, select the application module node and in the main menu choose **View** and then **Operations** when you want to execute a method you published for the application module client interface. You can also double-click the application module node to display the method testing panel.
   - In the data model tree, select the desired view object node and in the main menu choose **View** and then **Operations** when you want to execute a method you published on the client interface for a view object. You can also right-click the view object node and choose **Operations**.

3. To open the method testing panel for a method defined by a client row interface for a view object row, expand the data model tree, right-click the desired view object node and choose **Show Table**. Then in the overview panel for the view instance, select the desired row, and in the main menu, choose **View** and then **Operations**.

   Do not select a master view instance in the data model tree since view row operations are not permitted on master view objects. Always select a detail view instance or a view instance that is not specified in a master-detail hierarchy, as shown in Figure 13-25.

> **Tip:**
>
> In the case of a detail view instance, you can open the master view instance to navigate to the detail with the desired row. The Oracle ADF Model Tester automatically synchronizes the data displayed in the open overview panel with the master view instance that you navigate to.

Figure 13-25 Menu Selection for View Row Operations in the Oracle ADF Model Tester



OrdId	ItemId	ProductId	Price	Quantity	QuantityS
97	210	20106	9	1000	
97	211	30321	1500	50	

Name:AppModule.ItemView2 Definition:oracle.summit.model.appmodule.ItemView

4. In the method panel, select the desired service method from the dropdown list, enter values to pass as method parameters, and click **Execute**.

   Notice that the method testing panel displays the parameter names to help you identify where to enter the values to pass. This is particularly useful when the method signature defines multiple parameters of the same data type.

   You can view the return value (if any) and test result. The result displayed in the Oracle ADF Model Tester will indicate whether or not the method executed successfully.

What You May Need to Know About Method Signatures on the Client Interface

You can include any custom method in the client interface that obeys these implementation rules:

- If the method has a non-`void` return type, the type must be serializable.
- If the method accepts any parameters, all their types must be serializable.
- If the method signature includes a throws clause, the exception must be an instance of `JboException` in the `oracle.jbo` package.

In other words, all the types in its method signature must implement the `java.io.Serializable` interface, and any checked exceptions must be `JboException` or its subclass. Your method can throw any unchecked exception — `java.lang.RuntimeException` or a subclass of it — without disqualifying the method from appearing on the application module's client interface.

Note that method signatures of type `java.util.List` are allowed as long as the implementing class for the interface is serializable. For example, `java.util.ArrayList` and `java.util.LinkedList` are both serializable implementing classes. The same requirement applies to element types within the collection. The ADF Business Components runtime will produce an error if you instantiate a class that implements the interface yet does not implement the `java.io.Serializable` interface.

> **Note:**
>
> If the method you've added to the application module class doesn't appear in the **Available** list, first verify that it doesn't violate any of the method implementation rules. If it seems like it should be a legal method, try recompiling the application module class before visiting the overview editor for the application module again.

What You May Need to Know About Passing Information from the Data Model

The private implementation of an application module custom method can easily refer to any view object instance in the data model using the generated accessor methods. By calling the `getCurrentRow()` method on any view object, it can access the same current row for any view object that the client user interface sees as the current row. As a result, while writing application module business service methods, you may not need to pass in parameters from the client. This is true if you would be passing in values only from the current rows of other view object instances in the same application module's data model.

For example, the custom application module method in the following example accepts no parameters. Internally, the `createOrderItem()` method calls `getGlobals().getCurrentRow()` to access the current row of the `Globals` view object instance. Then it uses the strongly typed accessor methods on the row to access the values of the `Description` and `LineItemId` attributes to set them as the values of corresponding attributes in a newly created `OrderItem` entity object row.

```
// In AppModuleImpl.java, createOrderItem() method
GlobalsRowImpl globalsRow = (GlobalsRowImpl)getGlobals().getCurrentRow();
newOrder.setDescription(globalsRow.getDescription());
newOrder.setLineItemId(globalsRow.getLineItemId());
```

Working Programmatically with an Application Module's Client Interface

The ADF Business Components application module client interface lets you work programmatically with application modules.

After publishing methods on your application module's client interface, you can invoke those methods from a client.

How to Work Programmatically with an Application Module's Client Interface

To work programmatically with an application module's client interface, do the following:

- Cast `ApplicationModule` to the more specific client interface.
- Call any method on the interface.

> **Note:**
>
> For simplicity, this section focuses on working only with the custom application module interface; however, the same downcasting approach works on the client to use a `ViewObject` interface as a view object interface like `Customers` or a `Row` interface as a custom view row interface like `CustomersRow`.

The following example illustrates a `TestClientEntity` class that puts these two steps into practice. You could also use the `main()` method of this class to test application module methods, as described in How to Test the Custom Application Module Using a Static Main Method. Here you use it to call all of the same methods from the client using the `AppModule` client interface.

> **Note:**
>
> If you work with your application module using the default `ApplicationModule` interface in the `oracle.jbo` package, you won't have access to your custom methods. Make sure to cast the application module instance to your more specific custom interface like the `AppModule` interface in this example.

The basic logic of the following example follows these steps:

1. Retrieve the total for order 1011.
2. Retrieve the name of the customer for order 1011.
3. Set the status of order 1011 to the value "Y".
4. Create anew customer supplying a null customer name.
5. Create a new customer with a customer name and display its newly assigned customer ID.

```
package oracle.summit.model.appmodule.client;

import oracle.jbo.client.Configuration;
import oracle.jbo.*;
import oracle.jbo.domain.Number;
import oracle.jbo.domain.*;
import oracle.summit.model.appmodule.service.common.AppModule;

public class TestClientCustomInterface {
  public static void main(String[] args) {
      String amDef = "oracle.summit.model.appmodule.service.AppModule";
      String config = "AppModuleLocal";

      /*
       * This is the correct way to use application custom methods
       * from the client, by using the application module's automatically-
       * maintained custom service interface.
       */
      AppModule service =

(AppModule)Configuration.createRootApplicationModule(amDef,config);
      String total = service.findOrderTotal(1011);
      System.out.println("Total for Order # 1011 = " + total);
      String custName = service.findOrderAndCustomer(1011);
      System.out.println("Customer for Order # 1011 = " + custName);
      try {
         service.updateOrderStatus(1011,"Y");
      }
      catch (JboException ex) {
         System.out.println("ERROR: "+ex.getMessage());
      }
      long id = 0;
      try {
         id = service.createCustomer(null, "Oakville", 14);
      }
      catch (JboException ex) {
         System.out.println("ERROR: "+ex.getMessage());
      }
      id = service.createCustomer("Oakville Curling Club", "Oakville", 14);
      System.out.println("New customer created successfully with id = " + id);
      Configuration.releaseRootApplicationModule(service,true);
  }
}
```

Running the custom application module class calls the `main()` method in the above example and produces the following output:

```
Total for Order # 1011 = 99.99
Customer for Order # 1011 = Customer: Zibbers, Location: Boston
ERROR: JBO-27014: You must provide a value for Name.
New customer created successfully with id = 133
```

Notice that the first attempt to call `findOrderAndCustomer()` with a null for the customer name raises an exception due to the built-in mandatory validation on the `Name` attribute of the `Customer` entity object.

What Happens at Runtime: How the Application Module's Client Interface is Accessed

Because the client layer accessing your application module will be located in the same tier of the Java EE architecture, the application module is deployed in what is known as **local mode**. In local mode, the client interface is implemented directly by your custom application module Java class. You access an application module in local mode whenever you access the application module in the web tier of a JavaServer Faces application.

How to Access an Application Module Client Interface in a Fusion Web Application

The `Configuration` class in the `oracle.jbo.client` package makes it very easy to get an instance of an application module for *testing*. This eases writing test client programs like the test client program described in Regression Testing with JUnit as part of the JUnit regression testing fixture.

> **Best Practice:**
>
> For Fusion web applications you should always work though the binding layer to access the application module. While developers may be tempted to use the class `createRootApplicationModule()` and `releaseApplicationModule()` methods *anywhere* to access an application module, the best approach in the view layer is to use the declarative features of the ADF Model layer.

When working with Fusion web applications using the ADF Model layer for data binding, JDeveloper configures a servlet filter in your user interface project called the `ADFBindingFilter`. It orchestrates the automatic acquisition and release of an appropriate application module instance based on declarative binding metadata, and ensures that the service is available to be looked up as a data control using a known **action binding** or iterator binding, specified by any page definition file in the user interface project. You may eventually want to read about the ADF **binding container**, **data controls**, **page definition files**, and **ADF bindings**, as described in Using ADF Model in a Fusion Web Application. For now, it is enough to realize that you can access the application module's client interface from this `DCBindingContainer` by naming an ADF action binding or an ADF iterator binding. You can reference the **binding context** and call methods on the custom client interface in a JSF managed bean, as shown in the following examples for an action binding and for an iterator binding.

To access the custom interface of your application module using an action binding, follow these basic steps (as illustrated in the following example):

1. Access the ADF binding container.
2. Find a named action binding. (Use the name of any available action binding in the page definition files of the user interface project.)
3. Get the data control by name from the action binding.
4. Access the application module data provider from the data control.
5. Cast the application module to its client interface.
6. Call any method on the client interface.

```
package oracle.summit.model.viewobjects;

import oracle.summit.model.appmodule.service.common.SummitAppModule;
import oracle.adf.model.binding.DCBindingContainer;
import oracle.adf.model.binding.DCDataControl;
import oracle.jbo.ApplicationModule;
import oracle.jbo.uicli.binding.JUCtrlActionBinding;
public class YourBackingBean {
  public String commandButton_action() {
    // Example using an action binding to get the data control
    public String commandButton_action() {
    // 1. Access the binding container
    DCBindingContainer bc = (DCBindingContainer)getBindings();
    // 2. Find a named action binding
    JUCtrlActionBinding action =
                    (JUCtrlActionBinding)bc.findCtrlBinding("SomeActionBinding");
    // 3. Get the data control from the iterator binding (or method binding)
    DCDataControl dc  = action.getDataControl();
    // 4. Access the data control's application module data provider
    ApplicationModule am = (ApplicationModule)dc.getDataProvider();
    // 5. Cast the AM to call methods on the custom client interface
    SummitAppModule service = (SummitAppModule)am;
    // 6. Call a method on the client interface
    service.doSomethingInteresting();
    return "SomeNavigationRule";
  }
}
```

To access the custom interface of your application module using an iterator binding, follow these basic steps (as illustrated in the following example):

1. Access the ADF binding container.
2. Find a named iterator binding. (Use the name of any iterator binding in the page definition files of the user interface project.)
3. Get the data control by name from the iterator binding.
4. Access the application module data provider from the data control.
5. Cast the application module to its client interface.
6. Call any method on the client interface.

```
package oracle.summit.model.viewobjects;

import oracle.summit.model.appmodule.service.common.SummitAppModule;
import oracle.adf.model.binding.DCBindingContainer;
import oracle.adf.model.binding.DCDataControl;
import oracle.adf.model.binding.DCIteratorBinding;
import oracle.jbo.ApplicationModule;
public class YourBackingBean {
  public String commandButton_action() {
    // Example using an iterator binding to get the data control
    public String commandButton_action() {
    // 1. Access the binding container
    DCBindingContainer bc = (DCBindingContainer)getBindings();
    // 2. Find a named iterator binding
    DCIteratorBinding iter = bc.findIteratorBinding("SomeIteratorBinding");
    // 3. Get the data control from the iterator binding
    DCDataControl dc  = iter.getDataControl();
    // 4. Access the data control's application module data provider
    ApplicationModule am = (ApplicationModule)dc.getDataProvider();
    // 5. Cast the AM to call methods on the custom client interface
    SummitAppModule service = (SummitAppModule)am;
    // 6. Call a method on the client interface
    service.doSomethingInteresting();
    return "SomeNavigationRule";
  }
}
```

These backing bean examples depend on the helper method shown in the following example.

```
public BindingContainer getBindings() {
{
        return BindingContext.getCurrent().getCurrentBindingsEntry();
}
```

If you create the backing bean class by overriding a button that is declaratively bound to an ADF action, then JDeveloper will automatically generate this method in your class. Otherwise, you will need to add the helper method to your class yourself.

Overriding Built-in Framework Methods

You can enhance the default behavior of an ADF Application Module by overriding built-in ADF methods for the Application Module Java class.

The `ApplicationModuleImpl` base class provides a number of built-in methods that implement its functionality. While Most Commonly Used ADF Business Components Methods provides a quick reference to the most common code that you will typically write, use, and override in your custom application module classes, this section focuses on helping you understand the basic steps to override one of these built-in framework methods to augment the default behavior.

How to Override a Built-in Framework Method

To override a built-in framework method for an application module, use the Override Methods dialog, which you open for the application module Java class from the main menu.

Before you begin:

It may be helpful to have an understanding of the application module base class. For more information, see Overriding Built-in Framework Methods.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

Create the desired application modules, as described in How to Create an Application Module.

To override an application module framework method:

1. In the Applications window, double-click the application module for which you want to override framework methods.
2. In the overview editor, click the **Java** navigation tab and then click the linked file name of the application module Java class that you want to customize.

   The class file opens in the source editor.
3. In the main menu, choose **Source** and then **Override Methods**.

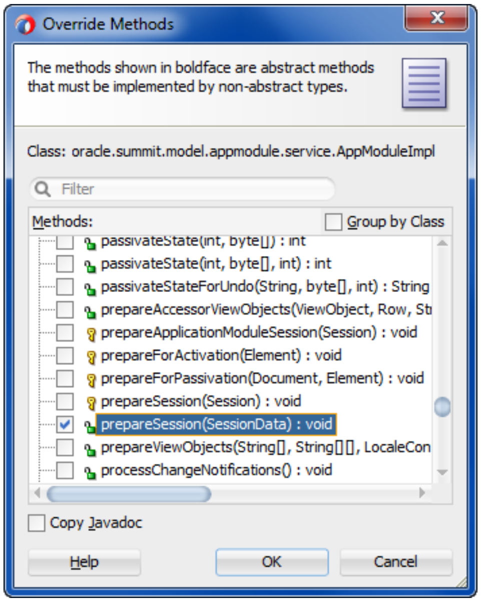
If the **Source** menu is not displayed, be sure that the desired Java class file is open and that the source editor is visible.

4. In the Override Methods dialog, scroll the list to locate the desired methods or type the first few letters of the method name to perform an incremental search.
5. Select one or more methods.

   The Override Methods dialog allows you to select any number of methods to override simultaneously.

   For example, if you wanted to override the application module's `prepareSession()` method to augment the default functionality when a new user session begins working with an application module service component for the first time, you would select the checkbox next to the `prepareSession(Session)` method, as shown in Figure 13-26.

Figure 13-26   Overriding a Built-in Framework Method



The methods shown in boldface are abstract methods that must be implemented by non-abstract types.

Class: oracle.summit.model.appmodule.service.AppModuleImpl

□ passivateState(int, byte[]) : int
□ passivateState(int, byte[], int) : int
□ passivateStateForUndo(String, byte[], int) : String
□ prepareAccessorViewObjects(ViewObject, Row, St
□ prepareApplicationModuleSession(Session) : void
□ prepareForActivation(Element) : void
□ prepareForPassivation(Document, Element) : void
□ prepareSession(Session) : void
☑ prepareSession(SessionData) : void
□ prepareViewObjects(String[], String[][], LocaleCon
□ processChangeNotifications() : void

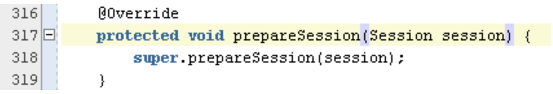
□ Copy Javadoc

6. Click **OK**.

What Happens When You Override a Built-in Framework Method

When you dismiss the Override Methods dialog, you return to the source editor with the cursor focus on the overridden method, as shown in Figure 13-27. Notice that the method appears with a single line that calls `super.prepareSession()`. This is the syntax in Java for invoking the default behavior that the base class would have normally performed for this method. By adding code before or after this line in the custom application module class, you can augment the default behavior before or after the default functionality.

Figure 13-27   Source Editor Margin Gives Visual Feedback About Overridden Methods



```
    @Override
    protected void prepareSession(Session session) {
        super.prepareSession(session);
    }
```

Also notice that when you override a method using the Override Methods dialog, the source editor inserts the JDK `@Override` annotation just before the overridden method. This causes the compiler to generate a compile-time error if the method in the application module class does not match the signature of any method in the superclass.

Be careful when you add method names to your class to override a method in the superclass; you must have the signature *exactly* the same as the base class method you want to override. Be sure to add the `@Override` annotation just before the method. This way, if your method does not match the signature of any method in the superclass, the compiler will generate a compile-time error. Also, when you write code for a method instead of calling the superclass implementation, you should have a thorough understanding of what built-in code you are suppressing or replacing.

How to Override prepareSession() to Set Up an Application Module for a New User Session

Since the `prepareSession()` method is invoked by the application module when it is used for the first time by a new user session, it's a useful method to override in your custom application module class to perform setup tasks that are specific to each new user that uses your application module. The following example illustrates an overridden `prepareSession()` method in the `AppModuleImpl` class that invokes a `setApplicationInfo()` helper method to specify database client information for the connected user.

```
public class AppModuleImpl extends SummitApplicationModuleImpl
                           implements AppModule {
...

    @Override
    protected void prepareSession(Session session) {
        super.prepareSession(session);
        setApplicationInfo ("AppModuleImpl", "prepareSession");
        String username = this.getUserPrincipalName();
        System.out.println(username);
    }

    protected void setApplicationInfo(String clientInfo, String clientIdentifier)
{
        DBTransactionImpl dbti = (DBTransactionImpl)getDBTransaction();
        CallableStatement statement =
            dbti.createCallableStatement("BEGIN "
          + "DBMS_APPLICATION_INFO.SET_CLIENT_INFO (client_info
=> :client_info);"
          + "DBMS_SESSION.SET_IDENTIFIER (:client_identifier);"
          + "END;", 0);
        try {
            statement.setString("client_info", clientInfo);
            statement.setString("client_identifier", clientIdentifier);
            statement.execute();
        } catch (SQLException sqlerr) {
            throw new JboException(sqlerr);
        } finally {
            try {
                if (statement != null) {
                    statement.close();
                }
            } catch (SQLException closeerr) {
                throw new JboException(closeerr);
            }
        }
    }
}
```

Calling a Web Service from an Application Module

Use the built-in web services wizard to create a proxy class, implement methods in this class, and use it to call web service methods in an ADF Application Module.

In a service-oriented architecture, your Oracle ADF application module may need to take advantage of functionality offered by a web service that is not based on an application module. A web service can be implemented in any programming language and can reside on any server on the network. Each web service identifies the methods in its API by describing them in a standard, language-neutral XML format. This XML document, whose syntax adheres to the Web Services Description Language (WSDL), enables JDeveloper to understand the names of the web service's methods, as well as the data types of the parameters they might expect and their eventual return value.

> **Note:**
>
> Application modules can also be exposed as web services so that they can be consumed across modules of the deployed Fusion web application. For details about reusing ADF Business Components using external services, see Creating SOAP Web Services with Application Modules.

JDeveloper's built-in web services wizards make this an easy task. Create a web service proxy class using the wizard, then call the service using method calls you add to a local Java object.

How to Call an External Service Programmatically

To call a web service from an application module, you create a web service proxy class for the service you want to invoke. A web service proxy is a generated Java class that represents the web service inside your application. It encapsulates the service URL of the web service and handles the lower-level details of making the call.

To work with a web service, you need to know the URL that identifies its WSDL document. If you have received the WSDL document as an email attachment, for example, and saved it to your local hard drive, the URL could be similar to:

```
file:///D:/temp/SomeService.wsdl
```

Alternatively, the URL could be an HTTP-based URL like:

```
http://someserver.somecompany.com/SomeService/SomeService.wsdl
```

Some web services make their WSDL document available by using a special parameter to modify the service URL. For example, a web service that expects to receive requests at the HTTP address of `http://someserver.somecompany.com/SomeService` might publish the corresponding WSDL document using the same URL with an additional parameter on the end, like this:

```
http://someserver.somecompany.com/SomeService?WSDL
```

Since there is no established standard, you will just need to know what the correct URL to the WSDL document is. With the URL information, you can then create a web service proxy class to call the service.

ADF Business Components services have URLs to the service of the following formats:

- On Integrated WebLogic Server, the URL has the format *`http://host:port/EJB-context-root/@WebService-name?WSDL`*, for example:

  ```
  http://localhost:8888/EJB-SummitService/SummitService?WSDL
  ```

- On Oracle WebLogic Server, the URL has the format *`http://host:port/context-root/@WebService-name?WSDL`*, for example:

  ```
  http://localhost:8888/SummitService/SummitService?WSDL
  ```

The web service proxy class presents a set of Java methods that correspond to the web service's public API. By using the web service proxy class, you can call any method in the web service in the same way as you work with the methods of any other local Java class.

To call a web service from an application module using a proxy class, you perform the following tasks:

1. Create a web service proxy class for the web service. To create a web service proxy class for a web service that you need to call, use the Create Web Service Client and Proxy wizard.
2. Implement the methods in the proxy class to access the desired web services.
3. Create an instance of the web service proxy class in your application module and invoke one or more methods on the web service proxy object.

Creating a Web Service Proxy Class to Programmatically Access the Service

To create a web service proxy class for a web service you need to call, use the Create Web Service Proxy wizard.

Before you begin:

It may be helpful to have an understanding of web services. For more information, see Calling a Web Service from an Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

To create a web service proxy class to programmatically access the service:

1. In the Applications window, right-click the project in which you want to create the web service proxy and choose **New** and then **Web Service Client and Proxy**.
2. In the Create Web Service Client and Proxy wizard, on the Select Web Service Description page, enter the URL for the WSDL of the service you want to call in your application, and then tab out of the field.

   When the wizard displays **Next** enabled, then JDeveloper has recognized and validated the WSDL document. If the **Next** button is not enabled, fix the problem after verifying the URL and repeat this step.

3. Continue through the pages of the wizard to specify details about the web service proxy.
4. Click **Finish**.

Calling the Web Service Proxy Template to Invoke the Service

After you create the web service proxy, you must implement the methods in the proxy class to access the desired web services.

Before you begin:

It may be helpful to have an understanding of web services. For more information, see Calling a Web Service from an Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

You will need to complete this task:

> Create the desired web service proxy class, as described in Creating a Web Service Proxy Class to Programmatically Access the Service.

To call the web service proxy template to invoke the service:

1. Open the proxy client class, called `*port_name*Client.java`, in the source editor, and locate the comment `// Add your own code to call the desired methods`, which is in the main method.
2. Add the appropriate code to invoke the web service.
3. Deploy the full set of client module classes that JDeveloper has generated, and reference this class in your application.

Calling a Web Service Method Using the Proxy Class in an Application Module

After you've generated the web service proxy class, you can use it inside a custom method of your application module, as shown in the following example. The method creates an instance of the web service proxy class and calls the web service method from the web service proxy class for the result.

```
// In YourModuleImpl.java
public void performSomeApplicationTask(String symbol) throws Exception {
  // application-specific code here
   :
  // Create an instance of the web service proxy class
  StockQuoteServiceSoapHttpPortClient svc =
            new StockQuoteServiceSoapHttpPortClient();
  // Call a method on the web service proxy class and get the result
  QuoteInfo quote = svc.quoteForSymbol(symbol);
  float currentPrice = quote.getPrice();
  // more application-specific code here
}
```

What Happens When You Create the Web Service Proxy

JDeveloper generates the web service proxy class in the package you've indicated with a name that reflects the name of the web service port it discovered in the WSDL document. The web service port name might be a human-readable name like `StockQuoteService`, or could be a less-friendly name like `StockQuoteServiceSoapHttpPort`. The port name is decided by the developer that published the web service you are using. If the port name of the service were `StockQuoteServiceSoapHttpPort`, for example, JDeveloper would generate a web proxy class named `StockQuoteServiceSoapHttpPortClient`.

The web service proxy displays in the Applications window as a single, logical node called *`WebServiceName`*`Proxy`. For example, the node for the `StockQuoteService` web service would appear in the Applications window with the name `StockQuoteServiceProxy`. As part of generating the proxy class, in addition to the main web service proxy class that you use to invoke the server, JDeveloper generates a number of auxiliary classes and interfaces. You can see these files in the Applications window under the *`WebServiceName`*`Proxy` node. The generated files are used as part of the lower-level implementation of invoking the web service.

The only auxiliary generated classes you need to reference are those created to hold structured web service parameters or return types. For example, imagine that the `StockQuoteService` web service has a `quoteForSymbol()` method that accepts one `String` parameter and returns a floating-point value indicating the current price of the stock. If the designer of the web service chose to return a simple floating-point number, then the web service proxy class would have a corresponding method like this:

```
public float quoteForSymbol(String symbol)
```

If instead the designer of the web service thought it useful to return multiple pieces of information as the result, then the service's WSDL file would include a named structure definition describing the multiple elements it contains. For example, assume that the service returns both the symbol name and the current price as a result. To contain these two data elements, the WSDL file might define a structure named `QuoteInfo` with an element named `symbol` of string type and an element named `price` of floating-point type. In this situation, when JDeveloper generates the web service proxy class, the Java method signature would instead look like this:

```
public QuoteInfo quoteForSymbol(String symbol)
```

The `QuoteInfo` return type references one of the auxiliary classes that comprises the web service proxy implementation. It is a simple bean whose properties reflect the names and types of the structure defined in the WSDL document. In a similar way, if the web service accepts parameters whose values are structures or arrays of structures, then you will work with these structures in your Java code using the corresponding generated beans.

How to Create a New Web Service Connection

After developing a web service proxy, you can generate additional connections for the proxy that you can use in testing and deployment situations. For example, you might want to create a connection that includes user name and password for testing purposes.

The connection information is stored in the `connections.xml` file along with the other connections in your application. This abstraction of the endpoint URL also allows you to edit the connection after deployment using Enterprise Manager without requiring modification to the client code.

Before you begin:

It may be helpful to have an understanding of web services. For more information, see Calling a Web Service from an Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Application Modules.

To create a new web service connection:

1. In the Applications window, right-click a web service proxy and choose **Create ADF Web Service Connection**.

   The New ADF Web Service Connection dialog displays the default settings for a connection associated with the selected proxy.

2. Modify the connection information as necessary, and click **OK**.

> **WARNING:**
>
> If you create a new web service connection with the same name as an existing connection, the existing connection will be overwritten with the new information.

After you create a new web service connection, you can modify your client to use this connection. You could use code similar to that shown in the following example to access the connection from your client.

```
Context ctx = ADFContext.getCurrent().getConnectionsContext();

WebServiceConnection wsc = (WebServiceConnection) ctx.lookup("MyAppModuleService");

MyAppModuleService proxy = wsc.getJaxWSPort(MyAppModuleService.class);
```

The argument that you pass to the `lookup()` method is the name that you gave to the web service connection. In this example, it is `MyAppModuleService`.

What Happens at Runtime: How the Web Service Proxy Handles a Web Service Invocation

When you invoke a web service from an application module, the web service proxy class handles the lower-level details of using the XML-based web services protocol described in SOAP. In particular, it does the following:

- Creates an XML document to represent the method invocation
- Packages any method arguments in XML
- Sends the XML document to the service URL using an `HTTP POST` request
- Unpackages the XML-encoded response from the web service

If the method you invoke has a return value, your code receives it as an appropriately typed object to work with in your application module code.

What You May Need to Know About Web Service Proxies

When you are implementing web service proxies in an application, you might want to use a try-catch block to handle web service exceptions or invoke an application module with a web service proxy class. The following sections contain additional information you might need to know about these and other features with regard to web service proxies.

Using a Try-Catch Block to Handle Web Service Exceptions

By using the generated web service proxy class, invoking a remote web service becomes as easy as calling a method in a local Java class. The only distinction to be aware of is that the web service method call could fail if there is a problem with the HTTP request involved. The method calls that you perform against a web service proxy should anticipate the possibility that the request might fail by wrapping the call with an appropriate `try...catch` block. The following example improves on the simpler example (shown in Calling a Web Service Method Using the Proxy Class in an Application Module) by catching the web service exception. In this case, it simply rethrows the error as a `JboException`, but you could implement more appropriate error handling in your own application.

```
// In YourModuleImpl.java
public void performSomeApplicationTask(String symbol) {
  // application-specific code here
  // :
  QuoteInfo quote = null;
  try {
    // Create an instance of the web service proxy class
    StockQuoteServiceSoapHttpPortClient svc =
               new StockQuoteServiceSoapHttpPortClient();
    // Call a method on the web service proxy class and get the result
    quote = svc.quoteForSymbol(symbol);
  }
  catch (Exception ex) {
    throw new JboException(ex);
  }
  float currentPrice = quote.getPrice();
  // more application-specific code here
}
```

Separating Application Module and Web Services Transactions

You will use some web services to access reference information. However, other services you call may modify data. This data modification might be in your own company's database if the service was written by a member of your own team or another team in your company. If the web service is outside your firewall, of course the database being modified will be managed by another company.

In either of these situations, it is important to understand that any data modifications performed by a web service you invoke will occur in their own distinct transaction, unrelated to the application module's current unit of work. For example, if you have invoked a web service that modifies data and then you later call `rollback()` to cancel the pending changes in the application module's current unit of work, this has no effect on the changes performed by the web service you called in the process. You may need to invoke a corresponding web service method to perform a compensating change to account for your rollback of the application module's transaction.

Setting Browser Proxy Information

If the web service you need to call resides outside your corporate firewall, you need to ensure that you have set the appropriate Java system properties to configure the use of an HTTP proxy server. The Java system properties to configure are:

- `http.proxyHost` — Set this to the name of the proxy server.
- `http.proxyPort` — Set this to the HTTP port number of the proxy server (often 80).
- `http.nonProxyHosts` — Optionally set this to a vertical-bar-separated list of servers not requiring the user of a proxy server (for example, `localhost|127.0.0.1|*.`*`yourcompany`*`.com`).

Within JDeveloper, you can configure an HTTP proxy server on the Web Browser and Proxy page of the Preferences dialog. When you run your application, JDeveloper includes appropriate `-D` command-line options to set these three system properties based on the settings you've indicated in this dialog.

Invoking Application Modules with a Web Service Proxy Class

If you use a web service proxy class to invoke an Oracle ADF service-based application module, you lose the ability to optimize the call when the calling component and the service you are calling are colocated. As an alternative, you can use the service interface approach described in Creating SOAP Web Services with Application Modules.

14 Sharing Application Module View Instances

This describes how to organize your ADF Business Components data model project to most efficiently share read-only data accessed from lookup tables or other static data source, such as a flat file. It describes the differences between ADF application modules that you may share at the application level and those that you may share at the session level.
This chapter includes the following sections:

About Shared Application Modules

You can create a shared ADF Business Components application module to allow multiple requests from multiple sessions to share a single application module. It helps prevent unnecessary overhead of repopulating data caches.

Web applications often utilize data that is required across sessions and does not change very frequently. An example of this type of **static data** might be displayed in the application user interface in a lookup list. Each time your application accesses the static data, you could incur an unnecessary overhead when the static data caches are repopulated from the database for each application session on every request. In order to optimize performance, a common practice when working with **ADF Business Components** is to cache the shared static data for reuse across sessions and requests. Creating a **shared application module** allows requests from multiple sessions to share a single application module instance which is managed by an application pool for the lifetime of the web server virtual machine.

Shared Application Module Use Cases and Examples

A **view accessor** in ADF Business Components is a value accessor object that points from an **entity object** attribute (or view object) to a destination **view object** or shared view instance in the same application workspace.

This ability to access view objects in different application modules makes **view accessors** particularly useful for:

- Validation rules that you set on the attributes of an entity object. For example, when the end user fills out a registration form, individual validation rules can verify the title, marital status, and contact code against lookup table data queried by view instances of the shared application module.
- List of Value (LOV) that you enable for the attribute of any view object. For example, to display a list of values to the end user at runtime.

Additional Functionality for Shared Application Modules

You may find it helpful to understand other **Oracle ADF** features before you start working with shared application modules. Following are links to other functionality that may be of interest.

- For details about configuring application module instances to improve runtime performance, see Using State Management in a Fusion Web Application and Tuning Application Module Pools.
- For a quick reference to the most common code that you will typically write, use, and override in your custom application module classes, see Most Commonly Used ADF Business Components Methods.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Sharing an Application Module Instance

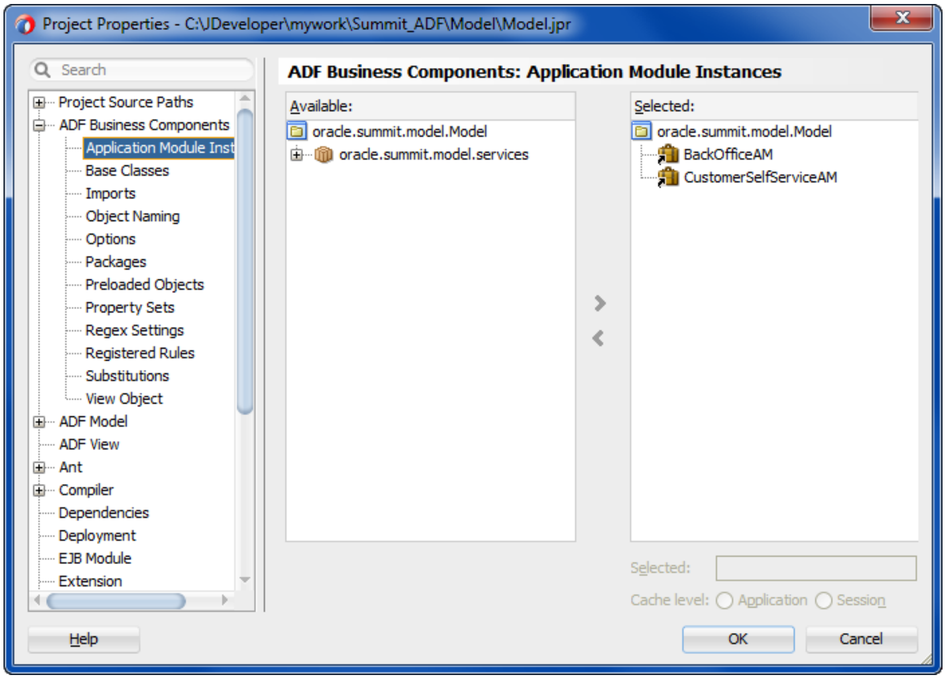
JDeveloper allows you to specify application-level or session-level ADF application module data model sharing.

Declarative support for shared data caches is available in JDeveloper through the Project Properties dialog. Creating a shared application module allows requests from multiple sessions to share a single application module instance which is managed by an application pool for the lifetime of the web server virtual machine.

> **Best Practice:**
>
> Use a shared application module to group view instances when you want to reuse lists of static data across the application. The shared application module can be configured to allow any user session to access the data or it can be configured to restrict access to just the UI components of a single user session. For example, you can use a shared application module to group view instances that access lookup data, such as a list of countries. The use of a shared application module allows all shared resources to be managed in a single place and does not require a scoped managed bean for this purpose.

As shown in Figure 14-1, the Project Properties dialog lets you specify application-level or session-level sharing of the application module's data model. In the case of **application-level sharing**, any HTTP user session will be able to access the same view instances contained in the shared application module. In contrast, the lifecycle of the **session-level shared** application module extends to an application module session (`SessionImpl`) that is in use by a single HTTP user session and applies to a single **root application module**. In this case, each distinct *root* application module used by a given HTTP user session will get its own distinct instance of a session-scoped shared application module. In other words, distinct root application modules used by the same HTTP session do not share data in a session-scoped shared application module.

Figure 14-1 Project Properties Dialog Defines Shared Application Module Instance



When you create the data model for the application module that you intend to share, be sure that the data in cached row sets will not need to be changed either at the application level or session level. For example, in the application-level shared application module, view instances should query only static data such as state codes or currency types. If a view object instance queries data that depends on the current user, then the query can be cached at the session level and shared by all components that reference the row-set cache. For example, the session-level shared application module might contain a view instance with data security that takes a manager as the current user to return the list of direct reports. In this case, the cache of direct reports would exist for the duration of the manager's HTTP user session. The ADF Business Components **application module pool** will re-create the session-scoped application module should an HTTP user session be assigned a recycled application module from the pool. This ensures that the duration of the session-scoped application module is tied to the HTTP session for as long as the HTTP session is able to continue to use the same root application module instance. Note that the cache of direct reports of the session-level shared application module cannot be accessed across distinct root application modules.

How to Create a Shared Application Module Instance

To create a shared application module instance, use the Project Properties dialog. You define a logical name for a distinct, separate root application module that will hold your application's read-only data.

Before you begin:

It may be helpful to have an understanding of lookup data. For more information, see Defining a Base View Object for Use with Lookup Tables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Shared Application Modules.

You will need to complete this task:

> Create the application module that you will share, as described in How to Create an Application Module.

To create a shared application module instance:

1. In the Application window, right-click the project in which you want to create the shared application module and choose **Project Properties**.
2. In the Project Properties dialog, expand **ADF Business Components** and select **Application Module Instances**.
3. On the ADF Business Components: Application Module Instances page, select one of these tabs:
    - When you want to define the shared application module for the context of the application, select the **Application** tab.
    - When you want to define the shared application module for the context of the current user session, select the **Session** tab
4. In the **Available Application Modules** list, select the desired application module and shuttle it to the **Application Module Instances** list.
5. Assign the application module a unique instance name.

    The shared application module instance (of either scope) must have a unique instance name. Supplying a meaningful name will also help to clarify which shared application module instance a given usage is referencing.
6. Click **OK**.

What Happens When You Define a Shared Application Module

JDeveloper automatically creates the `*AppModuleName*Shared` configuration when you create an application module. The presence of this configuration in the `bc4j.xcfg` file informs JDeveloper that the application module is a candidate to be shared, and allows JDeveloper to display the application module in the **Available Application Modules** list of the Project Properties dialog's Application Module Usage page.

The `*AppModuleName*Shared` configuration sets these properties on the application module to enable sharing and help to maintain efficient use of the shared resource at runtime:

- `jbo.ampool.isuseexclusive` is set to `false` to specify that requests from multiple sessions can share a single instance of the application module, which is managed by the application pool for the lifetime of the web server virtual machine. When you do not enable application module sharing, JDeveloper sets the value `true` to repopulate the data caches from the database for each application session on every request.
- `jbo.ampool.maxpoolsize` is set to `1` (one) to specify that only a single application module instance will be created for the ADF Business Components application module pool. This setting enforces the efficient use of the shared application module resource and prevents unneeded multiple instances of the shared application module from being created at runtime.

You can view the shared application module's configuration by opening the application module in the overview editor and choosing **Configurations** from the navigation menu. JDeveloper saves the bc4j.xcfg file in the ./common subdirectory relative to the application module's XML document. If you remove the configuration or modify the values of the jbo.ampool runtime properties (isuseexclusive, maxpoolsize), the application module will not be available to use as a shared application module instance.

For example, if you look at the bc4j.xcfg file in the ./src/oracle/summit/model/services/common directory of the SummitADF application workspace, you will see the two named configurations for the BackOfficeAppModule application module, as shown in the following example. Specifically, the BackOfficeAppModuleShared configuration sets the jbo.ampool runtime properties on the shared application module instance. For more information about the ADF Business Components application module pooling and runtime configuration of application modules, see Tuning Application Module Pools.

```
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
...
   <AppModuleConfigBag
      ApplicationName="oracle.summit.model.services.BackOfficeAppModule">
      <AppModuleConfig
            name="BackOfficeAppModuleLocal"
            jbo.project="oracle.summit.model.Model"
            ApplicationName="oracle.summit.model.services.BackOfficeAppModule"
            DeployPlatform="LOCAL" JDBCName="summit_adf">
         <Database jbo.TypeMapEntries="Java"/>
         <Security

AppModuleJndiName="oracle.summit.model.services.BackOfficeAppModule"/>
      </AppModuleConfig>
      <AppModuleConfig
            name="BackOfficeAppModuleShared"
            jbo.project="oracle.summit.model.Model"
            ApplicationName="oracle.summit.model.services.BackOfficeAppModule"
            DeployPlatform="LOCAL" JDBCName="summit_adf">
         <AM-Pooling jbo.ampool.maxpoolsize="1"
                  jbo.ampool.isuseexclusive="false"/>
         <Database jbo.TypeMapEntries="Java"/>
         <Security

AppModuleJndiName="oracle.summit.model.services.BackOfficeAppModule"/>
      </AppModuleConfig>
   </AppModuleConfigBag>
</BC4JConfig>
```

Because the shared application module can be accessed by any data model project (based on ADF Business Components) in the same application workspace, JDeveloper maintains the scope of the shared application module in the ADF Business Components project configuration file (.jpx). This file is saved in the src directory of the project. For example, if you look at the Model.jpx file in the ./src directory of the application's Model project, you will see that the SharedLookupService application module's usage definition specifies SharedScope = 2, corresponding to application-level sharing, as shown in the following example. An application module that you set to session-level sharing will show SharedScope = 1.

```
<JboProject
   xmlns="http://xmlns.oracle.com/bc4j"
   Name="Model"
   SeparateXMLFiles="true"
   PackageName="oracle.summit.model">
   . . .
   <AppModuleUsage
      Name="SharedLookupService"
      FullName="oracle.summit.model.services.BackOfficeAppModule"
      ConfigurationName="oracle.summit.model.services.BackOfficeAppModuleShared"
      SharedScope="2"/>
</JboProject>
```

What You May Need to Know About Design Time Scope of the Shared Application Module

Defining the shared application module in the Project Properties dialog makes the application module's data model available to other data model projects of the same application workspace only. When you want to make the data model available beyond the application workspace, you can publish the data model as an ADF Library, as described in Reusing Application Components .

When viewing a **data control** usage from the `DataBindings.cpx` file in the Structure window, do not set the **Configuration** property to a shared application module configuration. By default, for an application module named ***AppModuleName***, the Property window will list the configurations named ***AppModuleName*****Shared** and ***AppModuleName*****Local**. At runtime, Oracle Application Development Framework (Oracle ADF) uses the shared configuration automatically when you configure an application as a shared application module, but the configuration is not designed to be used by an **application module data control** usage. For more information about data control usage, see Working with the DataBindings.cpx File .

What You May Need to Know About the Design Time Scope of View Instances of the Shared Application Module

You define view accessors on the business component definition for the data model project that will permit access to view instances of the shared application module. The view accessor lets you point from an entity object or view object definition in one data model project to a view object definition or view instance in a shared application module. For details about creating view accessors for this purpose, see Accessing View Instances of the Shared Service.

What You May Need to Know About Managing the Number of Shared Query Collections

Similar to the way application module pooling works in ADF Business Components, shared query collections are stored in a query collection pool. To manage the query collection pool, the ADF Business Components framework removes query collections based on a maximum idle time setting. This behavior limits the growth of the cache and prevents rarely used query collections from occupying memory space.

As in application module and connection pooling, a query collection pool monitor wakes up after a user-specified sleep interval and then initiates the cleanup operation. Any query collection that exceeds the maximum idle time (length of time since it was last used), will be removed from the pool.

You can change the default values for the maximum idle time for the shared query collection (default is 900000 ms/15 min) and the sleep period for its pool monitor (default is 1800000 ms/30 min). You use the overview editor for application module configurations (on the bc4j.xcfg file) to configure these values on the selected ***AppModuleName*****Shared** configuration.

To display the application module configuration overview editor, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the shared configuration hyperlink. In the application module configuration overview editor, select the **Properties** tab and click **Add Property** to select the following properties from the Add Property dialog and click **OK**.

- jbo.qcpool.monitorsleepinterval
- jbo.qcpool.maxinactiveage

Then, in the **Properties** list enter the desired idle time and sleep period in milliseconds:

- jbo.qcpool.monitorsleepinterval the time (ms) that the shared query collection pool monitor should sleep between pool checks.
- jbo.qcpool.maxinactiveage the maximum amount of time (ms) that a shared query collection may remain unused before it is removed from the pool.

What You May Need to Know About Shared Application Modules and Connection Pooling

The default connection behavior for all application modules is to allow each root application module to have its own database connection. When your application defines more than one shared application module, you can configure the application to nest them under the same transaction in order to use a single database connection. This optimization allows the shared application module instances to share the same connection and entity cache and reduces the database resources that the application uses. This is particularly useful for shared application modules cases because they are read only and have longer life than transactional application modules.

> **Best Practice:**
>
> Oracle recommends nesting shared application module instances under a single transaction to reduce the database resources required by the application. You can make this shared application module optimization by setting the jbo.shared.txn property to use the same transaction name (an arbitrary identifier you supply) for each shared application module configuration the application defines.

Set the jbo.shared.txn property using the overview editor for application module configurations (on the bc4j.xcfg file). To display the application module configuration overview editor, double-click the shared application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink. In the application module configuration overview editor, select the **Properties** tab and click

Add Property to select the following property from the Add Property dialog and click **OK**.

- `jbo.shared.txn`

Then, in the **Properties** list enter the transaction name (where `SharedAMOptimization` is an arbitrary name) for the property:

- `jbo.shared.txn` = `SharedAMOptimization`

Repeat the `jbo.shared.txn` property setting using the same transaction name for each shared application module configuration that your application defines.

Currently, the application module configuration parameter `jbo.doconnectionpooling=true` is not supported for use with shared application modules. This feature is available to configure nonshared application modules when it is desirable to release JDBC connection objects to the database connection pool.

This feature is intentionally not supported for shared application modules to prevent decreases in performance that would result from managing state for shared access. Instead, the default use of `jbo.doconnectionpooling=false` is enforced.

The default connection pooling configuration ensures that each shared application module instance holds onto the JDBC connection object that it acquires from the pool until the application module instance is removed from the application module pool. For more information about the `jbo.doconnectionpooling` parameter and connection pool behavior, see Deployment Environment Scenarios and Pooling.

Defining a Base View Object for Use with Lookup Tables

Use an ADF application module to access static data that has been defined in a database lookup table. An ADF Business Components shared application module accesses such lookup tables to display static data.

When your application needs to display static data, you can define a shared application module with view instances that most likely will access lookup tables. A lookup table is a static, translated list of data to which the application refers. Lookup table data can be organized in the database in various ways. While it is possible to store related lookup data in separate tables, it is often convenient to combine all of the lookup information for your application within a single table. For example, a column `LOOKUP_TYPE` created for the `ORDERS_LOOKUPS` table would serve to partition one table that might contain diverse codes such as `FWK_TBX_YES_NO` for the values yes and no, `FWK_TBX_COUNTRY` for country names, and `FWK_TBK_CURRENCY` for the names of national currencies.

When your database schema organizes lookup data in a single database table, you want to avoid creating individual queries for each set of data. Instead, you will use the overview editor to define a single, base view object that maps the desired columns of the lookup table to the view object attributes you define. Since only the value of the `LOOKUP_TYPE` column will need to change in the query statement, you can add **view criteria** on the view object definition to specify a `WHERE` clause that will set the `LOOKUP_TYPE` value. In this way, your application encapsulates access to the lookup table data in a single view object definition that will be easy to maintain when a `LOOKUP_TYPE` value changes or your application needs to query additional lookup types.

How to Create a Base View Object Definition for a Lookup Table

The base view object that queries columns of the lookup table will be a read-only view object, since you do not need to handle updating data or require any of the benefits provided by entity-based view objects. (For a description of those benefits, see About View Objects.)

> **Note:**
>
> While read-only view objects you create to access lookup tables are ideal for inclusion in a shared application module, if you intend to share the view object in a shared application module instance, you must create the view object in the same package as the shared application module.

To create a read-only view object, use the Create View Object wizard, which is available from the New Gallery.

Before you begin:

It may be helpful to have an understanding of lookup data. For more information, see Defining a Base View Object for Use with Lookup Tables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Shared Application Modules.

You will need to complete this task:

Create the application module that you will share, as described in How to Create an Application Module.

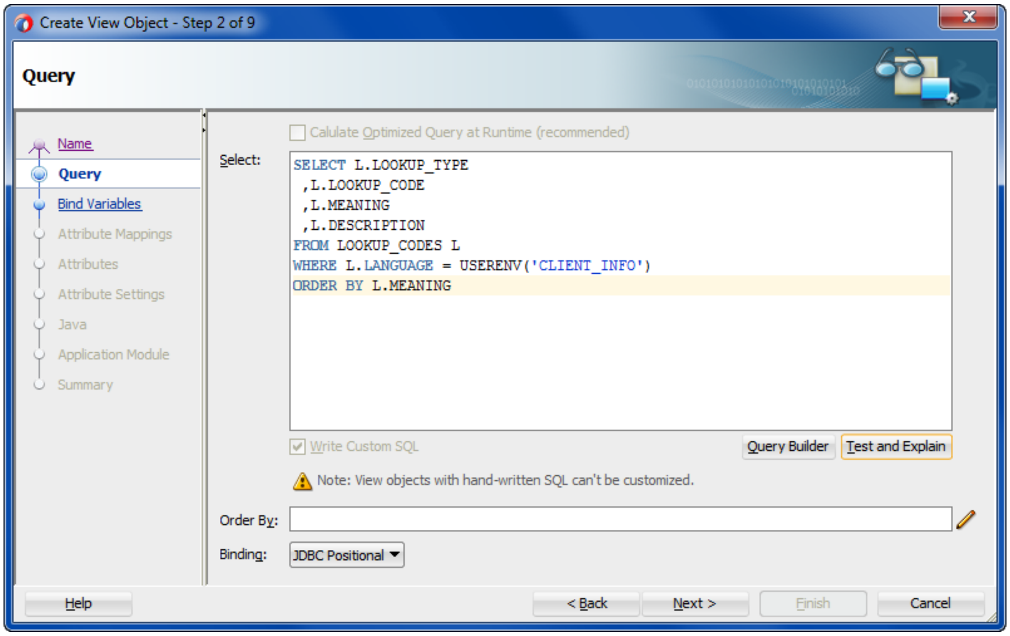
To create a base view object for a lookup table:

1. In the Application window, locate the shared application module, right-click its package node, and choose **New** and then **View Object**.
2. In the Create View Object wizard, on the Name page, enter a package name and a view object name.

   When naming the package, consider creating a separate package for the lookup.
3. Select **Custom SQL query** to indicate that you want this view object to manage data with read-only access and click **Next**.
4. On the Query page, enter your SQL statement directly into the **Select** text box.

   Your query names the columns of the lookup table, and should look similar to the SQL statement shown in Figure 14-2 which queries the `LOOKUP_CODE`, `MEANING`, and `DESCRIPTION` columns in the `LOOKUP_CODES` table.

Figure 14-2 Create View Object Wizard, SQL Query for Lookup Table



☐ Calulate Optimized Query at Runtime (recommended)

Select:

```
SELECT L.LOOKUP_TYPE
 ,L.LOOKUP_CODE
 ,L.MEANING
 ,L.DESCRIPTION
FROM LOOKUP_CODES L
WHERE L.LANGUAGE = USERENV('CLIENT_INFO')
ORDER BY L.MEANING
```

☑ Write Custom SQL

Note: View objects with hand-written SQL can't be customized.

Order By:

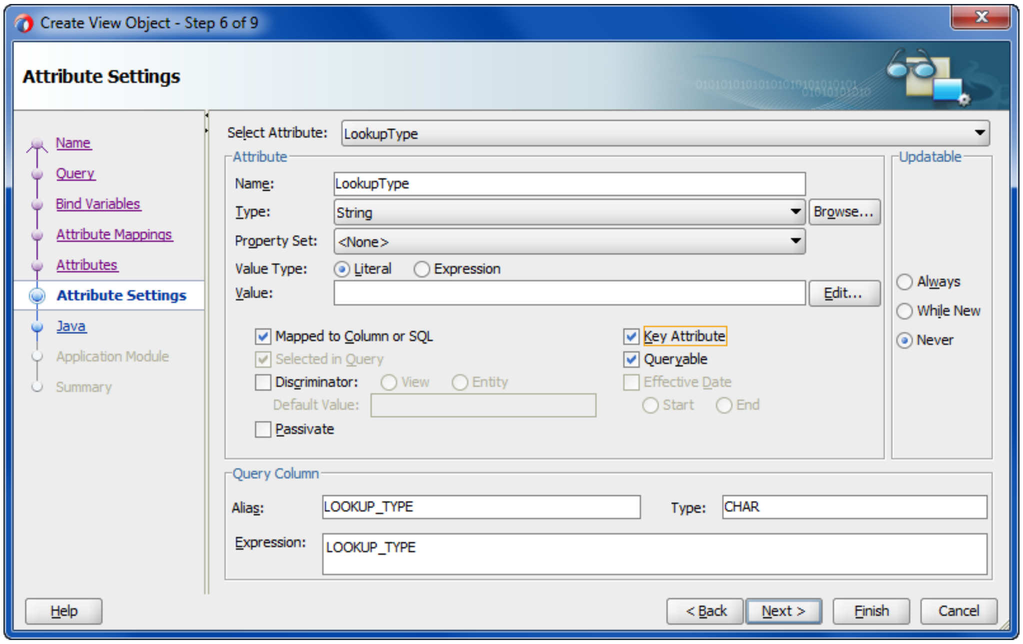
Binding: JDBC Positional

5. After entering the query statement, no other changes are required. Click **Next**.
6. On the Bind Variables page, click **Next**.
7. On the Attribute Mappings page, note the mapped view object attribute names displayed and click **Next**.

   By default, the wizard creates Java-friendly view object attribute names that correspond to the `SELECT` list column names.
8. On the Attribute Settings page, from the **Select Attribute** dropdown, select the attribute that corresponds to the primary key of the queried table and then enable the **Key Attribute** checkbox.

   Because the read-only view object is not based on an entity object, the Create View Object wizard does not define a key attribute by default. Failure to define the key attribute can result in unexpected runtime behavior for **ADF Faces** components with a data control based on the read-only view object collection. In the case of read-only view objects, define the key attribute, as shown in Figure 14-3.

Figure 14-3 Create View Object Wizard, Attribute Settings Page



Select Attribute: LookupType

Attribute

Name: LookupType

Type: String

Property Set: <None>

Value Type: ● Literal ○ Expression

Value:

☑ Mapped to Column or SQL

☑ Selected in Query

□ Discriminator: ○ View ○ Entity

Default Value:

□ Passivate

☑ Key Attribute

☑ Queryable

□ Effective Date

○ Start ○ End

Updatable

○ Always

○ While New

● Never

Query Column

Alias: LOOKUP_TYPE

Type: CHAR

Expression: LOOKUP_TYPE

9. If you want to rename individual attributes to use names that might be more appropriate, from the **Select Attributes** dropdown, choose the attribute and enter the desired name in the **Name** field. When you are finished, click **Next**.

   For example, you might rename the default attributes `LookupType` and `LookupCode` to `Type` and `Value` respectively. Changes you make to the view object definition will not change the underlying query.

10. On the Java page, click **Next**.

11. On the Application Module page, do not add an instance of the view object to the application module data model. Click **Finish**.

    The shared **application module data model** will include view instances based on view criteria that you add to the base view object definition. In this way, you do not need to create an individual view object to query each `LOOKUP_TYPE` value. For details about adding the view object instances to the data model, see Adding Master-Detail View Object Instances to an Application Module.

What Happens When You Create a Base View Object

When you create the view object definition for the lookup table, JDeveloper first describes the query to infer the following from the columns in the `SELECT` list:

- The Java-friendly view attribute names (for example, `LookupType` instead of `LOOKUP_TYPE`)

  By default, the wizard creates Java-friendly view object attribute names that correspond to the `SELECT` list column names.

- The SQL and Java data types of each attribute

JDeveloper then creates the XML document file that represents the view objects's declarative settings and saves it in the directory that corresponds to the name of its package. For example, the XML file created for a view object named `LookupsBaseVO` in the lookups package is ./lookups/LookupsBaseVO.xml under the project's source path.

To view the view object settings, expand the desired view object in the Application window, select the XML file under the expanded view object, and open the Structure window. The Structure window displays the list of definitions, including the SQL query and the properties of each attribute. To open the file in the editor, double-click the corresponding **.xml** node. As shown in the following example, the LookupsBaseVO.xml file defines one <SQLQuery> definition and one <ViewAttribute> definition for each mapped column. Without a view criteria to filter the query results, the view object query returns the LOOKUP_CODE, LOOKUP_MEANING, and LOOKUP_DESCRIPTION and maps them to view instance attribute values for Value, Name, and Description respectively. Key attributes are defined to ensure proper row set navigation when the base view object collection is bound to an ADF Faces component.

```
<ViewObject
    xmlns="http://xmlns.oracle.com/bc4j"
    Name="LookupsBaseVO"
    BindingStyle="OracleName"

</ViewObject>
```

How to Define the WHERE Clause of the Lookup View Object Using View Criteria

You create named view criteria definitions in the data model project when you need to filter view object results. View criteria that you define at design time can participate in UI scenarios that require filtering of data.

Use the Edit View Criteria dialog to create the view criteria definition for the lookup base view object you defined to query the lookup table. The editor lets you build a `WHERE` clause using attribute name instead of the target view object's corresponding SQL column names. The resulting definition will include:

- One view criteria row consisting of one view criteria group, with a single view criteria item used to define the lookup view object's `Type` attribute.
- The view criteria item will consist of an `Type` attribute name, the Equal operator, and the value of the `LOOKUP_TYPE` that will filter the query results.

Because a single view criteria is defined, no logical conjunctions are needed to bracket the `WHERE` clause conditions.

Before you begin:

It may be helpful to have an understanding of lookup data. For more information, see Defining a Base View Object for Use with Lookup Tables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Shared Application Modules.

You may also find it helpful to have an understanding of view criteria. For more information, see Working with Named View Criteria.

You will need to complete this task:

Create the base view object for the lookup data, as described in How to Create a Base View Object Definition for a Lookup Table.

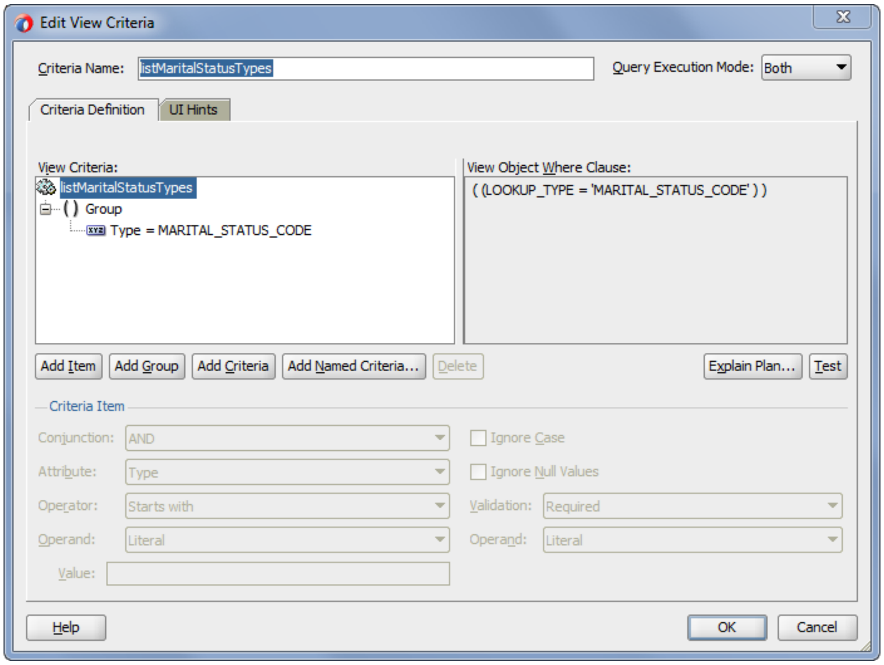
To create LOOKUP_TYPE view criteria for the lookup view object:

1. In the Application window, double-click the lookup base view object you defined.
2. In the overview editor, click the **View Criteria** navigation tab and click the **Create New View Criteria** button.
3. In the Create View Criteria dialog, on the View Criteria page, click the **Add Item** button to add a single criteria item to the view criteria group.
4. In the Criteria Item panel, define the criteria item as follows:
   - Choose **Type** as the attribute (or other name that you defined for the attribute the view object maps to the `LOOKUP_TYPE` column).
   - Choose **Equals** as the operator.
   - Keep **Literal** as the operand choice and enter the value name that defines the desired type. For example, to query the marital status codes, you might enter the value `MARITAL_STATUS_CODE` corresponding to the `LOOKUP_TYPE` column.

   Leave all other settings unchanged.

   The view object `WHERE` clause shown in the editor should display a simple criteria similar to the one shown in Figure 14-4, where the value `MARITAL_STATUS_CODE` is set to filter the `LOOKUP_TYPE` column.
5. Click **OK**.
6. Repeat this procedure to define one view criteria for each `LOOKUP_TYPE` that you wish to query.

Figure 14-4 Edit View Criteria Dialog with Lookup View Object View Criteria Specified



Criteria Name: listMaritalStatusTypes
Query Execution Mode: Both

View Criteria:
listMaritalStatusTypes
( ) Group
Type = MARITAL_STATUS_CODE

View Object Where Clause:
((LOOKUP_TYPE = 'MARITAL_STATUS_CODE'))

Conjunction: AND
Attribute: Type
Operator: Starts with
Operand: Literal
Value:
□ Ignore Case
□ Ignore Null Values
Validation: Required
Operand: Literal

What Happens When You Create a View Criteria with the Editor

The Create View Criteria dialog in JDeveloper lets you easily create view criteria and save them as named definitions. These named view criteria definitions add metadata to the target view object's own definition. Once defined, named view criteria appear by name in the View Criteria page of the overview editor for the view object.

JDeveloper then creates the XML document file that represents the view objects's declarative settings and saves it in the directory that corresponds to the name of its package. For example, the XML file created for a view object named `LookupsBaseVO` in the `lookups` package is `./lookups/LookupsBaseVO.xml` under the project's source path.

To view the view criteria, expand the desired view object in the Application window, select the XML file under the expanded view object, open the Structure window, and expand the View Criteria node. As shown in the following example, the `LookupsBaseVO.xml` file specifies the `<ViewCriteria>` definition that allows the `LookupsBaseVO` to return only the marital types. Other view criteria added to the `LookupsBaseVO` are omitted from this example for brevity.

```
<ViewObject
    xmlns="http://xmlns.oracle.com/bc4j"
    Name="LookupsBaseVO"
    BindingStyle="OracleName"
    CustomQuery="true"
    PageIterMode="Full"
    UseGlueCode="false">
  <SQLQuery>
    <![CDATA[SELECT L.LOOKUP_TYPE
     ,L.LOOKUP_CODE
     ,L.MEANING
     ,L.DESCRIPTION
     FROM LOOKUP_CODES L
     WHERE L.LANGUAGE = SYS_CONTEXT('USERENV','LANG')
     ORDER BY L.MEANING]]>
  </SQLQuery>
      ...
  <ViewCriteria
     Name="listMaritalStatusTypes"
     ViewObjectName="oracle.summit.model.lookups.LookupsBaseVO"
     Conjunction="AND"
     Mode="3"
     <Properties>
       <CustomProperties>
        <Property
          Name="autoExecute"
          Value="false"/>
        <Property
          Name="showInList"
          Value="true"/>
        <Property
          Name="mode"
          Value="Basic"/>
       </CustomProperties>
     </Properties>
     <ViewCriteriaRow
       Name="vcrow24">
       <ViewCriteriaItem
         Name="Type"
         ViewAttribute="Type"
         Operator="="
         Conjunction="AND"
         Value="MARITAL_STATUS_CODE"
         Required="Optional"/>
     </ViewCriteriaRow>
</ViewCriteria>
```

What Happens at Runtime: How a View Instance Accesses Lookup Data

When you create a view instance based on a view criteria, the next time the view instance is executed it augments its SQL query with an additional WHERE clause predicate corresponding to the view criteria that you've populated in the view criteria rows.

Accessing View Instances of the Shared Service

Use ADF Business Components view accessors to access view instances across shared application modules. You can set up validation rules or LOVs and use view accessors to access shared view instances.

View accessors in ADF Business Components are value accessor objects that point from an entity object attribute (or view object) to a destination view object or shared view instance in the same application workspace. The view accessor returns a row set that by default contains all rows from the destination view object. You can optionally filter this row set by applying view criteria to the view accessor. The base entity object or view object on which you create the view accessor and the destination view object need not be in the same project or application module, but they must be in the same application workspace.

Because view accessors give you the flexibility to reach across application modules to access the queried data, they are ideally suited for accessing view instances of shared application modules. For details about creating a data model of view instances for a shared application module, see How to Create a Shared Application Module Instance.

This ability to access view objects in different application modules makes view accessors particularly useful for:

- Validation rules that you set on the attributes of an entity object. In this case, the view accessor derives the validation rule's values from lookup data corresponding to a view instance attribute in the shared application module.
- List of Value (LOV) that you enable for the attribute of any view object. In this case, the view accessor derives the list of values from lookup data corresponding to a view instance attribute in the shared application module.

Validation rules with accessors are useful when you do not want the UI to display a list of values to the user, but you still need to restrict the list of valid values. Alternatively, consider defining an LOV for view object attributes to simplify the task of working with list controls in the user interface. Because you define the LOV on the individual attributes of business components, you can customize the LOV usage for an attribute once and expect to see the list control in the form wherever the attribute appears.

How to Create a View Accessor for an Entity Object or View Object

View accessors provide the means to access a data source independent of the application module. View accessors can be defined at the level of the entity object or individual view objects. However, because at runtime view accessor results are often filtered depending on the usage involved, it is recommended that you create unique view accessors for each usage in your application.

> **Best Practice:**
>
> Oracle recommends creating unique view accessors whenever your application needs to expose an LOV-enabled attribute. Reusing view accessors to create multiple list of values is discouraged because LOV results are often filtered at runtime. For example, the results of a saved search will filter the row set of the target view object until the end user unapplies the search criteria. Consequently, view accessors that get applied to this same destination view object will have their results filter too. To ensure the view accessor always returns the intended row set at runtime, create unique view accessors for each usage.

Defining view accessors on the entity object should be used carefully since view objects that you create based on the entity object will inherit the view accessors of their base entity objects. While defining the view accessor once on the entity object itself allows you to reuse the same view accessor, the view accessor must not be used in different application scenarios. If you intend to define validation rules for the entity object attributes and create LOV-enabled attributes for that entity object's view object, it is recommended that you create separate view accessors.

For example, assume the AddressEO entity object defines the Shared_CountriesVA view accessor and the AddressesVO view object inherits this view accessor. In this case, defining the view accessor on the entity object is useful: the accessor for AddressEO defines a validation rule on the CountryId attribute. But a different view accessor for AddressesVO should be used to enable an LOV on its CountryId attribute.

When you create a view accessor that accesses a view instance from a shared application module, you may want to use a prefix like Shared_ to name the view accessor. This naming convention will help you identify the view accessor when you need to select it for the entity object or view object.

Before you begin:

It may be helpful to have an understanding of view accessors. For more information, see Accessing View Instances of the Shared Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Shared Application Modules.

You will need to complete these tasks:

- Create the entity object or view object that you want to access, as described in Creating a Business Domain Layer Using Entity Objects and Defining SQL Queries Using View Objects.
- Enable application module sharing, as described in How to Create a Shared Application Module Instance.
- Create the base view object for the lookup data, as described in How to Create a Base View Object Definition for a Lookup Table.
- You can optionally refine the list returned by a view accessor by applying view criteria that you define on the view object. To create view criteria for use with a view accessor, see How to Define the WHERE Clause of the Lookup View Object Using View Criteria.

To create the view accessor:

1. In the Application window, double-click the entity object or view object on which you want to define the view accessor.

   Whether you create the view accessor on the entity object or on the view object will depend on the view accessor's intended usage. Generally, creating view accessors on the entity object ensures the widest possible usage.

2. In the overview editor, click the **Accessors** navigation tab and then, in the View Accessors section, click the **Create New View Accessors** button to add the accessor to the entity object or view object definition you are currently editing.

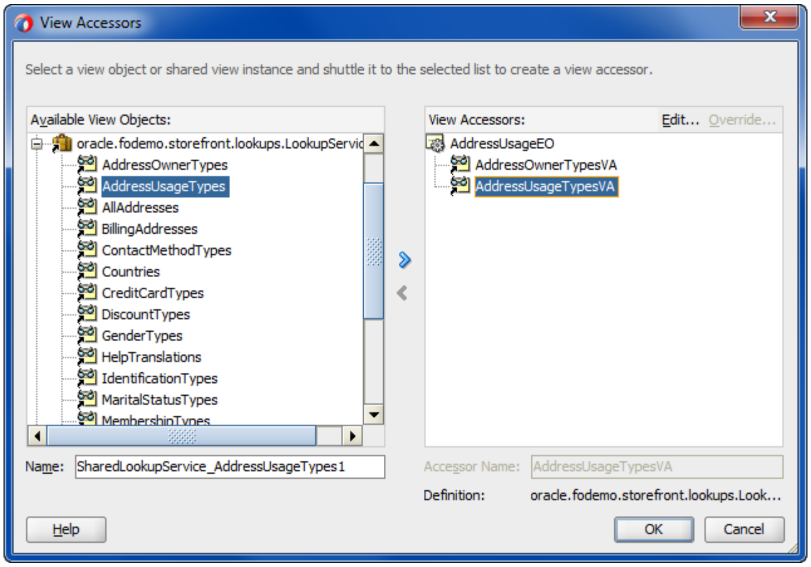
3. In the View Accessors dialog, select the view instance name you created for your lookup table from the shared application module node and shuttle it to the view accessors list.

   The dialog will display all view objects and view instances from your application. For example, the View Accessors dialog in Figure 14-5 shows the shared application module LookupServiceAM with the list of view instances, as shown .

   By default, the view accessor you create will display the same name as the view object instance (or will have an integer appended when it is necessary to distinguish it from a child view object of the same name). You can edit **Accessor Name** to give it a unique name.

For example, the View Accessors dialog in Figure 14-5 shows the view accessor `AddressUsageTypesVA` for the `AddressUsageTypes` view instance selection in the shared application module `LookupServiceAM`. This view accessor is created on the base entity object `AddressUsagesEO` and accesses the row set of the `AddressUsageTypes` view instance.

Figure 14-5 Defining a View Accessor on an Entity Object



View Accessors

Select a view object or shared view instance and shuttle it to the selected list to create a view accessor.

Available View Objects:

- oracle.fodemo.storefront.lookups.LookupServic
  - AddressOwnerTypes
  - AddressUsageTypes
  - AllAddresses
  - BillingAddresses
  - ContactMethodTypes
  - Countries
  - CreditCardTypes
  - DiscountTypes
  - GenderTypes
  - HelpTranslations
  - IdentificationTypes
  - MaritalStatusTypes
  - MembershipTypes

View Accessors:

- AddressUsageEO
  - AddressOwnerTypesVA
  - AddressUsageTypesVA

Name: SharedLookupService_AddressUsageTypes1

Accessor Name: AddressUsageTypesVA

Definition: oracle.fodemo.storefront.lookups.Look...

4. If you want to apply an existing view criteria to filter the accessor, with the view accessor selected in the overview editor, click the **Edit** icon.

   In the Edit View Accessor dialog, click **Edit** and perform the following steps to apply the view criteria:

   a. Select the view criteria that you want to apply and shuttle it to the **Selected** list.

      You can add additional view criteria to apply multiple filters (a logical AND operation will be performed at runtime).

   b. Enter the attribute name for the bind variable that defines the controlling attribute for the view accessor row set.

      Unlike view criteria that you set directly on a view object (to create a view instance, for example), the controlling attribute of the view accessor's view criteria derives the value from the view accessor's base view object.

   c. Click **OK**.

5. In the View Accessors dialog, click **OK**.

How to Validate Against the Attribute Values Specified by a View Accessor

View accessors that you create to access the view rows of a destination view object may be used to verify data that your application solicits from the end user at runtime. For example, when the end user fills out a registration form, individual validation rules can verify the title, marital status, and contact code against lookup table data queried by view instances of the shared application module.

You can apply view accessors you have defined on the entity object to these built-in declarative validation rules:

- The Compare validator performs a logical comparison between an entity attribute and a value. When you specify a view accessor to determine the possible values, the compare validator applies the `Equals`, `NotEquals`, `GreaterThan`, `LessThan`, `LessOrEqualTo`, `GreaterOrEqualTo` operator you select to compare against the values returned by the view accessor.
- The List validator compares an entity attribute against a list of values. When you specify a view accessor to determine the valid list values, the List validator applies an `In` or `NotIn` operator you select against the values returned by the view accessor.
- The Collection validator performs a logical comparison between an operation performed on a collection attribute and a value. When you specify a view accessor to determine the possible values, the Collection validator applies the Sum, Average, Count, Min, Max operation on the selected collection attribute to compare against the values returned by the view accessor.

Validation rules that you define to allow runtime validation of data for entity-based view objects are always defined on the attributes of the entity object. You use the editor for the entity object to define the validation rule on individual attributes. Any view object that you later define that derives from an entity object with validation rules defined will automatically receive attribute value validation.

Before you begin:

It may be helpful to have an understanding of view accessors. For more information, see Accessing View Instances of the Shared Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Shared Application Modules.

You will need to complete this task:

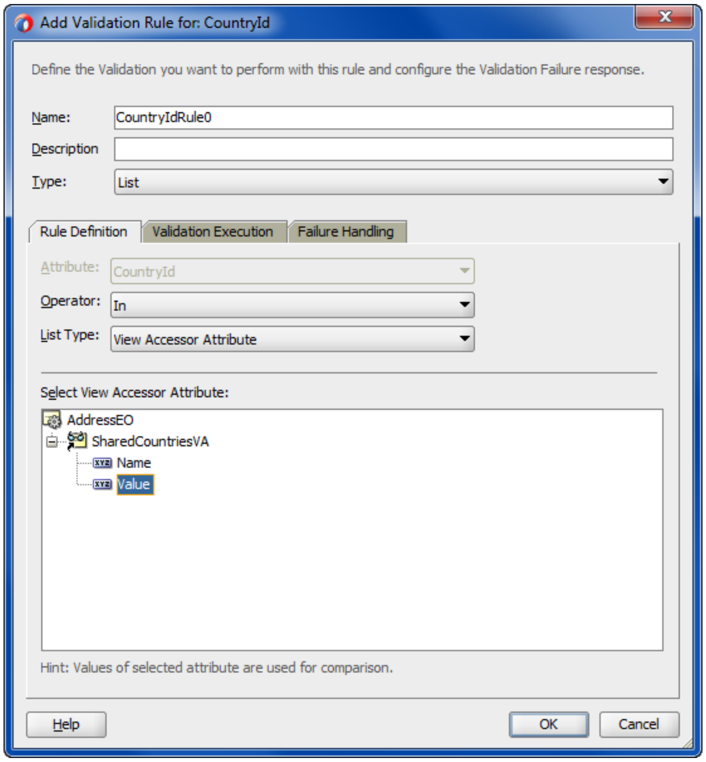
> Create the desired entity object, as described in How to Create Multiple Entity Objects and Associations from Existing Tables.

To validate against a view accessor comparison, list, or collection type:

1. In the Application window, double-click the desired entity object.
2. In the overview editor, click the **Business Rules** navigation tab.
3. In the Business Rules page, expand the entity object, select the attribute to be validated, and then click the **Create new validator** button to add the validation rule to the entity object attribute.
4. In the Add Validation Rule dialog, in the **Rule Type** dropdown list, select **Compare**, **List**, or **Collection**.
5. Make the selections required by the validator selection.
6. In the **Compare With** or **List Type** dropdown list, select **View Accessor Attribute**.
7. In the **Select View Accessor Attribute** group box, expand the desired view accessor from the shared service and select the attribute you want to provide as validation.

Figure 14-6 shows what the dialog looks like when you use a List validator to select a view accessor attribute.

Figure 14-6 List Validator Using a View Accessor



Add Validation Rule for: CountryId

Define the Validation you want to perform with this rule and configure the Validation Failure response.

Name: CountryIdRule0
Description:
Type: List

Attribute: CountryId
Operator: In
List Type: View Accessor Attribute

Select View Accessor Attribute:

Hint: Values of selected attribute are used for comparison.

8. Click the **Failure Handling** tab and enter a message that will be shown to the user if the validation rule fails.
9. Click **OK**.

What Happens When You Define a View Accessor Validator

When you use a List validator, a `<ListValidationBean>` tag is added to an entity object's XML file. The following example shows the XML code for the `CountryId` attribute in the `Address` entity object. A List validator has been used to validate the user's entry against the list of country ID values as retrieved by the view accessor from the `Countries` view instance.

```
<Attribute
   Name="CountryId"
   IsNotNull="true"
   Precision="2"
   ColumnName="COUNTRY_ID"
   Type="java.lang.String"
   ColumnType="CHAR"
   SQLType="VARCHAR"
   TableName="ADDRESSES">
   RetrievedOnUpdate="true"
   RetrievedOnInsert="true">
   <DesignTime>
         <Attr Name="_DisplaySize" Value="2"/>
   </DesignTime>
   <ListValidationBean
         xmlns="http://xmlns.oracle.com/adfm/validation"
         Name="CountryId_Rule_1"
         ResId="CountryId_Rule_0"
         OnAttribute="CountryId"
         OperandType="VO_USAGE"
         Inverse="false"
         ViewAccAttrName="Value"
         ViewAccName="SharedCountriesVA">
         <ResExpressions>
            <Expression
               Name="0"><![CDATA[SharedCountriesVA.Value]]>
            </Expression>
         </ResExpressions>
   </ListValidationBean>
   <Properties>
      <SchemaBasedProperties>
        <LABEL
          ResId="CountryId_LABEL"/>
      </SchemaBasedProperties>
   </Properties>
</Attribute>
```

What You May Need to Know About Dynamic Filtering with View Accessors

The View Object API setWhereClause() method allows you to add a dynamic WHERE clause to a view instance whose view accessor may already have view criteria specified at design time. At runtime, when your view accessor and its view criteria is applied to the view instance and you call the setWhereClause() method on the view instance to add an extra WHERE clause, the programmatically set WHERE clause is AND-ed with the WHERE clause of any already applied view criteria.

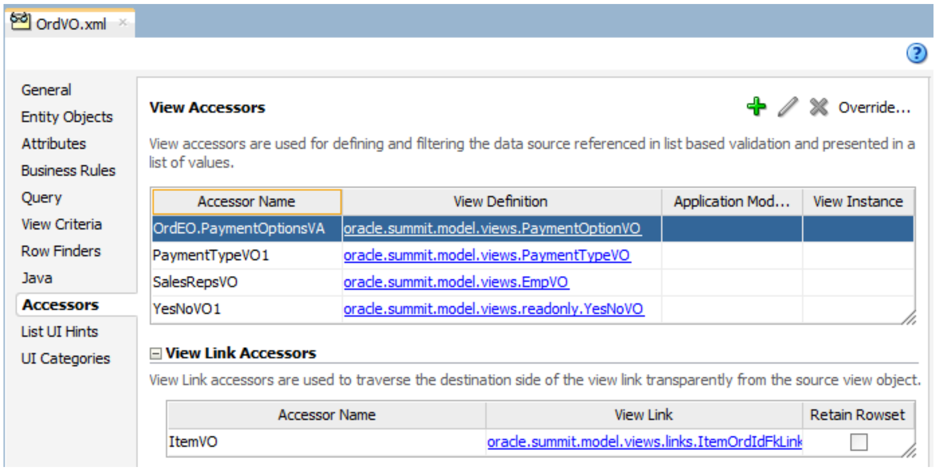
How to Create an LOV Based on a Lookup Table

View accessors that you create to access the view rows of a destination view object may be used to display a list of values to the end user at runtime. You first create a view accessor with the desired view instance as its data source, and then you can add the view accessor to an LOV-enabled attribute of the displaying view object. You will edit the view accessor definition for the LOV-enabled attribute so that it points to the specific lookup attribute of the view instance. Because you want to populate the row set cache for the query with static data, you would locate the destination view instance in a shared application module.

While the list usage is defined on the attribute of a view object bound to a UI list control, the view accessor definition exists on either the view object or the view object's base entity object. If you choose to create the view accessor on the view object's entity object, the Accessors page of the overview editor for the view object will display the inherited view accessor, as shown in Figure 14-7. Alternatively, if you choose to create the view accessor on the attribute's view object, you can accomplish this from either the editor for the LOV definition or from the Accessors page of the overview editor.

To ensure that the view accessor for the LOV always queries the latest data from the database table, you can enable the auto-refresh feature on the view accessor's destination view object.

Figure 14-7 Accessors Page of the Overview Editor



View Accessors

View accessors are used for defining and filtering the data source referenced in list based validation and presented in a list of values.

Accessor Name	View Definition	Application Mod...	View Instance
OrdEO.PaymentOptionsVA	oracle.summit.model.views.PaymentOptionVO		
PaymentTypeVO1	oracle.summit.model.views.PaymentTypeVO		
SalesRepsVO	oracle.summit.model.views.EmpVO		
YesNoVO1	oracle.summit.model.views.readonly.YesNoVO		

⊟ View Link Accessors

View Link accessors are used to traverse the destination side of the view link transparently from the source view object.

Accessor Name	View Link	Retain Rowset
ItemVO	oracle.summit.model.views.links.ItemOrdIdFkLink	□

Before you begin:

It may be helpful to have an understanding of view accessors. For more information, see Accessing View Instances of the Shared Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Shared Application Modules.

You may also find it helpful to understand additional examples of how to work with LOV-enabled attributes. For more information, see Working with List of Values (LOV) in View Object Attributes.

You will need to complete these tasks:

- Create the view object that is the data source for the view accessor, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.
- Create the view object that is the data source for the view accessor, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.
- Optionally, enable auto refresh for the view object, as described in How to Automatically Refresh the View Object of the View Accessor.

  If you need to ensure that your view accessor always queries the latest data from the lookup table, you can set the **Auto Refresh** property on the destination view object. This property allows the view object instance to refresh itself after a change in the database. The typical use case is when you define a view accessor for the destination view object.

To create an LOV that displays values from a lookup table:

1. In the Application window, double-click the view object that contains the desired attribute.
2. In the overview editor, click the **Accessors** navigation tab.
3. In the Accessors page, in the View Accessors list, check to see whether the view object inherited the desired view accessor from its base entity object. If no view

accessor is present, either create the view accessor on the desired entity object or click the **Create New View Accessors** button to add the accessor to the view object you are currently editing.

Validation rules that you define are always defined on the attributes of the view object's base entity object. It may therefore be convenient to define view accessors at the level of the base entity objects when you know that you will also validate entity object attributes using a view accessor list.

4. In the overview editor, click the **Attributes** navigation tab.
5. In the Attributes page, select the attribute that is to display the LOV, and then click the **List of Values** tab and click the **Add List of Values** button.
6. In the Create List of Values dialog, select the view accessor from the **List Data Source** dropdown list.

   The view accessor you select, will be the one created for the lookup table view object instances to use as the data source.
7. Select the attribute from this view accessor from the **List Attribute** dropdown list that will return the list of values for the attribute you are currently editing.

   The editor creates a default mapping between the view object attribute and the LOV-enabled attribute. In this use case, the attributes are the same. For example, the attribute `OrderId` from the `OrdersView` view object would map to the attribute `OrderId` from the `Shared_OrdersVA` view accessor.
8. If you want to specify supplemental values that your list returns to the base view object, click the **Add** button in **List Return Values** and map the desired view object attributes to the same attributes accessed by the view accessor.

   Supplemental attribute return values are useful when you do not require the user to make a list selection for the attributes, yet you want those attributes values, as determined by the current row, to participate in the update.

   For example, to map the attribute `StartDate` from the `OrdersView` view object, you would choose the attribute `StartDate` from the `Shared_OrdersVA` view accessor. Do not remove the default attribute mapping for the attribute for which the list is defined.
9. Click **OK**.

What Happens When You Define an LOV for a View Object Attribute

When you add an LOV to a view object attribute, JDeveloper updates the view object's XML file with an `LOVName` property in the `<ViewAttribute>` element. The definition of the LOV appears in a new `<ListBinding>` element. The metadata in the following example shows that the `PaymentTypeId` attribute refers to the `LOV_PaymentTypeId` LOV and sets the `choice` control type to display the LOV. The LOV definition for `LOV_PaymentTypeId` appears in the `<ListBinding>` element.

```
<ViewObject
  xmlns="http://xmlns.oracle.com/bc4j"
  Name="CustomerRegistrationVO"
  ...
   <ViewAttribute Name="PaymentTypeId"
                  LOVName="LOV_PaymentTypeId"
                  PrecisionRule="true"
                  EntityAttrName="PaymentTypeId"
                  EntityUsage="OrdEO"
```

```
                    AliasName="PAYMENT_TYPE_ID">
      <Properties>
         <SchemaBasedProperties>
            <CONTROLTYPE Value="choice"/>
         </SchemaBasedProperties>
      </Properties>
   </ViewAttribute>
  ...
  <ListBinding
    Name="LOV_PaymentTypeId"
    ListVOName="PaymentTypeVA"
    ListRangeSize="-1"
    NullValueFlag="start"
    NullValueId="LOVUIHints_NullValueId"
    MRUCount="0">
    <AttrArray Name="AttrNames">
      <Item Value="PaymentTypeId"/>
    </AttrArray>
    <AttrArray Name="ListAttrNames">
      <Item Value="Id"/>
    </AttrArray>
    <AttrArray Name="ListDisplayAttrNames">
      <Item Value="Payment Type"/>
    </AttrArray>
    <DisplayCriteria/>
  </ListBinding>
  ...
</ViewObject>
```

What Happens at Runtime: How the Attribute Displays the List of Values

The ADF Business Components runtime adds functionality in the attribute setters of the view row and entity object to facilitate the LOV-enabled attribute behavior. In order to display the LOV-enabled attribute values in the user interface, the LOV facility fetches the data source, and finds the relevant row attributes and mapped target attributes.

What You May Need to Know About Displaying List of Values From a Lookup Table

Unlike entity-based view objects, read-only, custom SQL view objects that you create, will not define a key attribute by default. While it is possible to create a read-only view object without defining its key attribute, in custom SQL mode it is a best practice to select the attribute that corresponds to the queried table's primary key and mark it as the key attribute. The presence of a key attribute ensure the correct runtime behavior for row set navigation. For example, the user interface developer may create an LOV component based on the read-only view object collection. Without a key attribute to specify the row key value, the LOV may not behave properly and a runtime error can result.

What You May Need to Know About Programmatically Invoking Database Change Notifications

When you create a databound UI component in a web page, you can enable the auto-refresh feature on the corresponding view object, as described in How to Automatically Refresh the View Object of the View Accessor. In this case, the **ADF Model** layer and ADF Business Components will handle processing database change notifications at runtime and the shared application module cache will be updated for you. However, when you create a method to programmatically refresh a view instance of a shared application module, your method needs to invoke the `processChangeNotification()` method on the shared application module before you refresh the view instance. Calling the `processChangeNotification()` method before refreshing the view instance ensures that the shared application module cache gets updated if the corresponding queried data has changed in the database.

To programmatically refresh a view instance of a shared application module, follow these steps (as illustrated in the following example from the `processChangeTestClient.java` example in the `SummitADF_Examples` workspace):

1. Call the `processChangeNotification()` method.
2. Get the view instance from the shared application module.
3. Refresh the view instance.

```
public class processChangeTestClient {
    public static void main(String[] args) {
        processChangeTestClient processChangeTestClient = new
processChangeTestClient();

        ApplicationModuleHandle handle = null;
        String amDef = "oracle.summit.model.services.BackOfficeAppModule";
        String config = "BackOfficeAppModuleLocal";
        try {
            handle = Configuration.createRootApplicationModuleHandle(amDef,
config);
            ApplicationModule am = handle.useApplicationModule();
            // 1. Update the shared application module cache with changed data.
            am.processChangeNotifications();
            // 2. Get the view instance to refresh.
            ViewObject vo = am.findViewObject("Inventory");
            // 3. Refresh the view instance with updated data.
            ((ViewObjectImpl)vo).refreshCollection(null, false, false);
            vo.reset();
            while (vo.hasNext()) {
                Row r = vo.next();
                System.out.println((String)r.getAttribute("Name"));
            }
        } finally {
            if (handle != null)
              Configuration.releaseRootApplicationModuleHandle(handle, false);
        }

    }
}
```

What You May Need to Know About Inheritance of AttributeDef Properties

When one view object extends another, you can create the LOV-enabled attribute on the base object. Then when you define the child view object in the overview editor, the LOV definition will be visible on the corresponding view object attribute. This inheritance mechanism allows you to define an LOV-enabled attribute once and apply it later across multiple view objects instances for the same attribute. For details about extending a view object from another view object definition, see How To Extend a Component After Creation.

You can also use the overview editor to extend the inherited LOV definition. For example, you may add extra attributes already defined by the base view object's query to display in selection list. Alternatively, you can create a view object instance that uses a custom WHERE clause to query the supplemental attributes not already queried by the base view object. For information about customizing entity-based view objects, see Working with Bind Variables.

What You May Need to Know About Using Validators

If you have created an LOV-enabled attribute for a view object, there is no need to validate the attribute using a List validator. You use an attribute validator only when you do not want the list to display in the user interface but still need to restrict the list of valid values. A List validator may be a simple static list or it may be a list of possible values obtained through a view accessor you define. Alternatively, you might prefer to use a Key Exists validator when the attribute displayed in the UI is one that references a key value (such as a primary, foreign, or alternate key). For information about declarative validation in ADF Business Components, see Defining Validation and Business Rules Declaratively.

Testing View Object Instances in a Shared Application Module

Use the interactive ADF Business Components application module testing tool in JDeveloper to test the data model. It helps you conducts tests without the need of an application user interface or test client program.

JDeveloper includes an interactive application module testing tool that you can use to test all aspects of its data model without having to use your application user interface or write a test client program. Running the Oracle ADF Model Tester can often be the quickest way of exercising the data functionality of your business service during development.

How to Test the Base View Object Using the Oracle ADF Model Tester

The application module is the transactional component that the Oracle ADF Model Tester (or UI client) will use to work with application data. The set of view objects used by an application module defines its data model, in other words, the set of data that a client can display and manipulate through a user interface. You can use the Oracle ADF Model Tester to test that the accessors you defined yield the expected validation result and that they display the correct LOV attribute values.

To test the view objects you added to an application module, use the Oracle ADF Model Tester, which is accessible from the Application window.

Before you begin:

It may be helpful to have an understanding of Oracle ADF Model Tester. For more information, see Testing View Object Instances in a Shared Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Shared Application Modules.

You may also find it helpful to understand the diagnostic messages specific to ADF Business Components debugging. For more information, see How to Enable ADF Business Components Debug Diagnostics.

You will need to complete this task:

Create the application module with view instances, as described in Creating and Modifying an Application Module.

To test view objects in an application module configuration:

1. In the Application window, right-click the application module and choose **Run**.

   Alternatively, choose **Debug** when you want to run the application in the Oracle ADF Model Tester with debugging enabled. For example, when debugging using the Oracle ADF Model Tester, you can view status message and exceptions, step in and out of source code, and manage breakpoints. The debugger process panel opens in the Log window and the various debugger windows.

2. In the Oracle ADF Model Tester, expand the tree list and double-click the desired view object node.

   Note that the view object instance may already appear executed in the testing session. In this case, the tester panel on the right already displays query results for the view object instance, as shown in Figure 14-8. The fields in the tester panel of a read-only view object will always appear disabled since the data it represents is not editable.

Figure 14-8 Testing the Data Model in the Oracle ADF Model Tester

How to Test LOV-Enabled Attributes Using the Oracle ADF Model Tester

To test the LOV you created for a view object attribute, use the Oracle ADF Model Tester, which is accessible from the Application window. For details about displaying the tester and the supported control types, see How to Test LOV-Enabled Attributes Using the Oracle ADF Model Tester.

What Happens When You Use the Oracle ADF Model Tester

When you launch the Oracle ADF Model Tester, JDeveloper starts the tester tool in a separate process and the Oracle ADF Model Tester appears. The tree at the left of the dialog displays all of the view object instances in your application module's data model. Figure 14-8 shows just one instance in the expanded tree, called `ProductImages`. After you double-click the desired view object instance, the Oracle ADF Model Tester will display a panel to inspect the query results, as shown in Figure 14-8.

The test panel will appear disabled for any read-only view objects you display because the data is not editable. But even for the read-only view objects, the tool affords some useful features:

- You can validate that the UI hints based on the Label Text **control hint** and format masks are defined correctly.
- You can also scroll through the data using the toolbar buttons.

The Oracle ADF Model Tester becomes even more useful when you create entity-based view objects that allow you to simulate inserting, updating, and deleting rows, as described in How to Test Entity-Based View Objects Interactively.

What Happens at Runtime: How Another Service Accesses the Shared Application Module Cache

When a shared application module with application scope is requested by an LOV, then the ADF Business Components runtime will create an `ApplicationPool` object for that usage. There is only one `ApplicationPool` created for each shared usage that has been defined in the ADF Business Components project configuration file (`.jpx`). The runtime will then use that `ApplicationPool` to acquire an application module instance that will be used like a user application module instance, to acquire data. The reference to the shared application module instance will be released once the application-scoped application module is reset. The module reference is released whenever you perform an unmanaged release or upon session timeout.

Since multiple threads will be accessing the data caches of the shared application module, it is necessary to partition the iterator space to prevent race conditions between the iterators of different sessions. This will help ensure that the next request from one session does not change the state of the iterator that is being used by another session. The runtime uses ADF Business Components support for multiple iterators on top of a single `RowSet` to prevent these race conditions. So, the runtime will instantiate as many iterators as there are active sessions for each `RowSet`.

An application-scoped shared application module lifecycle is similar to the lifecycle of any application module that is managed by the `ApplicationPool` object. For example, once all active sessions have released their shared application module, then the application module may be garbage-collected by the `ApplicationPool` object. The shared pool may be tuned to meet specific application requirements.

Session-scoped shared application modules are simply created as nested application module instances within the data model of the root, user application module. For details about nested application modules, Defining Nested Application Modules.

15

Creating SOAP Web Services with Application Modules

This chapter describes how to publish ADF application modules and how to define a SOAP service interface connection to make them available as external web services in a Fusion web application. It also describes how to incorporate the published application module as an external service in a Fusion web application.
This chapter includes the following sections:

About Service-Enabled Application Modules

Service-enabled ADF Business Components application modules are made available to SOAP service customers through a service interface.

A **service-enabled application module** is an ADF application module that you advertise through a service interface to service consumers. There are three scenarios for service consumers to consume a published service-enabled application module: web service access, Service Component Architecture (SCA) composite access, and access by another ADF application module.

Service Component Architecture (SCA) provides an open, technology-neutral model for implementing remotable services that are defined in terms of business functionality and that make middleware functions more accessible to application developers. **ADF Business Components** supports an SCA-compliant solution through application modules you can publish with a service interface.

When you service-enable your application module, JDeveloper generates the necessary artifacts comprising: 1) The Java interface defining the service, 2) an EJB 3.0 session bean that implements this Java interface, 3) a WSDL file that describes the service's operations, and (4) XML schema documents (XSD) that defines the service's data structures. The service interface is described for Fusion web application clients in a language-neutral way by the combination of WSDL and XSD.

SCA defines two kinds of service:

- Remotable services, typically coarse-grained and designed to be published remotely in a loosely coupled SOA architecture
- Local services, typically fine-grained and designed to be used locally by other implementations that are deployed concurrently in a tightly coupled architecture

ADF Business Components services fall into the first category, and should only be used as remotable services.

ADF Business Components services, including data access and method calls, defined by the remote application modules are interoperable with any other application module. This means the same application module can support interactive web user interfaces using ADF **data controls** and web service clients.

Service-Enabled Application Module Use Cases and Examples

Any development team can publish a service-enabled application module to contribute to the Fusion web application. The Fusion web application assembled from remote web services also does not require the participating services to run on a single application server.

Although the web applications may run on separate application servers, the appearance that SCA provides is one of a unified application. Consuming client projects use the ADF service factory lookup mechanism to access the data and any business methods encapsulated by the service-enabled application module. At runtime, the calling client and the ADF web service may or may not participate in the same transaction, depending on the protocol used to invoke the service (either SOAP or RMI). Only the RMI protocol and a Java Transaction API (JTA) managed transaction support the option to call the service in the same transaction as the calling client. By default, to support the RMI protocol, the ADF web service is configured to participate in the same transaction.

Additional Functionality for Service-Enabled Application Modules

You may find it helpful to understand other **Oracle ADF** features before you start working with ADF Business Components services. Following are links to other functionality that may be of interest.

- For information about the SCA and service data object (SDO) standards, see the Specifications section of the website for the Organization for the Advancement of Structured Information Standards (OASIS) through the Open Composite Services Architecture (CSA) at `http://www.oasis-opencsa.org`.
- For further background about web services and Oracle WebLogic Server support for web services, see Overview of Web Services in *Understanding Web Services*
- For details about the predefined authorization policies supported by Oracle Web Services Manager (OWSM), including `binding_permission_authorization_policy` used to enable authorization for RMI clients. For more information, see the "Predefined Policies" appendix in *Securing Web Services and Managing Policies with Oracle Web Services Manager*.
- For local service support, use the `ApplicationModule` interface and `ViewObject` interface support described in Working Programmatically with an Application Module's Client Interface.
- For API documentation related to the `oracle.jbo` package, see the following Javadoc reference document:
  - *Java API Reference for Oracle ADF Model*

Publishing Service-Enabled Application Modules

Use the ADF Application Module to enable a SOAP-based web service and make available rows of view object data.

The application module is ADF Business Components framework component that encapsulates business logic as a set of related business functions. Application modules are mapped to services. You use the overview editor for your application module to enable a web service interface and publish rows of **view object** data as service data object (SDO) components.

The SDO framework upon which the SDO components are based abstracts the data of the view object and standardizes the way that data structures are passed between Java and XML. This data abstraction simplifies working with heterogeneous data sources in a service-oriented architecture (SOA) and lets you selectively service-enable view objects using the same view object to support interactive web user interfaces and web service clients.

JDeveloper allows you to expose application modules as web services which use SDO components based on view instance that your application module defines to standardize the way that data structures are passed between Java and XML. JDeveloper also generates the WSDL service description that is used by the web service client in the consuming application.

> **Note:**
>
> JDeveloper only supports generating SDO components for view objects of a service-enabled application module. Currently, no other ADF Business Components may be defined as SDO components.

The service-enabled application module exposes the view objects, custom methods, built-in data manipulation operations, and specialized find methods based on named **view criteria** to be used by the client. Once you have enabled the application module service interface, you will need to create an ADF Business Components Service Interface deployment profile and deploy it to the target application server.

> **Note:**
>
> It is important to note that you don't implement methods with SDO parameters directly. The SDO framework is used to wrap the view row types during runtime only.

How to Enable the Application Module Service Interface

You edit the application module in JDeveloper to create a web service interface that exposes the top-level view objects and defines the available service operations it supports. Top-level view objects that you may service-enable and make accessible by the service client are:

- View instances of standalone view objects (does not participate in a hierarchical relationship)
- Master view instances of master-detail related view objects (does not include the child view instance)

- View instances of view objects that extend a parent view object (must not include a subtype discriminator attribute to define a polymorphic view object)

View objects that do not automatically participate in the service interface are:

- Child view instances of master-detail related view objects

  You can add child view objects individually to the service interface. For information on how to create SDO classes for child view objects, see How to Service-Enable Individual View Objects.

- View instances of polymorphic view objects (as defined by a subtype discriminator attribute)

  In JDeveloper, you can create a web service proxy client to access and manipulate for polymorphic view objects. For an example of a JAX-WS client, see Accessing Polymorphic Collections in the Consuming Application.

The primary purpose of the standard service operations is to expose data manipulation operations on the view objects. Any business logic that you have defined on the underlying framework objects (for example, business rule validation) will be applied when you invoke a standard service operation.

Table 15-1 shows the list of standard operations that service view instances support.

Table 15-1 Standard View Instance Data Manipulation Operations

Operation	Method Name	Operation Description
`Create`	`create<`*`VOName`*`>`	Creates an ADF Business Components view row.
`Update`	`update<`*`VOName`*`>`	Updates an ADF Business Components view row.
`Delete`	`delete<`*`VOName`*`>`	Deletes an ADF Business Components view row.
`Merge`	`merge<`*`VOName`*`>`	Updates an ADF Business Components view row if one exists; otherwise, creates a new one.
`GetByKey`	`get<`*`VOName`*`>`	Gets a single ADF Business Components view row by primary key.
`Find` (by view criteria applied to view object query statement)	`find<`*`VOName`*`>`	Finds and returns a list of ADF Business Components view rows using an SDO-based view criteria that is applied to the selected view object's query statement. Note that the query must not specify a bind variable defined as required for the query to execute. The service interface does not expose required bind variables at runtime. For details about creating a find method for this scenario, see How to Expose a Declarative Find Operation Filtered By a Required Bind Variable.

Table 15-1 (Cont.) Standard View Instance Data Manipulation Operations

Operation	Method Name	Operation Description
`Find` (by view criteria)	`find<VOName><VCName>`	Finds and returns a list of single ADF Business Components view rows by named view criteria and values for the required bind variables. This is the preferred way to filter the ADF Business Components view rows that rely on a required bind variable.
`Process`	`process<VOName>`	Performs a Create, Update, Delete, or Merge operation on a list of ADF Business Components view rows. The specified operation is applied to all objects in the given list.
`ProcessChangeSummary`	`processCS<VOName>`	Performs a Create, Update, or Delete operation on a list of ADF Business Components view rows. Different operations may be applied to different objects, depending on what is specified in the `ChangeSummary` object.

Additionally, several built-in methods can be optionally added to the client service interface of the application module (`AppModuleService.java`). Table 15-2 shows the list of built-in methods that provide runtime support for service view instances that you enable.

Table 15-2 Built-In Service Interface Methods

Operation	Method Name and Async Method Name	Method Description

`Generate Object and Attribute Control Hint Operations`	`getDfltObjAttrHints()`
	`getDfltObjAttrHintsAsync()`
		Returns the base UI hints, including object and attribute display name labels, for an object based on a specific locale. The method takes the name of the object, at the service, to get the hints and the locale name (in ISO 639-1 format) to drive localization of base hints.
		This method may be used by the web service consuming application to generate a user interface with the correct labels for the service view instance and its attributes. For details about specifying display name UI hints, see How to Set Display Names for Service View Instances and Attributes.

Table 15-2 (Cont.) Built-In Service Interface Methods

Operation	Method Name and Async Method Name	Method Description

`Generate Last Update Time Operations`	`getServiceLastUpdateTime()`
	`getServiceLastUpdateTimeAsyncResponse()`
		Returns the last modified time for the service schema files at the SOAP service endpoint.
		This method may be used by the web service consuming application that caches the service view instance schema files (XSD) to determine when the object has been updated.

`Generate Entity List Operation`	`getEntityList()`
	`getEntityListAsync()`
		Returns the list of service view instance names and flags that indicate whether each service view object at the SOAP service endpoint supports Create, Update, Merge, and Delete operations.
		This method may be used by the web service consuming application that uses custom object services to determine the available operations. Custom object services are not created using the ADF Business Components web service design time and are not described in this documentation.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF application modules and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

When you create the service-enabled application module, do not create it in a project that already contains a standard web service (a Java class or interface with the `@WebService` annotation). JDeveloper deployment profiles do not support deploying a standard web service and an ADF Business Service web service from the same project. If you attempt to deploy the ADF Business Service web service from the same project as a standard web service, the deployment will fail with an Oracle WebLogic Server exception error.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

- Create the desired view objects, as described in How to Create an Entity-Based View Object and How to Create a Custom SQL Mode View Object.
- Create the desired application module, as described in How to Create an Application Module.
- Optionally, set JDeveloper preferences to specify a default suffix for the names of generated SDO classes, modify the default subpackage where the service interface and classes reside, and set the default namespace prefix for the

generated SDO schema and web service, as described in How to Set Preferences for Generating the ADF Web Service Interface.

- If you want to expose custom find operations on the service, create declarative view criteria to specify the custom query, as described in How to Create Named View Criteria Declaratively.

To create the web service interface:

1. In the Applications window, double-click the application module.
2. In the overview editor, click the **Service Interface** navigation tab and then click the **Enable support for Service Interface** button.

   Use the Create Service Interface wizard to configure the desired options.
3. In Create Service Interface wizard, on the Service Interface page, enter the name and target namespace for the web service.

   The target namespace is a URI for the service that you can assign to group similar services together by entering the same URI. The default target namespace is the package name of the application module combined with package names that you specify in the Preferences dialog.

   > **Tip:**
   >
   > You can define JDeveloper preferences that will shape the URI and allow you to define a unique target namespace for your service. For details about namespace URI shaping preferences, see How to Set Preferences for Generating the ADF Web Service Interface.
4. To expose the methods of the application module as asynchronous service methods and enable both synchronous and asynchronous operations on the web service, select **Generate Asynchronous Web Service Methods**.

   By default, the web service supports synchronous service methods. This forces the invoking client application to wait for the response to return before it can continue with its work. In cases where the response returns immediately, this method of invoking the web service is common. However, because request processing can be delayed, it is often useful for the client application to continue its work and to handle the response later on.
5. The **Service Categories** list will appear empty unless role shaping has been defined based on previously defined customization roles. Leave the Selected list empty unless your organization is classifying services.

   This feature has no impact on the service WSDL file and has no relevance to the operation of web services.
6. On the Service Built-in Methods page, optionally, select **Generate Object and Attribute Control Hints Operation** to generate a method that will return the static control hints (UI hints) defined on a view instance and its attributes.

   When you enable this option, the wizard adds the `getDfltObjAttrHints()` method to the client service interface (`AppModuleService.java`). The web service consuming application can invoke this method to resolve UI hints on the server without requiring a database roundtrip. The method takes a service view object name and a locale name and returns the base UI hints, including object and attribute display name labels, for an object based on a specific locale. If the locale name is not specified, the method uses the default locale.

7. Optionally, select **Generate Last Update Time Operation** to generate a method that will return the last modified time for the service schema files.

   When you enable this option, the wizard adds the `getServiceLastUpdateTime()` method to the client service interface (`AppModuleService.java`). Before any customization occurs, this method returns the file timestamp of the last updated schema file. When a schema is customized at runtime, the last-update timestamp is updated, and this latest timestamp will be returned. This feature is primarily useful in web service consuming applications that cache the service XSD.

8. Optionally, select **Generate Entity List Operation** to generate a method that will return the list of service view instances.

   When you enable this option, the wizard adds the `getEntityList()` method to the client service interface (`AppModuleService.java`). The method returns the list of service view instance names, XSD type, and flags that indicate whether the service view supports Create, Update, Merge, and Delete operations. This feature is primarily useful in web service consuming applications that require customization.

9. On the Service Custom Methods page, add the custom methods you want to expose in the service interface and define the data types of each method's parameters and return value.

   The parameters and non-void return value of the custom service methods you enable must be one of the service-interface supported data types, such as a Java primitive type, or a list of the service-interface supported data types (including `oracle.jbo.server.ViewRowImpl`, `java.util.List<`*`ViewRowImpl`*`>`, `oracle.jbo.AttributeList`, `java.util.List<`*`AttributeList`*`>`, or `java.util.List<`*`PrimitiveType`*`>`).

   Note that although both `ViewRowImpl` and `AttributeList` data types expose the identical row structure to the web service client, at runtime there will be a fundamental difference. For a description of the supported data types, see What You May Need to Know About Method Signatures on the ADF Web Service Interface.

   After selecting a qualifying custom method to appear in the service interface, for each parameter and return value using the `ViewRowImpl` or `AttributeList` data type, you must in turn select the name of the view object instance corresponding to the row structure:

   a. In the Selected list, expand **return** or **parameters** and select the item.

   b. Enter the Java element data type in **Element Java Type**.

   c. In the case where the Java element type is `ViewRowImpl` or `AttributeList`, enter the view object instance name to identify the row structure in **Element View Object**.

      For example, if you define a custom method to return a single row of the `CustomerInfo` view object instance, you would need a custom method signature like this:

      ```
      public ViewRowImpl findCustomerInfo(int id)
      ```

      Then, after selecting the `findCustomerInfo()` custom method to appear in the service interface, you would select its return value in the tree and configure its

View Object property to be `CustomerInfo`, the view instance name whose row structure should be used at runtime.

10. To expose service information messages for a custom method or warnings for process operation methods, select **Include Warnings in Return Service Data Object**.

    For example, you might want to display an informational message when a method returns the total employee compensation and the total is outside of the desired range.

    If **Include Warnings** is not selected, no informational messages will be returned with the service response.

    This option is only enabled when the method does not return a view row or a list of view rows. When the method returns view rows, the underlying view object determines whether the method supports warnings, as described How to Service-Enable Individual View Objects.

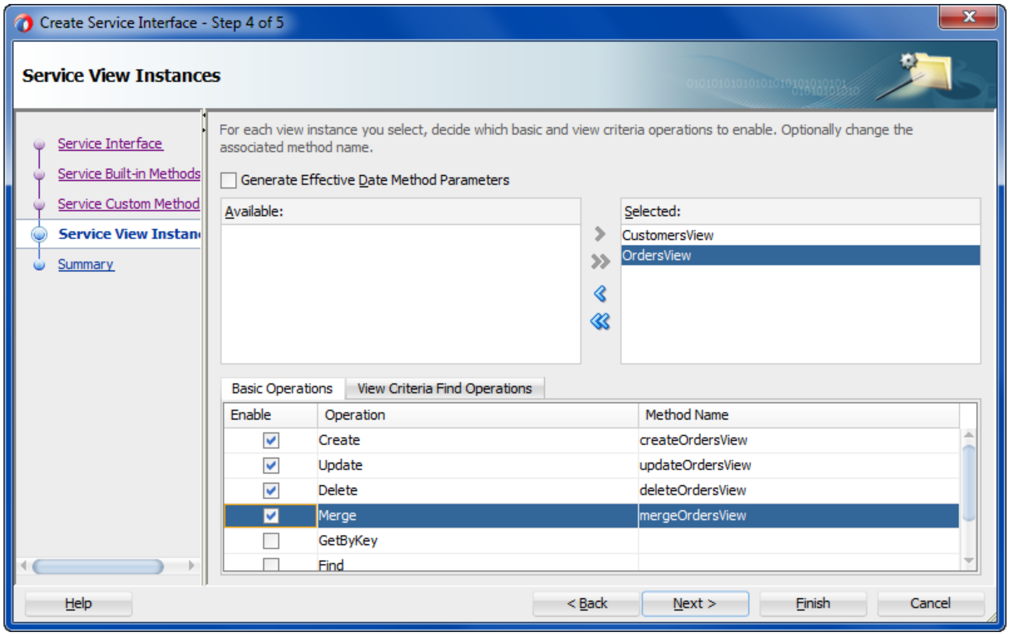
    The informational messages (and warnings) are reported as part of the return object. JDeveloper generates appropriate wrappers as the return objects, and the wrappers contain the actual method return and the informational messages.

11. On the Service View Instances page, select the top-level view instances in the application module that you want to expose in the service interface.

    View object subtypes of the top-level view instance will automatically be service-enabled.

    Also, on this page, you can enable the available data manipulation operations supported on the exposed methods, as shown in Figure 15-1.

Figure 15-1   View Instances and CRUD Operation Selection



Create Service Interface - Step 4 of 5

Service View Instances

For each view instance you select, decide which basic and view criteria operations to enable. Optionally change the associated method name.

☐ Generate Effective Date Method Parameters

Available:

Selected:
CustomersView
OrdersView

Enable	Operation	Method Name
☑	Create	createOrdersView
☑	Update	updateOrdersView
☑	Delete	deleteOrdersView
☑	Merge	mergeOrdersView
☐	GetByKey	
☐	Find	

12. In the Basic Operations tab, select the data manipulation operations for the currently selected view instance and in the **Method Name** field, change the names of the selected service operations to the names that you prefer to expose in the service interface.

The primary purpose of the standard service operations is to expose data manipulation operations on the view objects. Any business logic that you have defined on the underlying framework objects (for example, business rule validation) will be applied when you invoke the service operations. For a description of the operations that service view instances support, see Table 15-1.

In the case of the find method operation that you can select, the find method must not reference a required bind variable in the view object's query statement. A required bind variable is one that makes the query execution dependent on the availability of a valid value for the bind variable. The service interface does not expose required bind variables at runtime. For details about defining a find operation for this scenario, see How to Expose a Declarative Find Operation Filtered By a Required Bind Variable.

13. To expose declarative find operations, select the **View Criteria Find Operations** tab and click the **Add View Criteria** icon.

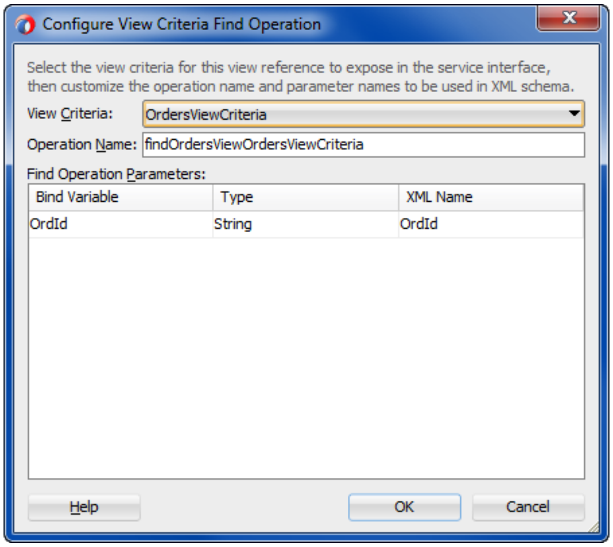
    You can define custom find operations when you want the service to support executing a predefined query. For information about defining a named view criteria, see Working with Named View Criteria.

    > **Caution:**
    >
    > The service interface find operations are based on specific view criteria that your project defines. This means that the bind variables of the view criteria must match the parameters of the corresponding find operation method. If you change the number or order of the bind variables after the find operation is defined and the service interface generated, the corresponding method will not execute at runtime. Therefore, after changing the underlying view criteria, you must regenerate the service interface.

    a. In the Configure View Criteria Find Operation dialog, choose the named view criteria for the find operation.

       The dialog displays the list of view criteria exposed by the referenced view object. For example, `OrdersView` defines `OrdersViewCriteria` with a bind variable `OrdId` that specifies the order ID, as shown in Figure 15-2.

Figure 15-2 Specialized Find Methods Based on Named View Criteria



Configure View Criteria Find Operation

Select the view criteria for this view reference to expose in the service interface, then customize the operation name and parameter names to be used in XML schema.

View Criteria: OrdersViewCriteria

Operation Name: findOrdersViewOrdersViewCriteria

Find Operation Parameters:

Bind Variable	Type	XML Name
OrdId	String	OrdId

b. If the view criteria uses a bind variable, you can double-click the XML name to customize the name as it will appear in the XML definition for the service.

14. Click **Next** to review the custom methods that your service view instances will expose.

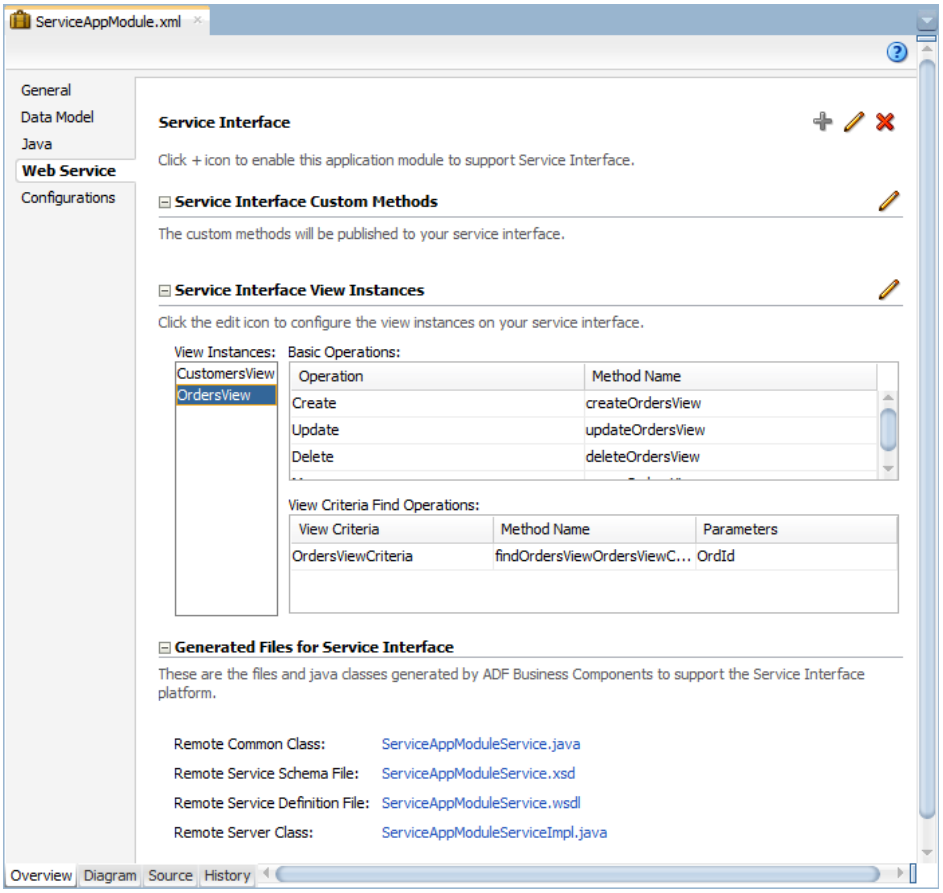
15. Click **Finish**.

What Happens When You Create an Application Module Service Interface

JDeveloper generates the service interface class and enables any view instance options you have chosen, as shown in Figure 15-3.

Do not modify the generated files for the service-enabled application module. The generated files implement required methods of the service interface. An exception to this are use cases that require adding Java annotations to the service implementation class. For example, annotations that you add in the service implementation class let you attach security policies, as described in How to Secure the ADF Web Service for Access By SOAP Clients.

Figure 15-3 Service Interface Page of the Overview Editor for an Application Module



Service Interface

Click + icon to enable this application module to support Service Interface.

Service Interface Custom Methods

The custom methods will be published to your service interface.

Service Interface View Instances

Click the edit icon to configure the view instances on your service interface.

View Instances:

- CustomersView
- OrdersView

Basic Operations:

Operation	Method Name
Create	createOrdersView
Update	updateOrdersView
Delete	deleteOrdersView

View Criteria Find Operations:

View Criteria	Method Name	Parameters
OrdersViewCriteria	findOrdersViewOrdersViewC...	OrdId

Generated Files for Service Interface

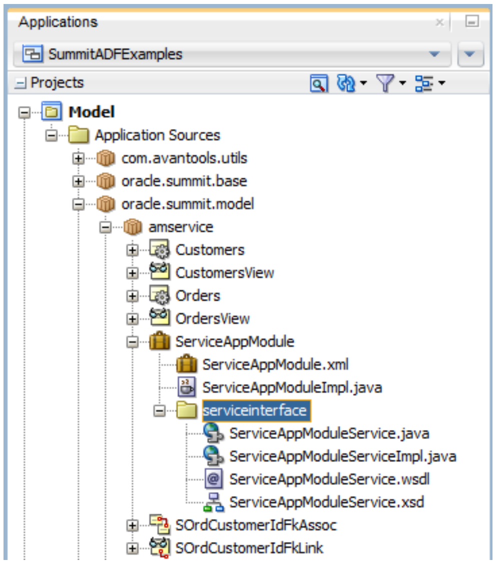
These are the files and java classes generated by ADF Business Components to support the Service Interface platform.

Remote Common Class:	ServiceAppModuleService.java
Remote Service Schema File:	ServiceAppModuleService.xsd
Remote Service Definition File:	ServiceAppModuleService.wsdl
Remote Server Class:	ServiceAppModuleServiceImpl.java

The following types of files are generated and are listed in the Applications window in the Projects panel, under the application module's **serviceinterface** node, as shown in Figure 15-4.

- Web service interface, for example, `ServiceAppModuleService.java`
- Web service schema file, for example, `ServiceAppModuleService.xsd`
- Web service definition file, for example, `ServiceAppModuleService.wsdl`
- Web service implementation class, for example, `ServiceAppModuleServiceImpl.java`

Figure 15-4 Service Interface Files Appear Below Application Module



In addition, the `connections.xml` file is created when you first create an ADF Business Components service. Although this file is only used by the web service client (the consuming application), it is generated with the service-enabled application module as a convenience. This file appears in the Applications window in the Application Resources panel, under the **Descriptors** and **ADF META-INF** nodes.

Annotations Generated in the Web Service Interface

The web service interface uses metadata annotations specified by the web service specification (JSR-181) to indicate how the interface should be exposed as a web service. This example shows part of `ServiceAppModuleService.java`, which is the web service interface class for the `ServiceAppModule` application module in the `oracle.summit.model.amservice` package in the `SummitADF_Examples` workspace.

```
package oracle.summit.model.amservice.common.serviceinterface;
...
import javax.jws.WebMethod;
import javax.jws.WebParam;
import javax.jws.WebResult;
import javax.jws.soap.SOAPBinding;
...
import oracle.summit.model.amservice.common.CustomerViewSDO;
import oracle.summit.model.amservice.common.OrderViewSDO;
...
import oracle.webservices.annotations.PortableWebService;
import oracle.webservices.annotations.SDODatabinding;
...
@SOAPBinding(parameterStyle = SOAPBinding.ParameterStyle.WRAPPED,
style=SOAPBinding.Style.DOCUMENT)
@PortableWebService(targetNamespace="http://www.globalcompany.com/
ServiceAppModuleService",
    name="ServiceAppModuleService",
    wsdlLocation=
            "oracle/summit/model/amservice/common/serviceinterface/
ServiceAppModuleService.wsdl")
```

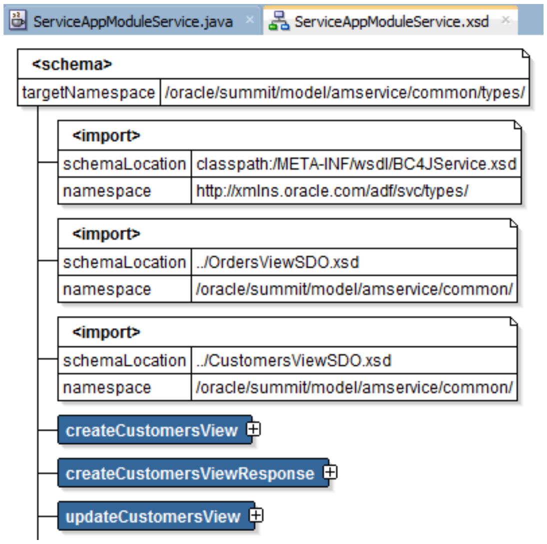
```
@SDODatabinding(schemaLocation=
            "oracle/summit/model/amservice/common/serviceinterface/
ServiceAppModuleService.xsd")
public interface ServiceAppModuleService
{
    public static final String NAME =
("http://www.globalcompany.com/ServiceAppModuleService")

    @WebMethod(action="www.globalcompany.example.com/createCustomersView",
        operationName="createCustomersView")
    @RequestWrapper(targetNamespace="www.globalcompany.example.com/types/",
        localName="createCustomersView")
    @ResponseWrapper(targetNamespace="www.globalcompany.example.com/types/",
        localName="createCustomersViewResponse")
    @WebResult(name="result")
    CustomersViewSDO createCustomersView(@WebParam(mode =
WebParam.Mode.IN, name="customerView")
        CustomersViewSDO customersView) throws ServiceException;
    ...
}
```

Web Service Schema Generated in the Web Service Schema File

The web service schema file is an XML schema file which represents the web service schema, as shown in Figure 15-5.

Figure 15-5 Web Service Schema File



ServiceAppModuleService.java
ServiceAppModuleService.xsd

<schema>
targetNamespace /oracle/summit/model/amservice/common/types/

<import>
schemaLocation classpath:/META-INF/wsdl/BC4JService.xsd
namespace http://xmlns.oracle.com/adf/svc/types/

<import>
schemaLocation ../OrdersViewSDO.xsd
namespace /oracle/summit/model/amservice/common/

<import>
schemaLocation ../CustomersViewSDO.xsd
namespace /oracle/summit/model/amservice/common/

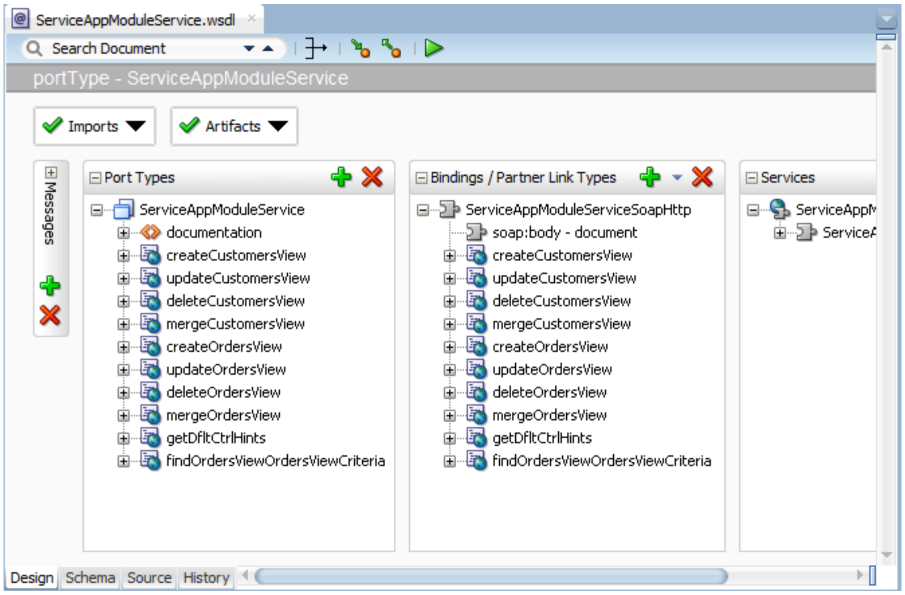
createCustomersView
createCustomersViewResponse
updateCustomersView

WSDL Generated in the Web Service Definition File

The web service definition file is a XML-structured document file that conforms to the Web Service Definition Language (WSDL) specification that describes the generated web service as a collection of endpoints, or ports. A port is defined by associating a network address with a reusable binding. The client application that connects to the web service reads the WSDL to determine what functions are available on the server. The WSDL also specifies the endpoint for the service itself, which you can use to locate and test your deployed service.

Figure 15-6 shows the WSDL for the web service generated for the `ServiceAppModule` application module in the WSDL visual editor. You can see the WSDL as an XML document by selecting the **Source** tab.

Figure 15-6 WSDL Document



Stateless Session Bean Specified by the Service Implementation Class

The service implementation class is an EJB 3.0 stateless session bean that implements the web service interface and extends the `oracle.jbo.server.svc.ServiceImpl` class, the generic service implementation for ADF Business Components. The following example shows part of `ServiceAppModuleServiceImpl.java`, which is the service implementation class for the `ServiceAppModule` application module in the `oracle.summit.model.amservice` package in the `SummitADF_Examples` workspace.

```
package oracle.summit.model.amservice.server.serviceinterface;
...
import oracle.summit.model.amservice.common.CustomersViewSDO;
import oracle.summit.model.amservice.common.OrdersViewSDO;
import
oracle.summit.model.amservice.common.serviceinterface.ServiceAppModuleService;

...
import oracle.webservices.annotations.PortableWebService;

@Interceptors({ ServiceContextInterceptor.class })
@Stateless(name="oracle.summit.model.amservice.common.ServiceAppModuleServiceBean
",
                    mappedName="ServiceAppModuleServiceBean")
@Remote(ServiceAppModuleService.class)
@PortableWebService(targetNamespace="http://www.globalcompany.com/
ServiceAppModuleService",
    serviceName="ServiceAppModuleService",
portName="ServiceAppModuleServiceSoapHttpPort",
    endpointInterface="oracle.summit.model.amservice.common.
```

```
                                     serviceinterface.ServiceAppModuleService")
public class ServiceAppModuleServiceImpl extends ServiceImpl implements
ServiceAppModuleService
{
    ...
    public CustomersViewSDO createCustomersView(CustomersViewSDO customersView)
        throws ServiceException {
        return (CustomersViewSDO) create(customersView, "CustomersView");
    }

    public CustomersViewSDO updateCustomersView(CustomersViewSDO customersView)
        throws ServiceException {
        return (CustomersViewSDO) update(customersView, "CustomersView");
    }
...
}
```

Lookup Defined in the connections.xml File

The connections.xml file allows the web service client to look up the service with the factory class oracle.jbo.client.svc.ServiceFactory. The ADF Business Components service factory provides the mechanism that allows the service client to look up the service. The service factory relies on ADF connection architecture and the connections.xml file to manage service endpoint locations. The connections.xml file is created when you first create an ADF Business Components service. This file appears in the Applications window in the Application Resources panel, under the **Descriptors** and **ADF META-INF** nodes.

The following example shows the initial connections.xml entry created by JDeveloper when you first create an ADF Business Components service.

```
<Reference name="{http://www.globalcompany.com}ServiceAppModuleService"
                    className="oracle.jbo.client.svc.Service" xmlns="">

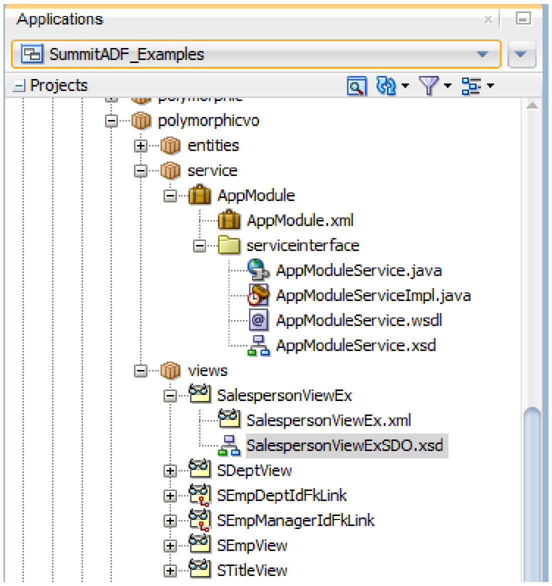
What Happens When You Create an Application Module Service Interface With Polymorphic View Objects

When your model project defines subtype view objects that extend a base view object, the generated SDO service interface will be strongly-typed for the base view objects, but not for the polymorphic subtypes. For example, assume `SalespersonViewEx` extends the `SEmpView` and adds an attribute `CommissionPct` to define the subtype. When you generate the service interface for the service-enabled view instances, the Applications window displays the service interface and service objects, as shown in Figure 15-7.

Figure 15-7 Service Object Generated for Polymorphic Subtype



> **Note:**
>
> After generating the SDO service interface from a ADF Model project that defines base view objects and subtype view objects, the generated service schema definition will be strongly-typed for the base view object, but not for the polymorphic subtype. Therefore, web service clients that need to access polymorphic subtype view objects use the approach described in Accessing Polymorphic Collections in the Consuming Application.

Because the polymorphic subtype is specified in application module data model as an import on the base service-enabled view instance, JDeveloper automatically generates the subtype service object from the base service object. The following example shows the `SalespsersonViewExSDO.xsd` subtype schema definition with the additional attribute `CommissionPct` defined. The subtype schema includes the attributes of base service object `SEmpViewSDO`.

```
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema" targetNamespace="/oracle/model/
polymorphicvo/views/common/"
     xmlns="/oracle/model/polymorphicvo/views/common/" elementFormDefault="qualified">
    <xsd:include schemaLocation="SEmpViewSDO.xsd"/>
    <xsd:complexType name="SalespersonViewExSDO">
        <xsd:annotation>
            <xsd:appinfo source="http://xmlns.oracle.com/adf/svc/metadata/">
                <key xmlns="http://xmlns.oracle.com/adf/svc/metadata/">
                    <attribute>Id</attribute>
                </key>
            </xsd:appinfo>
        </xsd:annotation>
        <xsd:complexContent>
            <xsd:extension base="SEmpViewSDO">
                <xsd:sequence>
                    <xsd:element name="CommissionPct" type="xsd:decimal"
                                 minOccurs="0" nillable="true"/>
                </xsd:sequence>
            </xsd:extension>
        </xsd:complexContent>
    </xsd:complexType>
    <xsd:element name="salespersonViewExSDO" type="SalespersonViewExSDO"/>
</xsd:schema>
```

The generated service interface uses the XSD `<import>` element to expose the polymorphic subtype. The following example shows the service interface XSD `AppModuleService.xsd` with the import definition for the `SalespersonViewExSDO` subtype.

```
<schema xmlns="http://www.w3.org/2001/XMLSchema" elementFormDefault="qualified"
                    targetNamespace="http://xmlns.oracle.com/apps/hr/service/types/"
xmlns:tns="http://xmlns.oracle.com/apps/hr/service/types/"
     xmlns:ns0="/oracle/model/polymorphicvo/views/common/"     xmlns:ns1="http://
xmlns.oracle.com/adf/svc/types/">     <import namespace="http://xmlns.oracle.com/adf/svc/types/"
                    schemaLocation="classpath:/META-INF/wsdl/BC4JService.xsd"/>     <import
namespace="/oracle/model/polymorphicvo/views/common/"
                    schemaLocation="../../../../views/common/SalespersonViewExSDO.xsd"/>
     <import namespace="/oracle/model/polymorphicvo/views/common/"
                    schemaLocation="../../../../views/common/SDeptViewSDO.xsd"/>     <import
namespace="/oracle/model/polymorphicvo/views/common/"
                    schemaLocation="../../../../views/common/SEmpViewSDO.xsd"/>
```

Figure 15-8 shows how the web service schema represents the various strongly-typed service objects, as well as the import definition for the polymorphic subtype `SalespersonViewExSDO`.

What You May Need to Know About Method Signatures on the ADF Web Service Interface

You can define two different kinds of interfaces for an application module: the client interface and the service interface. The client interface is used by the **ADF Model** layer for UI clients. The service interface is for application integration and is used by external web services or other application services (either programmatically or automatically using the service-enabled entity feature).

An application module can support no interface at all, only client interfaces, only service interfaces, or both client interfaces and service interfaces combined. However, be aware that the two kinds of interfaces differ in the data types that are supported for the parameters and/or return values of your custom methods that you define for the respective interfaces. The types supported on the client interface are described in What You May Need to Know About Method Signatures on the Client Interface.

The service interface, in contrast to the client interface, supports a more narrow set of data types for custom method parameters and return values and is limited to:

- Java primitive types and their object wrapper types (for example, `int`, `Integer`, and `Long`)
- `java.lang.String`
- `java.math.BigDecimal`
- `java.math.BigInteger`
- `java.sql.Date`
- `java.sql.Time`
- `java.sql.Timestamp`
- `java.util.Date`
- `oracle.jbo.AttributeList`
- `oracle.jbo.domain.BlobDomain`
- `oracle.jbo.domain.Char`
- `oracle.jbo.domain.ClobDomain`
- `oracle.jbo.domain.DBSequence`
- `oracle.jbo.domain.Date`
- `oracle.jbo.domain.NClobDomain`
- `oracle.jbo.domain.Number`
- `oracle.jbo.domain.Timestamp`
- `oracle.jbo.domain.TimestampLTZ`
- `oracle.jbo.domain.TimestampTZ`
- `oracle.jbo.server.ViewRowImpl` or any subtype
- `java.util.List<`*aType*`>`, where *aType* is any of the service-interface supported data types, including Java primitive type

> **Note:** The service interface specifically does not support Java `Map` collection. This means it is not possible to return a collection of objects that are of different types. However, a collection is not limited to view row attributes, a return type can be defined as a list of any service-interface supported data type. For example, `List<DataObject>`, `List<AttributeList>`, and `List<String>` are all valid types.

You can define a custom method that returns a type of `AttributeList` when you want to allow the client developer to work with the list of attributes and perform custom operations without the need to involve framework behavior before the custom method executes. As an alternative, when the client developer wants the framework to manage rows (create, find, and populate), define custom methods that return `ViewRowImpl` or `List<ViewRowImpl>` instead. In summary, if your method signature defines `ViewRowImpl` or `List<ViewRowImpl>` as the data type, then the application automatically:

1. Looks up the row in the corresponding view object instance by primary key and/or alternate key
2. If the row is not found, then creates a new row
3. Applies the attribute changes in the found or new row

Whereas, if your method signature defines the `AttributeList` data type, then no automatic behavior is provided, and the actions performed and data modified by the custom method will be limited to your custom method's code.

What You May Need to Know About Row Finders and the ADF Web Service Operations

When you create a row finder for a view object, the service operations of the exposed service view instance support row lookup using non-key attributes defined by the row finder. For example, the service can invoke the row finder to locate the employee by their email address instead of the employee ID (a row key attribute). When the row finder is defined on a non-key attribute of the view object and the end user supplies a value for this attribute in the web service payload, the service will automatically invoke the row finder to identify the matching rows. Where the email address is the row finder's only required value, the service update operation would allow the end user to update the record of an employee who is identified only by their email address. For details about defining a row finder for use with the service view instance, see Working with Row Finders.

How to Service-Enable Individual View Objects

As a result of enabling the web service interface using the overview editor for the application module, JDeveloper automatically enables your parent view instance selections as Service Data Object (SDO) components. The generated SDO components for each view instance will reference the same namespace and will be configured with the same settings for options such as whether or not warnings are supported. You can use the Java page of the overview editor to customize the SDO definition of these existing service-enabled view objects. You can also use the Java page to service-enable view objects that were not added already to the service interface. For example, if you selected a parent view object that represents the master in a **master-detail relationship**, the child view object will not be automatically service-enabled. You can use the Java page of the overview editor for the child view object to individually add it to the service interface.

You use the Java page of the overview editor for the view object to configure the SDO name and namespace for a view object, or to selectively service-enable child view objects.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.
2. Enable the service interface for the application module, as described in How to Enable the Application Module Service Interface.
3. Optionally, set JDeveloper preferences to specify a default suffix for the names of generated SDO classes, modify the default subpackage where the service interface and classes reside, and set the default namespace prefix for the generated SDO schema and web service, as described in How to Set Preferences for Generating the ADF Web Service Interface.

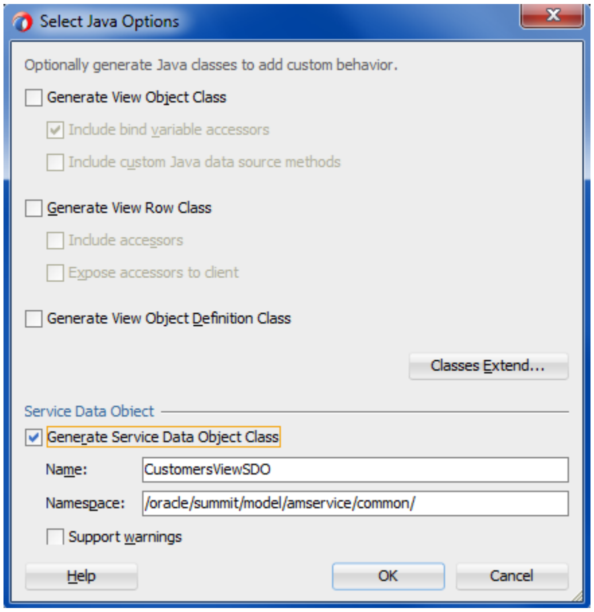
To set the SDO name and namespace for a view object:

1. In the Applications window, double-click the view object.
2. In the overview editor, click the **Java** navigation tab and then click the **Edit java options** button.
3. In the Select Java Options dialog, in the **Service Data Object** section, select **Generate Service Data Object Class**. Enter a value for the service data object name and the service data object's target namespace.

   The target namespace is a URI for the SDO component that you can assign to group similar SDO components together by entering the same URI.

   A default SDO namespace is created for you based on the SDO component's package name with periods replaced by "/". If you have defined a prefix for the namespace in the Service page of the Preferences dialog, the prefix will be added at runtime to the beginning of the namespace. For example, Figure 15-9 shows the default namespace based on the package name.

Figure 15-9 Service Data Object Name and Namespace Options



Optionally generate Java classes to add custom behavior.

☐ Generate View Object Class

☑ Include bind variable accessors

☐ Include custom Java data source methods

☐ Generate View Row Class

☐ Include accessors

☐ Expose accessors to client

☐ Generate View Object Definition Class

Service Data Object

☑ Generate Service Data Object Class

Name: CustomersViewSDO

Namespace: /oracle/summit/model/amservice/common/

☐ Support warnings

4. When you want to be able to extract warnings associated with the view rows of the service interface object, select **Support Warnings**.

   For example, your view object might have a range validator defined on the `Salary` attribute and failure handling for the validator is specified as Informational Warning.

   If **Support Warnings** is not selected, no informational messages will be returned with the service response.

   When enabled and a warning is generated from the underlying ADF business component object for one of the standard service operations or custom operations, the warning information will be captured by the response object. You can use the methods generated for the service object result class to extract the messages from the view rows, as described in Container Object Implemented by SDO Result Class and Interface.

5. Click **OK**.

How to Customize the SDO Properties of Service-Enabled View Objects

You can use the overview editor for the view object to customize the SDO component definition of the service-enabled view object. By default, all attributes of the service-enabled view object will be exposed as SDO properties. By customizing the view object definition, you can exclude individual SDO properties from participating in the service interface. In the case of SDO properties that define numeric values, you can associate two properties so they appear as a single complex type in the service interface. For example, you can associate one property that defines a currency code or unit of measure with another property that displays the numeric value. Currently, only the complex service types `AmountType` (a currency code) and `MeasureType` (a unit of measure) are supported.

Excluding Individual SDO Properties in a Generated SDO Component

As a result of enabling the web service interface using the overview editor for the application module, JDeveloper automatically enables your parent view instance selections as SDO components. Additionally, you can selectively service-enable individual child view objects and generate SDO components. By default, generated SDO components expose all attributes of their base view object definition as SDO properties. You can hide any attribute that you do not want the service interface to return as an SDO property.

You use the Attributes page of the overview editor to select the view object attribute that you want to exclude from the service interface. You then use the Details tab in the overview editor for the view object to hide the selected attribute from the SDO component.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.
2. Service-enable the desired view object, as described in How to Service-Enable Individual View Objects.

To exclude an SDO property from a service-enabled view object:

1. In the Applications window, double-click the view object.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute corresponding to the property that you want to exclude and then click the **Details** tab and deselect **SDO Property**.

Associating Related SDO Properties Using Complex Data Types

As a result of service-enabling the view object, JDeveloper automatically exposes SDO properties as XSD-defined service types that correspond to the data types of the underlying view object's attributes. In the case of attributes that define numeric values, you can change the SDO property's service type to associate a related property using one of these predefined service types:

- `AmountType` service type, for use with any property that defines a currency code
- `MeasureType` service type, for use with any property that defines a unit of measure

When you change the service type of an SDO property to either of these complex types, the service interface associates the two properties together and returns them as a single XML element. Both properties of the SDO component must be defined by attributes in the base service-enabled view object.

For example, suppose that your view object defines the `OrderTotal` attribute and a `CurrencyCode` attribute to specify the currency code of allowed countries. By default, the service interface exposes these attributes as SDO properties and returns each property as a separate XML element:

```
<OrderTotal>100.00</Price>
<CurrencyCode>USD</CurrencyCode>
```

If you change the type of the `OrderTotal` property (assume that the XSD file defines this property as a `decimal` type) to the complex type `AmountType` and then associate the `CurrencyCode` property, the service interface will return them as one XML element:

```
<OrderTotal CurrencyCode="USD">123.00</OrderTotal>
```

Also, when you generate a web service proxy, as described in Calling a Web Service Method Using the Proxy Class in an Application Module, the class treats the two values as one object:

```
AmountType price;
...
price.setValue(123.00);
price.setCurrencyCode("USD");
```

You use the Attributes page of the overview editor to select the view object attribute whose service type you want to customize. You use the Edit Attribute dialog that you display from the Attributes page of the overview editor to associate SDO properties for the selected attribute and select the predefined complex service type.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Create the desired view objects, as described in How to Create an Entity-Based View Object, and How to Create a Custom SQL Mode View Object.
2. Service-enable the desired view object, as described in How to Service-Enable Individual View Objects.

To associate SDO properties in a service-enabled view object:

1. In the Applications window, double-click the view object.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute corresponding to the property that you will associate with another SDO property.

   The attribute you select must define a numeric type. For example, to associate a currency code with the attribute that displays the amount paid by a customer, you might select the `OrderTotal` attribute in the `Orders` service-enabled view object.
4. With the attribute selected, click the **Details** tab and then from the **XSD Type** dropdown list, choose the desired service type.

If the **XSD Type** dropdown is not enabled, return to the attribute list and select an attribute of type numeric. Attributes whose values are not a numeric type cannot be associated with the available complex service types.

The SDO framework supports the complex service types AmountType and MeasureType. Choose AmountType when the property you want to associate specifies currency information. Choose MeasureType when the property you want to associate specifies a unit of measure.

5. In the **currencyCode** or **unitCode** dropdown list, select the view object attribute to define the complex type.

   The dialog changes to display the dropdown list appropriate to the XSD type selection. Choose the attribute that is used to determine the currency code or unit of measure.

How to Support Nested Processing in Service-Enabled Master-Detail View Objects

When your data model defines master-detail relationships between parent and child view objects, the service operations that you enable for the master view object may not automatically be executed on the detail view object. Post operations on the detail view object are supported by default when the primary source **entity object** of the master view object is composed with the primary destination entity object of the detail view object. This master-detail relationship is known as a composition association and is created in JDeveloper when the source entity object contains the destination entity object as a logical, nested part, as described in What You May Need to Know About Composition Associations.

To support create/merge/update/process methods that post child details along with the parent, you will need to create a **view link** to define the master-detail relationship according to one of these scenarios:

- The view link uses the composition association, then post operations on the detail view object are supported by default.
- The view link is based on an association, and the association has the destination accessor generated, and the association has a custom property SERVICE_PROCESS_CHILDREN=true defined.
- The view link is not based on an association but has a custom property SERVICE_PROCESS_CHILDREN=true defined.

The custom property provides an alternative to using a composition association that makes it convenient to support nested processing for any view objects with a view link defined. You can define SERVICE_PROCESS_CHILDREN as a custom property in the overview editor for either the view link or the view link's association (when present).

To support get and find methods that retrieve child details along with the parent, the view link between the master and detail view objects must have the destination accessor generated. The destination accessor permits traversal of the hierarchy from the master to the detail view object.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to have an understanding of how master-detail relationships are defined using view links or **entity associations**:

- For more information about view links, see Working with Multiple Tables in a Master-Detail Hierarchy.
- For more information about associations, see Creating and Configuring Associations.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Create the desired view objects and service-enable the child view object in the master-detail hierarchy, as described in How to Service-Enable Individual View Objects.
2. If the view link is not based on an association, confirm that a destination accessor exists for the view link by opening the view link in the overview editor and viewing the Relationship page. To generate the accessor so it appears in the Relationship page, click the **Edit Accessors** button, and then, in the View Link Properties dialog, select **Generate Accessor in View Object** for the destination accessor.

   If the view link is based on an association, then the destination accessor must exist for the association's destination entity object. To generate one, use the Relationship page of the overview editor for the association.

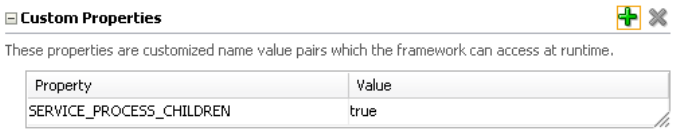
To support nested processing in a master-detail hierarchy:

1. If the view link for the master-detail hierarchy is not based on an association, then in the Applications window, double-click the view link; otherwise, if the view is based on an association, then in the Applications window, double-click the association.

   You can confirm how the view link was created in the Relationship page of the overview editor. The Attributes section names the source and destination attributes. When the view link is based on an association, the attribute hyperlinks will contain the names of the association. Otherwise, the hyperlinks will contain the names of the base entity objects.
2. In the overview editor, click the **General** navigation tab.

   The overview editor for the view link and the association display similar selections.
3. In the General page, expand the **Custom Properties** section, and then click the **Add Custom Property** icon and enter `SERVICE_PROCESS_CHILDREN` for the property and `true` for the property value, as shown in Figure 15-10.

Figure 15-10   Custom Property to Support Nested Processing



These properties are customized name value pairs which the framework can access at runtime.

Property	Value
SERVICE_PROCESS_CHILDREN	true

What Happens When You Create SDO Classes

When you create SDO classes, the following files are generated and appear in the Applications window under the owning view object:

- Service data object interface
- Service data object class
- Service data object schema file
- Service data object result class and Interface, generated when **Support Warnings** is enabled in the Select Java Options dialog

Do not modify the files generated for service-enabled view objects. The generated files implement required methods of the view object SDO interface.

Property Accessors Generated in the SDO Interface

The view object SDO interface contains strongly typed accessors for the SDO properties, as shown in the following example.

```
package oracle.summit.model.amservice.common;
  public interface OrdersViewSDO extends java.io.Serializable {
  public java.math.Integer getId();
  public void setId(java.lang.Integer value);
...}
```

View Object Interface Implemented by SDO Class

The view object SDO class implements the view object SDO interface and extends the `SDODataObject` class, which is Oracle's implementation of the SDO specification.

At runtime an instance of an SDO object represents a row in memory.

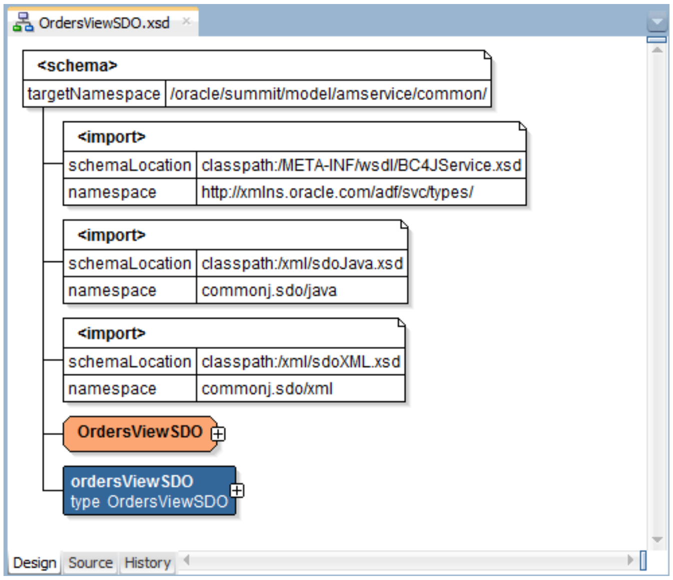
The SDO class is similar to the view row class, as shown in the following example.

```
package oracle.summit.model.amservice.common;
import org.eclipse.persistence.sdo.SDODataObject;
public class OrdersViewSDOImpl extends SDODataObject implements OrdersViewSDO
  {
  ...
  }
```

View Object Schema Generated in the SDO Schema File

The view object SDO schema file, as shown in Figure 15-16, is an XML Schema file which represents the SDO schema.

Figure 15-11 Generated SDO Schema



<schema>
targetNamespace /oracle/summit/model/amservice/common/

<import>
schemaLocation classpath:/META-INF/wsdl/BC4JService.xsd
namespace http://xmlns.oracle.com/adf/svc/types/

<import>
schemaLocation classpath:/xml/sdoJava.xsd
namespace commonj.sdo/java

<import>
schemaLocation classpath:/xml/sdoXML.xsd
namespace commonj.sdo/xml

Container Object Implemented by SDO Result Class and Interface

The view object SDO result class is a container object that allows a service operation to return a list of view rows (wrapped in service data objects) and a list of warnings associated with these view rows. Specifically, the service get operation returns the original object, while the create/update/merge/find/process operations return a wrapper object that contains a list of the original object and a list of information messages, and the delete operation returns only the informational message. If you have enabled the **Support Warnings** option for the service-enabled view object, you can use the generated method result interface to extract warnings.

The view object SDO result class, as shown in the following example, is similar to the view row class.

```
package oracle.summit.model.amservice.common;
import oracle.sdo.SDODataObject;
public class OrdersViewSDOResultImpl extends
   oracle.jbo.common.service.types.MethodResultImpl implements OrdersViewResult {

   public static final int START_PROPERTY_INDEX =
          oracle.jbo.common.service.types.MethodResultImpl.END_PROPERTY_INDEX +
1;
   public static final int END_PROPERTY_INDEX = START_PROPERTY_INDEX + 0;
   public OrdersViewResultImpl() {}
   public java.util.List getValue() {
      return getList(START_PROPERTY_INDEX + 0);
   }

   public void setValue(java.util.List value) {
      set(START_PROPERTY_INDEX + 0 , value);
   }
}
```

How to Expose a Declarative Find Operation Filtered By a Required Bind Variable

The ADF service interface framework allows you to expose declarative find operations to execute the query define by a view object you select. However, when that query uses a bind variable to filter the query results, the bind variable must not be specified as **Required** and **Updatable**. Because the service interface does not expose required, updatable bind variables, a find operation that you execute for such a view object would fail to return any result.

When you want to filter a query result using bind parameters, use the view criteria and expose it as a find operation on the service interface. A service interface find operation based on a view criteria that you create can specify required bind variables.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to have an understanding of how to filter view object queries using bind variables. For more information, see Working with Bind Variables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Create the desired application module, as described in How to Create an Application Module.
2. Create the view criteria, as described in How to Create Named View Criteria Declaratively. In the Edit View Criteria dialog, set the criteria item as a bind variable and set the **Validation** field to **Required**. This selection ensures that the query will not execute without a valid value.

To expose a find operation for a view criteria with required bind variable:

1. In the Applications window, double-click the application module.
2. In the overview editor, click the **Service Interface** navigation tab and then click the **Edit attributes of Service Interface** icon.

   Alternatively, you can select **Edit Service Custom Methods** if you have already defined the service interface.
3. In the Edit Service Interface dialog, select **Service View Instances** from the navigation list and add the view object that you want to filter with its named view criteria to the **Selected** list.
4. To expose the find operation, select the view instance, click the **View Criteria Find Operations** tab and then click the **Add View Criteria** button.
5. In the Configure View Criteria Find Operation dialog, choose the named view criteria for the find operation.

   The dialog displays the bind variable for the selected view criteria.

6. If you want to customize the bind variable name shown in the XML definition for the service, in the **Find Operations Parameters** section, double-click the XML name and edit the name.
7. Click **OK**.

How to Expose a Custom Find Method Filtered By a Required Bind Variable

As an alternative to exposing a declarative find operation that relies on a view criteria, you can define a service method in your data model project's application module implementation class. The class you create for this purpose allows you to encapsulate business service functionality into a single method that you implement. For details about the purpose of the custom application module implementation class, see Customizing an Application Module with Service Methods.

The following example shows a custom find method implemented in the *AppModuleName*`Impl.java` file to set the bind variable and execute the view object instance query. It uses `setNamedWhereClauseParam()` on the view object instance to set the bind variable. Before executing the query, the find method sets the view object in forward-only mode to prevent caching the view rows that the find method iterates over.

```
public class AppModuleImpl extends ApplicationModuleImpl
{
   public List<ViewRowImpl> findProducts(String location)
   {
      List<ViewRowImpl> result = new ArrayList<ViewRowImpl>();
      ViewObjectImpl vo = getProductsView1();
      vo.setNamedWhereClauseParam("TheLocation", location);
      vo.setForwardOnly(true);
      vo.executeQuery();
      while (vo.hasNext()) {
        result.add((ViewRowImpl)vo.next());
      }
      return result;
   }
}
```

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to have an understanding of how to filter view object queries using bind variables. For more information, see Working with Bind Variables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Create the custom application module class, as described in How to Generate a Custom Class for an Application Module.

2. Create the custom find method to programmatically filter a query result and set the required bind variable, as described in How to Add a WHERE Clause with Named Bind Variables at Runtime.

To expose a find method that sets a required bind variable:

1. In the Applications window, double-click the application module.
2. In the overview editor, click the **Service Interface** navigation tab and then click the **Edit attributes of Service Interface** icon.

   Alternatively, you can click the **Edit Service Custom Methods** icon if you have already defined the service interface.
3. In the Edit Service Interface dialog, select **Service View Instances** from the navigation list and add the find method that you defined to the **Selected** list.
4. Click **OK**.

How to Generate Asynchronous ADF Web Service Methods

By default, the web service supports synchronous service methods. This forces the invoking client application to wait for the response to return before it can continue with its work. In cases where the response returns immediately, this method of invoking the web service is common. However, because request processing can be delayed, it is often useful for the client application to continue its work and to handle the response later on.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to have an understanding of invoking web services using asynchronous request-response. For more information, see the "Overview of Asynchronous Web Services" section of the "Developing Asynchronous Web Services" chapter in *Developing Oracle Infrastructure Web Services*.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete this task:

> Before you can deploy an asynchronous web service, you must configure the queues used to store the request and response. For information about configuring the request and response queues, see the "Creating the Request and Response Queues" section of the "Developing Asynchronous Web Services" chapter in *Developing Oracle Infrastructure Web Services*.

To expose asynchronous web service methods:

1. In the Applications window, double-click the application module.
2. In the overview editor, click the **Service Interface** navigation tab and then click the **Edit attributes of Service Interface** icon.
3. In the Edit Service Interface dialog, in the Service Interface page, select **Generate Asynchronous Web Service Methods**.

4. Click **OK**.

What Happens When You Generate Asynchronous ADF Web Service Methods

JDeveloper generates the service interface for the web service and enables the asynchronous service operation. As shown in the following example, the class annotation `@AsyncWebService` declares the `EmpService` service interface asynchronous and for each synchronous method in the interface, the service exposes an asynchronous method with the same method name and "`Async`" appended.

Exposing both synchronous and asynchronous methods in the same interface allows the web service client developer to decide how to invoke the operation through a web service proxy: by calling the appropriately named method. Note that developers must not invoke asynchronous methods through the ADF Business Components service proxy that is returned from `oracle.jbo.client.svc.ServiceFactory.getServiceProxy()` method.

In this example, because the `EmpService` service is enabled for asynchronous operation, the interface exposes the `getEmployeeAsync()` method and declares the `getEmployee()` method synchronous using the method annotation `@CallbackMethod(exclude=true)` to override the default operation (it is the `exclude=true` part that declares a method in the asynchronous service as synchronous). No annotation is required to declare the asynchronous service methods when the class annotation `@AsyncWebService` is present.

```
import javax.xml.ws.Action;
...
import oracle.webservices.annotations.async.AsyncWebService;
import oracle.webservices.annotations.async.CallbackMethod;

@SOAPBinding(parameterStyle=SOAPBinding.ParameterStyle.WRAPPED,
style=SOAPBinding.Style.DOCUMENT)
@PortableWebService(targetNamespace="http://xmlns.example.com/apps/service/",
name="EmpService",
                    wsdlLocation="oracle/apps/service/EmpService.wsdl")
@SDODatabinding(schemaLocation="oracle/apps/service/EmpService.xsd")
@AsyncWebService
public interface EmpService
{
   ...

   @WebMethod(action="http://xmlns.example.com/apps/service/getEmployee",
                       operationName="getEmployee")
   @RequestWrapper(targetNamespace="http://xmlns.example.com/apps/service/
types/",
                       localName="getEmployee")
   @ResponseWrapper(targetNamespace="http://xmlns.example.com/apps/service/
types/",
                       localName="getEmployeeResponse")
   @WebResult(name="result")
   @CallbackMethod(exclude=true)
   Emp getEmployee(@WebParam(mode = WebParam.Mode.IN, name="empno") Integer
empno)
      throws ServiceException;

   @WebMethod(action="http://xmlns.example.com/apps/service/getEmployeeAsync",
                        operationName="getEmployeeAsync")
   @RequestWrapper(targetNamespace="http://xmlns.example.com/apps/service/
types/",
                        localName="getEmployeeAsync")
   @ResponseWrapper(targetNamespace="http://xmlns.example.com/apps/service/
types/",
                        localName="getEmployeeAsyncResponse")
   @WebResult(name="result")
   @Action(input="http://xmlns.example.com/apps/service/getEmployeeAsync",
           output="http://xmlns.example.com/apps/service/
getEmployeeAsyncResponse")
   Emp getEmployeeAsync(@WebParam(mode = WebParam.Mode.IN, name="empno") Integer
empno);
}
```

The duplicate asynchronous methods delegate to the synchronous methods in the service implementation, as shown in the following example. This ensures that the underlying business logic is the same for operations declared as either synchronous or asynchronous.

```
...
import oracle.webservices.annotations.async.AsyncWebService;

@Stateless(name="oracle.apps.service.EmpServiceBean",
mappedName="EmpServiceBean")
@Remote(EmpService.class)
@PortableWebService(targetNamespace="http://xmlns.oracle.com/apps/service/",
                     serviceName="EmpService", portName="EmpServiceSoapHttpPort",
                     endpointInterface="oracle.apps.service.EmpService")
@Interceptors(ServiceContextInterceptor.class)
@AsyncWebService
public class EmpServiceImpl extends ServiceImpl implements EmpService
{
   ...

   /**
    * getEmployee: generated method. Do not modify.
    */
   public Emp getEmployee(Integer empno)
      throws ServiceException
   {
      return (Emp) get(new Object[] { empno }, "Employee", Emp.class);
   }

   /**
    * getEmployeeAsync: generated method. Do not modify.
    */
   public Emp getEmployeeAsync(Integer empno)
      throws ServiceException
   {
      return getEmployee(empno);
   }
}
```

What Happens at Runtime: How the Asynchronous Call Is Made

From the client's point of view, an asynchronous call consists of two one-way message exchanges. The sequence diagram in Figure 15-12 depicts the following flow:

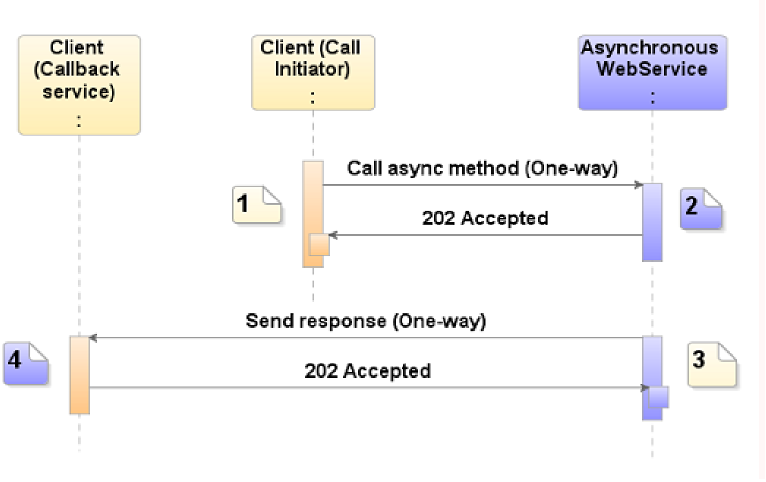
1. The client calls for the asynchronous operation. (In the figure, Step 1.)

2. The asynchronous service receives the request and returns the HTTP acknowledgement back to the client without actually processing the request. (In the figure, Step 2)
3. Eventually the asynchronous operation will complete and the module on the server side will send the response to the client side. (In the figure, Step 3.)

   To receive the response at the client side, the client must have some kind of HTTP listener, for example, a servlet or a web service.
4. The client side-generated web service (the Callback Service) receives the asynchronous responses. (In the figure, Step 4.)

   The module in Step 3 on the server side acts like a client to the callback service and so is referred as the callback client.

Figure 15-12 Asynchronous Call Sequence



Client (Callback service) :
Client (Call Initiator) :
Asynchronous WebService :
Call async method (One-way)
1
202 Accepted
2
Send response (One-way)
4
202 Accepted
3

How to Set Preferences for Generating the ADF Web Service Interface

You have additional control of the service generated by JDeveloper. You can set JDeveloper preferences to perform the following tasks:

- Specify a default suffix for the names of generated SDO classes
- Modify the default subpackage where the service interface and classes reside
- Shape the URI of the generated SDO schema and web service target namespace by setting a default namespace prefix and by specifying the names of packages that you want to exclude from the URI.

To set the SDO class name suffix:

1. In the main menu, choose **Tools** and then **Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and choose **Class Naming**.
3. In the **View Object** suffix list, enter a suffix for **SDO**, for example, `SDO`.

To set the default subpackage for the generated service interface:

1. In the main menu, choose **Tools** and then **Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and choose **Packages**.
3. In the **Relative Package Specification for Classes** list, specify the default package names:
   - To set the Service Interface package name, enter a value for the **Client Interface**. (The **Service Interface** displays the same package name you specify for the client interface). The default package name is `common`.
   - Enter a value for the **Service Interface Subpackage** of the **Service Interface**. The default subpackage name is `serviceinterface`.

   For example, if you enter `common` for **Service Interface** and `serviceinterface` for **Service Interface Subpackage** (the defaults), service interfaces for data model components in the data model package `oracle.summit.model.amservice` will be placed in the subpackage `oracle.summit.model.amservice.common.serviceinterface`.

To shape the URI of the generated SDO schema and service interface target namespace:

1. In the main menu, choose **Tools** and then **Preferences**.
2. In the Preferences dialog, expand **ADF Business Components** and choose **Service**.
3. Enter a value for the **Default Namespace Prefix** to be added to the beginning of the target namespace of the generated SDO schema and web service.

   For example, when you enable **Generate Service Data Object Class** in the Java page of the Create View Object wizard, a namespace prefix `www.globalcompany.example.com` would be added to the package name for the SDO to create the target namespace `www.globalcompany.example.com/oracle/summit/model/amservice/common/`.
4. Enter a semi-colon separated list of package names for the **Packages to Exclude** to shape the URI of the default target namespace.

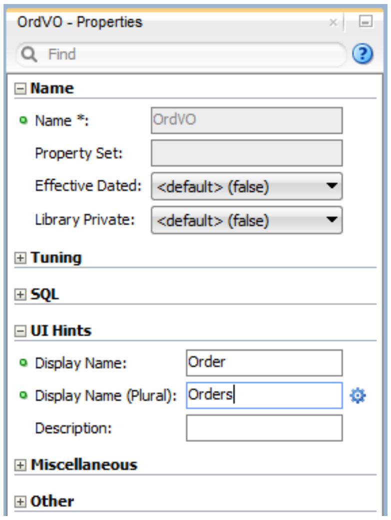
   For example, when you enter a namespace prefix `www.globalcompany.example.com` and the package name of the SDO is `globalcompany.summit.model.amservice/` the generated target namespace would incorrectly duplicate the package name `globalcompany`. In this situation, you can exclude the package name `globalcompany` to shape the URI for the target namespace as `www.globalcompany.example.com/summit/model/amservice/common/`.

   More than one package name can be excluded in a semi-colon separated list, as `a;a.b` to yield `<`*`namespace-prefix`*`>/c/d`. In the case of subpackage names, be sure to specify fully-qualified package names. For example to exclude package `c` in the package name `a.b.c.d`, enter `a.b.c`. In this case, the default target namespace yields `<`*`namespace-prefix`*`>/a/b/d/`.

How to Set Display Names for Service View Instances and Attributes

Display names are labels that support the web service consuming application to programmatically generate a user interface and to display the service view instance and its attributes with the correct identifying labels. To enable access to these display names at runtime by the consuming application, you use the Create Service Interface wizard to add the built-in method `getDfltObjAttrHints()` to the remote client service interface. This method lets the consuming application developer programmatically retrieve the **Display Name** UI hint associated with the service view instance and its attributes. You define the UI hints in the Property window for the view object, where you can define a singular label and a plural label for each view instance name and attribute name. For example, as Figure 15-13 shows, you may define UI hints for the `OrdersVO` view object with the labels `Order` and `Orders`.

Figure 15-13 Display Name UI Hints for View Objects



Name *: OrdVO
Property Set:
Effective Dated: <default> (false)
Library Private: <default> (false)
Display Name: Order
Display Name (Plural): Orders
Description:

Before you begin:

You will need to complete this task:

> Define the built-in method `getDfltObjAttrHints()` in the remote client service interface, as described in How to Enable the Application Module Service Interface.

To set UI Hint labels for the view instance and its attributes:

1. In the Applications window, double-click the application module that defines the view instance for the SDO.
2. In the Data Model list, select the view instance name and, below the list, click the **View Definition** link.
3. In the overview editor for the view object, click the **General** navigation tab.
4. In the main menu, choose **View** and then **Property Inspector**.
5. In the Property Inspector, to set the label for the view object instance, expand **UI Hints** and enter the labels for the **Display Name** and **Display Name (Plural)**.
6. In the overview editor for the view object, click the **Attributes** navigation tab and select the attribute that you want to label.
7. In the Property Inspector, to set the label for the view object attribute, expand **UI Hints** and enter the labels for the **Label** and **Display Name (Plural)**.

How to Secure the ADF Web Service for Access By SOAP Clients

At runtime, the web service client will invoke the service-enable methods of the application module through the SOAP protocol. You can configure an Oracle Web Service Manager (OWSM) security policy to enable authentication and authorization on the service. The security policy that you select will require the SOAP client call to provide credential information (or SAML token) as part of the SOAP header. You can also configure other policies to enable message protection (integrity and confidentiality) for inbound SOAP requests, for instance.

To secure the web service for SOAP clients:

1. Configure an OWSM authentication policy.
2. Configure an OWSM authorization policy.

You can enable authentication to require users to supply credentials before they have access to the service methods on the service interface. The type of authentication required is configured on the service implementation class using an OWSM authentication policy annotation.

You can enable permission checking to enable only users with sufficient privileges to invoke a service method on the service interface. Permission checking is configured on the service implementation class using this OWSM authorization annotation:

- `binding_permission_authorization_policy`

  This policy provides simple permission-based authorization for the request based on the authenticated Subject at the SOAP binding level. This policy ensures that the Subject has permission to perform the operation. This policy should follow an authentication policy where the Subject is established and can be attached to any SOAP-based endpoint.

As an alternative to the permission checking policy, you can configure one of these role-based OWSM security policies:

- `binding_authorization_denyall_policy`

  This policy provides simple role-based authorization for the request based on the authenticated Subject at the SOAP binding level. This policy denies all users with any roles. It should follow an authentication policy where the Subject is established and can be attached to any SOAP-based endpoint.
- `binding_authorization_permitall_policy`

  This policy provides a simple role-based authorization for the request based on the authenticated Subject at the SOAP binding level. This policy permits all users with any roles. It should follow an authentication policy where the Subject is established and can be attached to any SOAP-based endpoint.

For further details about the authorization policies, see Security Policies—Authorization Only in *Securing Web Services and Managing Policies with Oracle Web Services Manager*.

ADF service interface framework also provides an EJB interceptor `ServicePermissionCheckInterceptor` which does the same permission check as `oracle/binding_permission_authorization_policy`, and additionally covers RMI invocation to services. If your services will always be invoked through SOAP, you should attach the OWSM `oracle/binding_permission_authorization_policy` authorization policy. If your services will also be invoked through RMI, you should attach the EJB interceptor `ServicePermissionCheckInterceptor`.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to have an understanding of the predefined authentication policies supported by OWSM. For more information, see Security Policies-Authentication Only in *Securing Web Services and Managing Policies with Oracle Web Services Manager*.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete this task:

> Grant users access to the service, as described in How to Grant Test Users Access to the Service.

To configure an authentication and authorization:

1. In the Applications window, expand the application module, expand the **serviceinterface** node, and then double-click the service implementation class (*`AppModule`*`ServiceImpl.java`) node.

   In the web service generated from the `ServiceAppModule` application module in the `oracle.summit.model.amservice` package in the `SummitADF_Examples` workspace, the service implementation class is `ServiceAppModuleServiceImpl.java`.

2. If your services will always be invoked exclusively through SOAP (and not RMI), you should use an OWSM authorization policy as follows:

   a. In the source for the service implementation class, place your cursor on the `@PortableWebService` annotation.

      For example, `ServiceAppModuleServiceImpl.java` shows the annotation for the service as follows:

```
...
@PortableWebService(
  targetNamespace="/oracle/summit/model/amservice/common/",
  serviceName="ServiceAppModuleService",
  portName="ServiceAppModuleServiceSoapHttpPort",
  endpointInterface=
   "oracle.summit.model...common.serviceinterface.ServiceAppModuleService")
```

   b. In the Properties window, expand the **Policies** section, and click the button next to the **Multiple Policies** field.

   c. In the Edit Property: Multiple Policies dialog, select the desired security policy and click **OK**.

      For details about the security policies supported by OWSM, see Security Policies—Authorization Only in *Securing Web Services and Managing Policies with Oracle Web Services Manager*.

   d. Return to the source file and note that annotation `@PolicySet` is configured.

The @PolicySet annotation that you define for the service implementation class specifies the security requirements to potential clients. In this example, the annotation shows both the permission-checking authorization policy (oracle/binding_permission_authorization_policy) and an authentication policy:

```
...
@PortableWebService(
  targetNamespace="/oracle/summit/model/amservice/common/",
  serviceName="ServiceAppModuleService",
  portName="ServiceAppModuleServiceSoapHttpPort",
  endpointInterface=
   "oracle.summit.model...common.serviceinterface.ServiceAppModuleService")
@PolicySet(references = {
   @PolicyReference(value =
                        "oracle/wss_username_token_service_policy"),
   @PolicyReference(value =
                        "oracle/binding_permission_authorization_policy")
})
```

3. If your services will be invoked through SOAP and RMI, you should use ServicePermissionCheckInterceptor only (there is no need to use an OWSM authorization policy) as follows.

   In the source editor, place your cursor in the @Interceptors annotation and add ServicePermissionCheckInterceptor.class to enable permission checking at runtime.

```
...
@Interceptors({ ServiceContextInterceptor.class,
                ServicePermissionCheckInterceptor.class })
@Stateless(name=
            "oracle.summit.model.amservice.common.ServiceAppModuleServiceBean",
           mappedName="ServiceAppModuleServiceBean")
```

4. Save the service implementation class file.

How to Secure the ADF Web Service for Access By RMI Clients

Because the ADF web service is implemented as an EJB and deployed on Oracle WebLogic Server as Oracle Web Service's PortableWebService, the client application can invoke the service-enable methods of the application module through the RMI protocol.

To secure the web service for RMI clients:

1. Configure JNDI context properties to enable authentication.
2. Enable permission checking to configure an authorization policy.

Before you begin:

It may be helpful to have an understanding of the predefined authorization policies supported by OWSM. For more information, see Security Policies—Authorization Only in *Securing Web Services and Managing Policies with Oracle Web Services Manager*.

Enabling Authentication for RMI Clients

When the ADF web service is invoked through RMI, authentication is handled with the common JAAS login module. The login module can be passed the principal and credential as part of the JNDI initial context for the EJB in the calling application. If you do not define the JNDI context properties, the login module will attempt to obtain the caller's current security context.

When you choose to define remote JNDI context information, then these four JNDI context properties need to be added to the `connections.xml` file.

> **Note:**
>
> When you intend to test the service in JDeveloper using Integrated WebLogic Server, before deploying the service you can edit the JNDI context properties in the `connections.xml` file directly. However, when you deploy the service to standalone Oracle WebLogic Server, you will use Oracle Enterprise Manager to configure the JNDI context properties.

- `jndiFactoryInitial` should be set to `weblogic.jndi.WLInitialContextFactory`.
- `jndiProviderURL` is the JNDI provider URL that indicates the location of the JNDI server. The URL should be composed as `t3://<`*`hostname`*`>:<`*`server port`*`>`.

  When you test the service in JDeveloper, and your service is deployed to Integrated WebLogic Server, specify the JNDI provider URL of Integrated WebLogic Server: `t3://<`*`hostname`*`>`:7101.

  When you deploy the service to remote Oracle WebLogic Server, specify a URL like: `t3://localhost:8888`, where `t3` is the Oracle WebLogic protocol, `localhost` is the host name that the remote Oracle WebLogic Server instance runs in, `8888` is the port number.
- `jndiSecurityPrincipal` specifies the principal (user name) with permission to access the remote JNDI.

  When you test the service in JDeveloper Integrated WebLogic Server, you should omit this context property since no security is configured for the JNDI server on Integrated WebLogic Server.

  When you deploy the service to standalone Oracle WebLogic Server, the user name can be read from the file.
- `jndiSecurityCredentials` specifies the credentials (password) to be used for the security principal.

  When you test the service in JDeveloper Integrated WebLogic Server, you should omit this context property since no security is configured for the JNDI server on Integrated WebLogic Server.

  When you deploy the service to standalone Oracle WebLogic Server in a test environment, you can specify credentials in plain text for the JNDI provider. For example, you can specify `weblogic/weblogic1`, which are the default administrator user name/password credentials with sufficient privileges to access JNDI provider for Oracle WebLogic Server.

  When you deploy the service to a production environment, you must remove the plain text password to avoid creating a security vulnerability, and the `connections.xml` file must contain `<SecureRefAddr addrType="jndiSecurityCredentials"/>` with no password. To configure the service password for standalone Oracle WebLogic Server, you must use Oracle

Enterprise Manager, which will store the encrypted password in Oracle's credential store.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

To configure JNDI context properties to handle authentication:

1. In the Application Resources panel, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click **connections.xml**.
2. If the source editor, use the JNDI context properties to specify the principal and credentials.

   If you are testing the service in JDeveloper's Integrated WebLogic Server, you only need to specify the `jndiProviderURL` property, as shown in the following example.

   ```
   <References xmlns="http://xmlns.oracle.com/adf/jndi">
     <Reference name="{www.globalcompany.com}ServiceAppModuleService"
                className="oracle.jbo.client.svc.Service" xmlns="">
        <Factory className="oracle.jbo.client.svc.ServiceFactory"/>
        <RefAddresses>
          ...
          <StringRefAddr addrType="jndiFactoryInitial">
             <Contents>weblogic.jndi.WLInitialContextFactory</Contents>
          </StringRefAddr>
          <StringRefAddr addrType="jndiProviderURL">
              <Contents>t3://a_hostname:7101</Contents>
          </StringRefAddr>
          ...
        </RefAddresses>
     </Reference>
     ...
   </References>
   ```

   If you are deploying the service for testing purposes to standalone Oracle WebLogic Server, you can use the `connections.xml` file to specify credentials for the JNDI provider. As the following example shows, you can specify `weblogic/weblogic1`, which are the default administrator user name/password credentials with sufficient privileges to access JNDI provider for Oracle WebLogic Server.

   ```
   <References xmlns="http://xmlns.oracle.com/adf/jndi">
     <Reference name="{www.globalcompany.com}ServiceAppModuleService"
                className="oracle.jbo.client.svc.Service" xmlns="">
        <Factory className="oracle.jbo.client.svc.ServiceFactory"/>
        <RefAddresses>
          ...
          <StringRefAddr addrType="jndiFactoryInitial">
             <Contents>weblogic.jndi.WLInitialContextFactory</Contents>
          </StringRefAddr>
          <StringRefAddr addrType="jndiProviderURL">
              <Contents>t3://localhost:8888</Contents>
          </StringRefAddr>
          <StringRefAddr addrType="jndiSecurityPrincipal">
   ```

```
            <Contents>weblogic</Contents>
        </StringRefAddr>
        <SecureRefAddr addrType="jndiSecurityCredentials">
            <Contents>weblogic1</Contents>
        </SecureRefAddr>
        ...
      </RefAddresses>
   </Reference>
   ...
</References>
```

If you are deploying the service to production Oracle WebLogic Server, you can use the connections.xml file to specify the user name. As shown in the following example, you must not specify the password.

```
<References xmlns="http://xmlns.oracle.com/adf/jndi">
  <Reference name="{www.globalcompany.com}ServiceAppModuleService"
             className="oracle.jbo.client.svc.Service" xmlns="">
     <Factory className="oracle.jbo.client.svc.ServiceFactory"/>
     <RefAddresses>
       ...
       <StringRefAddr addrType="jndiFactoryInitial">
          <Contents>weblogic.jndi.WLInitialContextFactory</Contents>
       </StringRefAddr>
       <StringRefAddr addrType="jndiProviderURL">
           <Contents>t3://localhost:8888</Contents>
       </StringRefAddr>
       <StringRefAddr addrType="jndiSecurityPrincipal">
           <Contents>a_username</Contents>
       </StringRefAddr>
       <SecureRefAddr addrType="jndiSecurityCredentials/">
       ...
     </RefAddresses>
  </Reference>

</References>
```

3. Save the file.

Configuring Authorization for RMI Clients

You can enable permission checking to allow only users with sufficient privileges to invoke a service method on the service interface. In order to enable permission checking, the ADF service interface framework provides an EJB interceptor named ServicePermissionCheckInterceptor. This EJB interceptor ensures permission checking is enforced at runtime. Currently, the interceptor is coded with the same logic that OWSM implements for the authorization policy binding_permission_authorization_policy.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Configure the authentication policy for the service in the `connections.xml` file of the client application (the one invoking the service), as described in Enabling Authentication for RMI Clients.
2. Grant users access to the service, as described in How to Grant Test Users Access to the Service.

To configure a permission-based authorization policy:

1. In the Applications window, expand the **META-INF** node of the web service project and double-click the **ejb-jar.xml** node.
2. In the source editor, add the following `JpsInterceptor` definition required by the EJB for application roles evaluation.

```
<?xml version = '1.0' encoding = 'windows-1252'?>
<ejb-jar xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
         xsi:schemaLocation="http://java.sun.com/xml/ns/javaee
         http://java.sun.com/xml/ns/j2ee/ejb-jar_3_0.xsd" version="3.0"
         xmlns="http://java.sun.com/xml/ns/javaee">
  <enterprise-beans>
    ...
  </enterprise-beans>
  <interceptors>
     <interceptor>
        <interceptor-class>
            oracle.security.jps.ee.ejb.JpsInterceptor
        </interceptor-class>
           <env-entry>
              <env-entry-name>application.name</env-entry-name>
              <env-entry-type>java.lang.String</env-entry-type>
              <env-entry-value>ApplicationName</env-entry-value>
              <injection-target>
                  <injection-target-class>
                      oracle.security.jps.ee.ejb.JpsInterceptor
                  </injection-target-class>
                  <injection-target-name>
                      application_name
                  </injection-target-name>
              </injection-target>
           </env-entry>
     </interceptor>
     ...
  <interceptors>
  <assembly-descriptor>
     <interceptor-binding>
        <ejb-name>*</ejb-name>
        <interceptor-class>
             oracle.security.jps.ee.ejb.JpsInterceptor
        </interceptor-class>
     </interceptor-binding>
  </assembly-descriptor>
</ejb-jar>
```

3. In the Applications window, expand the application module, expand the **serviceinterface** node, and then double-click the service implementation class (*`AppModule`*`ServiceImpl.java`) node.

4. In the source editor, place your cursor at the end of your annotations section and add the annotation named `ServicePermissionCheckInterceptor` to enable permission checking at runtime.

```
...
@Stateless(name="oracle.summit.model.amservice.common.
                                        ServiceAppModuleServiceBean")
@Remote(ServiceAppModuleService.class)
@PortableWebService(targetNamespace="http://www.globalcompany.com/
                       ServiceAppModuleService",
                       serviceName="ServiceAppModuleService",
                       portName="ServiceAppModuleServiceSoapHttpPort",
                       endpointInterface="oracle.summit.model.amservice.
                            common.serviceinteface.ServiceAppModuleService")
@CallByReference
@Interceptors({ServiceContextInterceptor.class,
                        ServicePermissionCheckInterceptor.class})
```

5. Save the files.

How to Grant Test Users Access to the Service

After you have configured the authorization policy for the service, you must configure the Oracle Platform Security Services (OPSS) security provider to specify which users can invoke method on the service. At design time, you perform this task by editing the `jazn-data.xml` configuration file to create application roles and make an invoke permission grant to the desired application roles. Then when you deploy the service, the administrator for the target Oracle WebLogic Server will associate enterprise users with the application roles you specify. This allows you to confer the right to invoke a service method to any user who is a member of that application role. Users who are members of a role that has not been granted the invoke permission, will denied access to the service method.

The invoke permission for Oracle Web Services is defined by the `oracle.wsm.security.WSFunctionPermission` class. You can grant the invoke permission to the application roles you define for all the methods of the service or just to individual methods.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to have an understanding of application roles and the OPSS security provides. For more information, see the "Introduction to Oracle Platform Security Services" chapter in *Securing Applications with Oracle Platform Security Services*.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Configure authentication and authorization policies for your service, as described in How to Secure the ADF Web Service for Access By SOAP Clients, or How to Secure the ADF Web Service for Access By RMI Clients.

2. Add the OPSS security provider configuration file to your project by creating a `jazn-data.xml` deployment descriptor. For more information about deployment descriptors, see the "Deploying Applications" chapter in *Developing Applications with Oracle JDeveloper*.

   Note that in JDeveloper you open the New Gallery, expand **General**, select **Deployment Descriptors** and then **Oracle Deployment Descriptors**, and click **OK**.

3. Create the desired application roles that you want to make grants to, as described in Creating Application Roles.
4. For the purpose of testing your web service in JDeveloper using Integrated WebLogic Server, you can populate the application roles with test users, as described in Creating Test Users.

To grant the web service permission to application roles in the jazn-data.xml file:

1. In the main menu, choose either **Application > Secure > Resource Grants** or **Application > Secure > Entitlement Grants**.

   You can grant multiple privileges to an application role as an entitlement set or you can grant individual privileges to a resource. Create an entitlement grant to aggregate privileges that together secure a specific end user duty. For details about entitlement grants, see How to Aggregate Resource Grants as Entitlement Grants.

2. In the editor window for the `jazn-data.xml` file, click the **Source** tab.
3. In the source for the `jazn-data.xml` file, expand the `<policy-store>` element to view all ADF security policies that you already defined for your application.

   Currently, this release does not provide an editor to create an application security policy; you will need to manually create the policy in the source for the `jazn-data.xml` file.

4. Inside the `<jazn-policy>` element, create a `<grant>` element that defines the `<grantee>` with the desired application role and the `<permission>` with the fully qualified class name of the OWSM permission class (`oracle.wsm.security.WSFunctionPermission`), the permission target name that uniquely identifies the service method, and the invoke method action that you want to grant to the application role principal.

   Your finished source should look similar to this:

```
<grant>
  <grantee>
    <principals>
      <principal>
         <class>oracle.security.jps.service.policystore.ApplicationRole</
class>
         <name>customers</name>
      </principal>
     </principals>
  </grantee>
  <permissions>
     <permission>
       <class>oracle.wsm.security.WSFunctionPermission</class>
      <name>www.globalcompany.example.com/
                                 ServiceAppModuleService#CreateAccount</name>
       <actions>invoke</actions>
     </permission>
```

```
   </permissions>
</grant>
```

The `<principal>` element is defined by the application role class name `oracle.security.jps.service.policystore.ApplicationRole` and an application role name that you already created. For example, if you created an application role `customers` and you want to grant invoke service method permission to the members of that role, then enter `customers`.

The `<permission>` element is defined by the OWSM class name `oracle.wsm.security.WSFunctionPermission` and the permission target name. The permission target name is formed by appending */serviceInterfaceName* and *#serviceMethodName* (or wildcard character) to the service target namespace.

> **Tip:**
>
> You can find the target namespace and service name from the WSDL definition file for the service. In the Applications window, double-click the WSDL file under the **serviceinterface** node to view the `name` and `targetNamespace` definitions.

For example, the WSDL definition file for the Summit ADF sample application might define the following name and namespace:

```
<wsdl:definitions
     name="ServiceAppModuleService"
     targetNamespace="www.globalcompany.example.com"
```

Assume that you want to grant a permission to allow authorized users to invoke a `CreateOrder` service method on the service interface with these `SummitADF_Examples` workspace name and namespace, you would enter the target name like this:

```
www.globalcompany.example.com/ServiceAppModuleService#CreateOrder
```

Alternatively, you can enter the target name using the wildcard character * to grant all operations of the service interface in a single permission:

```
www.globalcompany.example.com/ServiceAppModuleService#*
```

The actions that you can enter are defined by the permission class. In this case, `oracle.wsm.security.WSFunctionPermission` defines the single action `invoke`.

5. Save the changes to the `jazn-data.xml` file.

How to Enable Support for Binary Attachments for SOAP Clients

The ADF service interface framework supports using Message Transmission Optimization Mechanism (MTOM) to handle sending binary data in any service method that operates on a `ViewRow` with a `BlobDomain/ClobDomain` attribute. This permits binary data to accompany XML messages, for example when images are required to document an insurance claim. The SDO data objects of the service-enabled application module maps `BlobDomain/ClobDomain` to `javax.activation.DataHandler`. These `DataHandler` properties could be passed as attachments during SDO data object marshalling/unmarshalling when the web service is called using the SOAP protocol.

To enable MTOM support for your SOAP protocol, you must add the `@MTOM` annotation to the service implementation class (for example, `ServiceAppModuleServiceImpl.java`) and your method must operate on a view row with `BlobDomain`/`ClobDomain` attribute.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete this task:

> Configure a character encoding format that the ADF service interface framework can use to convert data defined by the view object as ClobDomain attribute, as described in How to Specify Character Encoding for ClobDomain Type Attributes.

To enable support for sending binary data attachments:

1. In the Applications window, expand the application module, expand the **serviceinterface** node, and then double-click the service implementation class (`*AppModule*ServiceImpl.java`) file.

   In the web service generated from the `ServiceAppModule` application module in the `oracle.summit.model.amservice` package in the `SummitADF_Examples` workspace, the service implementation class is `ServiceAppModuleServiceImpl.java`.

2. In the source for the service implementation class, place your cursor anywhere in the annotation section.

   For example, in the `ServiceAppModuleServiceImpl.java` the annotation section for the service is:

```
...
@Stateless(name="oracle.summit.model....common.ServiceAppModuleServiceBean",
    mappedName="ServiceAppModuleServiceBean")
@Remote(ServiceAppModuleService.class)
@PortableWebService(targetNamespace="www.globalcompany.example.com",
    serviceName="ServiceAppModuleService",
    portName="ServiceAppModuleServiceSoapHttpPort",
    endpointInterface=
       "oracle.summit.model...common.serviceinterface.ServiceAppModuleService")
...
```

3. In the Properties window, expand the **Web Services** section and select **Enable MTOM**.

   JDeveloper adds the `@MTOM` annotation to the annotations section of the file.

```
...
@Stateless(name="oracle.summit.model....common.ServiceAppModuleServiceBean",
    mappedName="ServiceAppModuleServiceBean")
@Remote(ServiceAppModuleService.class)
```

```
@PortableWebService(targetNamespace="www.globalcompany.example.com",
    serviceName="ServiceAppModuleService",
    portName="ServiceAppModuleServiceSoapHttpPort",
    endpointInterface=
       "oracle.summit.model...common.serviceinterface.ServiceAppModuleService")
@MTOM
...
```

How to Specify Character Encoding for ClobDomain Type Attributes

A consequence of working with large string data, defined in the database as CLOB type, is the character encoding used when converting string data to and from binary data. When you work with `ClobDomain` attributes in your service data objects, the ADF service interface framework streams the data by mapping the attribute value to a base64-encoded SDO property. This mapping to base64 binary stream does not include the character set of the original data.

To support converting string data to and from binary data, the ADF service interface framework allows you to configure the encoding character set for individual `ClobDomain` attributes of the view object. Alternatively, you can configure the encoding character set at the level of the view object definition, when you want all `ClobDomain` attributes to be converted using the same character encoding scheme.

When the framework needs to convert the binary stream to and from characters for `ClobDomain` attributes, it can apply the character encoding specified as a value for either of these custom properties that you have defined on the view object:

- `SERVICE_USE_SERVER_DEFAULT_CHARSET`
- `SERVICE_CLOB_CONVERSION_CHARSET`

The custom property `SERVICE_USE_SERVER_DEFAULT_CHARSET` is useful when you do not know the specific character encoding used by the database. Since the character set of the server JVM will be locale dependent, you should take that into account when defaulting to the server's encoding character set.

The ideal configuration for `ClobDomain` attributes relies on the custom property `SERVICE_CLOB_CONVERSION_CHARSET` and the character encoding that you specify. This configuration assumes that you can verify the character encoding of the target data to ensure that the ADF service interface framework does not convert using a different encoding character set.

> **Note:**
>
> When no custom property is defined on the view object to configure character encoding, at runtime, the ADF service interface framework will default to the UTF-8 character encoding scheme to handle conversion of `ClobDomain` data. UTF-8 is a Unicode encoding that provides multilingual support for CLOB data that is supported by Oracle Database.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete this task:

> Enable MTOM support by adding the `@MTOM` annotation to the service implementation class to allow service methods to operate on a view row with `ClobDomain` attributes, as described in How to Enable Support for Binary Attachments for SOAP Clients.

To configure character encoding for individual ClobDomain attributes of the view object:

1. In the Applications window, double-click the view object that contains ClobDomain attributes.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute with **Clob** displayed in the **Type** column.
4. Click the **Custom Properties** tab, click the **Add** icon and choose **Non-Translatable Property** from the dropdown list and then enter one of the following predefined custom properties in the **Property** name field:

   `SERVICE_USE_SERVER_DEFAULT_CHARSET` - when you want the character encoding of the JVM to be used to convert the data. Enter `true` for the **Value**.

   `SERVICE_CLOB_CONVERSION_CHARSET` - when you want to specify a known character encoding that corresponds to the character encoding of the data. Enter the desired character encoding for the **Value**. For example, you might enter `UTF-16`. Note, when no value is supplied, the default UTF-8 will be used.

To configure character encoding for all ClobDomain attributes of the view object:

1. In the Applications window, double-click the view object that contains ClobDomain attributes.
2. In the overview editor, click the **General** navigation tab.
3. In the General page, expand the **Custom Properties** section, click the **Add** icon and choose **Non-Translatable Property** from the dropdown list and then enter one of the following predefined custom properties in the **Property** name field:

   `SERVICE_USE_SERVER_DEFAULT_CHARSET` - when you want the character encoding of the JVM to be used to convert the data. Enter `true` for the **Value**.

   `SERVICE_CLOB_CONVERSION_CHARSET` - when you want to specify a known character encoding that corresponds to the character encoding of the data. Enter the desired character encoding for the **Value**. For example, you might enter UTF-16. Note, when no value is supplied, the default UTF-8 will be used.

How to Test the Web Service Using Integrated WebLogic Server

You can run the web service in JDeveloper using Integrated WebLogic Server. You can also deploy the web service to Oracle WebLogic Server to test the service.

To run and test using Integrated WebLogic Server:

1. In the Applications window, expand the application module, expand the **serviceinterface** node, and then select the service implementation class (`AppModuleServiceImpl.java`) file.

   In the web service generated from the `ServiceAppModule` application module in the `oracle.summit.model.amservice` package in the `SummitADF_Examples` workspace, the service implementation class is `ServiceAppModuleServiceImpl.java`.

2. Right-click the service implementation class file, and choose **Run** or **Debug**.

   The Create Default Domain dialog appears the first time you run the application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

   JDeveloper initializes the server instance, and then deploys the application and starts the web service. During this time, the output from these processes is displayed in the **Running** tab of the Log window. After the web service has started, the target URL is also displayed in the Log window.

   > **Tip:**
   >
   > In the Log window, you can click the target URL link to launch the HTTP Analyzer. This is a convenient shortcut for testing with JDeveloper Integrated WebLogic Server. For more information about the HTTP Analyzer, see the "Auditing and Monitoring Java Projects" chapter in *Developing Applications with Oracle JDeveloper*.

3. Copy the target URL (beginning with `http://`) from the Log window.

   For example, if the Log window displays:

   ```
   http://<ipaddress>/ADFServiceDemo-ADFModel-context-root
   ```

   Integrated WebLogic Server will display the service endpoint URL. So there is no need to append the service name.

4. Launch a web browser, paste the target URL you copied from the Log window into the browser address field, and submit the HTTP request.

5. In the test page, choose the operation you want to invoke from the **Operations** dropdown list and enter sample data in its parameter fields.

6. When you are ready, press **Invoke** to submit the operation and view the results for the operation in the Test Results page.

   The Test Results page displays the XML Soap format of the information returned by the operation.

How to Prevent Custom Service Methods from Timing Out

When you test the web service you may find that some of your custom methods exceed the established timeout limitation established by the Java Transaction API (JTA). The JTA timeout setting establishes an execution boundary for service methods that by default may not exceed 30 seconds. You can use the Administration Console for Oracle WebLogic Server to increase the JTA timeout setting. If you still receive a timeout exception or you anticipate that the custom methods of the service interface may be long running, you can specify an EJB transaction attribute for the stateless session bean to prevent the EJB from executing those methods in a JTA transaction.

For example, calls to the `afterCommit()` method to execute JDBC SQL statements from view objects or entity objects can result in the following `SQLException`: `java.sql.SQLException: The transaction is no longer active - status: 'Committed'. No further JDBC access is allowed within this transaction`

To perform custom operations in the case of the afterCommit() method, the service-enabled method annotation `TransactionAttribute` must be configured as `NOT_SUPPORTED`. To make a custom method exempt from timing out, you set `TransactionAttributeType.NOT_SUPPORTED` in the Properties window specifically for that method. As the following example shows, JDeveloper updates the method by adding the annotation `@TransactionAttribute(TransactionAttributeType.NOT_SUPPORTED)`.

```
@TransactionAttribute(TransactionAttributeType.NOT_SUPPORTED)
public void updateCustomerInterests(List<String> pCategoryIds) throws
                                                       ServiceException {
        invokeCustom((Method) _map.get("updateCustomerInterests"),
             new Object[] { pCategoryIds }, new String[] { null }, false);
}
```

Because a method with this transaction attribute setting will not be executed in the JTA transaction, it is your responsibility to enforce control over the transaction using the ADF Business Components methods of the `oracle.jbo.ApplicationModule` and `oracle.jbo.Transaction` interfaces. For instance, as the following example shows, the methods of the implementation class of the application module that you service-enabled, will need to call `am.getDBTransaction().commit()` or `rollback()` in order to complete the transaction.

```
public void updateCustomerInterests(List pCategoryIds) {
     try
     {
        if (pCategoryIds != null && pCategoryIds.size() > 0) {
            List<Integer> copyOfCategoryIds = (List<Integer>)
                                       this.cloneList(pCategoryIds);
            ViewObject selectedCategories =
                                       this.getSelectedCategoriesShuttleList();
            RowSetIterator rsi = selectedCategories.createRowSetIterator(null);
            // remove rows for the current user not in the list of product keys
            while (rsi.hasNext()) {
                Row r = rsi.next();
                Number interestId = (Number)r.getAttribute("CategoryId");
                // existing row is in the list, we're ok, so remove from list.
                if (copyOfCategoryIds.contains(interestId)) {
                    copyOfCategoryIds.remove(interestId);
                }
                // if the existing row is in not list, remove it.
                else {
                    r.remove();
                }
            }
            rsi.closeRowSetIterator();
            // at this point, add new rows for the keys that are left
                    for (int i =0 ;i < copyOfCategoryIds.size(); i++ )  {
                        Row newRow = selectedCategories.createRow();
                        selectedCategories.insertRow(newRow);
                        newRow.setAttribute("CategoryId", (String)
                                       copyOfCategoryIds.get(i).toString());
                    }
        this.getTransaction().commit();
        }
     }
     catch (JboException e)
     {
        this.getTransaction().rollback();
        throw e;
     }
}
```

You should not change the default transaction attribute setting for the standard service methods generated for the service interface (see Table 15-1). The standard methods will execute within the default execution boundary set for the JTA transaction.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

To prevent custom methods from executing in a JTA transaction:

1. In the Applications window, expand the application module, expand the **serviceinterface** node, then double-click the service implementation class (`AppModuleServiceImpl.java`) file.

   In the web service generated from the `ServiceAppModule` application module in the `oracle.summit.model.amservice` package in the `SummitADF_Examples` workspace, the service implementation class is `ServiceAppModuleServiceImpl.java`.

2. In the source editor, locate the custom method that you want to prevent from timing out and place your cursor on the method.

3. In the Properties window, expand **Stateless Session Bean**, and then select **TransactionAttributeType.NOT_SUPPORTED** from the **TransactionAttribute** dropdown list.

   As shown in `updateCustomerInterests()` in the NOT_SUPPORTED annotation for the service method example above, JDeveloper updates the custom service method with the annotation.

4. Save the service implementation class.

5. In the Applications window, double-click the application module implementation class (`AppModuleImpl.java`) file.

   The implementation class defines the custom methods that you exposed through the service interface. In the `SummitADF_Examples` workspace, the application module implementation class is `oracle.summit.model.amservice.ServiceAppModuleImpl.java`.

6. In the source editor, in the custom method that implements the service method that you previously set the **TransactionAttribute** property on, add the custom code that will commit and roll back the transaction.

As the above implementation example for the service method shows, if you configured the **TransactionAttribute** property on the service method named `updateCustomerInterests()`, then you would open the implementation class for the application module, locate the custom method `updateCustomerInterests()`, and add `am.getDBTransaction().commit()` and `rollback()` as part of the method's `try` and `catch` statements.

7. Save the application module implementation class.

How to Deploy Web Services to Oracle WebLogic Server

You can deploy the web service to Oracle WebLogic Server, for example to perform a second stage of testing the service.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. If your project contains a standard web service (a Java class or interface with the `@WebService` annotation), you must remove the `@WebService` annotation from the Java class before you can deploy the Business Components web service. If you attempt to deploy the Business Components web service from the same project as the standard web service, deployment will fail with an Oracle WebLogic Server exception error. It is therefore necessary to create standard web services in a separate project from your ADF Business Components service.
2. If you created an asynchronous web service, before you can deploy the service you must configure the queues used to store the request and response. For information about configuring the request and response queues, see the "Creating the Request and Response Queues" section of the "Developing Asynchronous Web Services" chapter in *Developing Oracle Infrastructure Web Services*.
3. If you configured authorization for the web service, as described in How to Secure the ADF Web Service for Access By SOAP Clients, edit the `weblogic-application.xml` file to define application ID parameters. This file appears in the Applications window in the Application Resources panel, under the **Descriptors** and **META-INF** nodes.

   Add the following `<application-param>` definition as the first element:

```
<weblogic-application xmlns="http://www.bea.com/ns/weblogic/weblogic-
application"
                  xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
                  xsi:schemaLocation=
                        "http://www.bea.com/ns/weblogic/weblogic-
application.xsd">
   <application-param>
      <param-name>jps.policystore.applicationid</param-name>
      <param-value>ApplicationName</param-value>
   </application-param>
   ...
</weblogic-application>
```

Note that the *ApplicationName* that you enter must match the name identified in the `jazn-data.xml` policy store definition:

```
<jazn-data>
   <policy-store>
        <applications>
            <application>
                <name>ApplicationName</name>
                <app-roles>
                    ...
                </app-roles>
                <jazn-policy>
                    ...
                </jazn-policy>
            </application>
        </applications>
    </policy-store>
</jazn-data>
```

4. Edit the `ejb-jar.xml` file to add the following `JpsInterceptor` definition required by the EJB for application roles evaluation. This file appears in the Applications window under the **META-INF** node of the web service project.

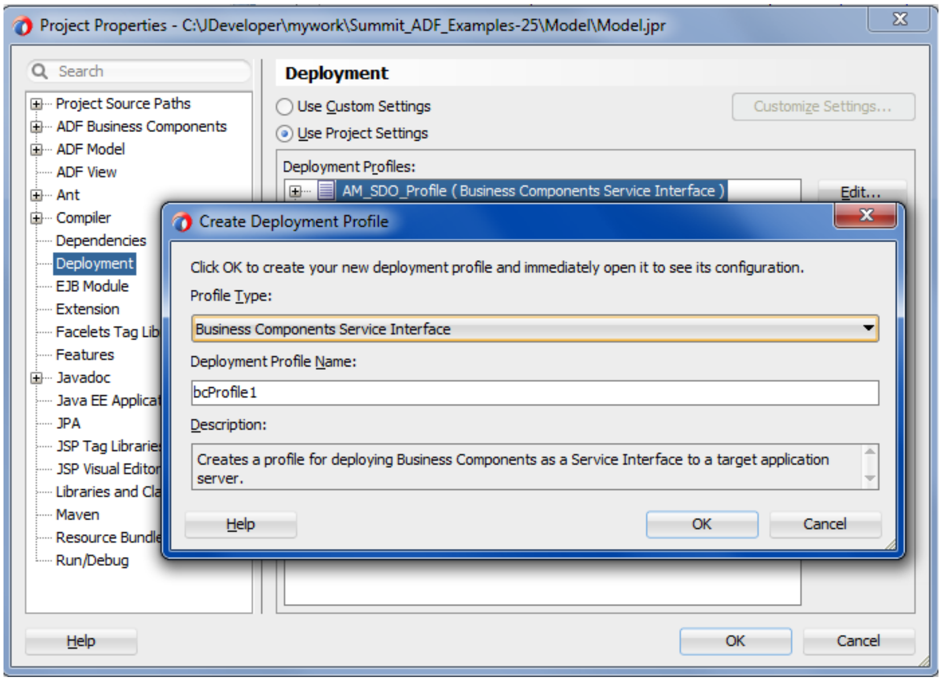
```
<?xml version = '1.0' encoding = 'windows-1252'?>
<ejb-jar xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
         xsi:schemaLocation="http://java.sun.com/xml/ns/javaee
         http://java.sun.com/xml/ns/j2ee/ejb-jar_3_0.xsd" version="3.0"
         xmlns="http://java.sun.com/xml/ns/javaee">
  <enterprise-beans>
    ...
  </enterprise-beans>
  <interceptors>
     <interceptor>
        <interceptor-class>
            oracle.security.jps.ee.ejb.JpsInterceptor
        </interceptor-class>
           <env-entry>
              <env-entry-name>application.name</env-entry-name>
              <env-entry-type>java.lang.String</env-entry-type>
              <env-entry-value>ApplicationName</env-entry-value>
              <injection-target>
                  <injection-target-class>
                      oracle.security.jps.ee.ejb.JpsInterceptor
                  </injection-target-class>
                  <injection-target-name>
                      application_name
                  </injection-target-name>
              </injection-target>
           </env-entry>
     </interceptor>
     ...
  <interceptors>
  <assembly-descriptor>
     <interceptor-binding>
        <ejb-name>*</ejb-name>
        <interceptor-class>
             oracle.security.jps.ee.ejb.JpsInterceptor
        </interceptor-class>
     </interceptor-binding>
  </assembly-descriptor>
</ejb-jar>
```

Note that *ApplicationName* must also match the application name identified in the jazn-data.xml policy store definition.

To deploy to Oracle WebLogic Server:

1. Create an application server connection to Oracle WebLogic Server:
   a. In the main menu, choose **Window** and then **Application Servers**.
   b. In the Application Servers window, right-click the **Application Servers** node and choose **New Application Server**, and complete the Create Application Server Connection wizard.
2. Create a service deployment profile:
   a. In the Applications window, right-click the project that contains the web service and choose **Project Properties**.
   b. In the Project Properties dialog, open the Deployment page and click **New**.
   c. In the Create Deployment Profile dialog, choose **Business Components Service Interface** as the archive type, as shown in Figure 15-14.

Figure 15-14 Dialog for Creating a Business Components Service Deployment Profile



Project Properties - C:\JDeveloper\mywork\Summit_ADF_Examples-25\Model\Model.jpr

Deployment

○ Use Custom Settings
● Use Project Settings

Deployment Profiles: AM_SDO_Profile (Business Components Service Interface)

Create Deployment Profile

Click OK to create your new deployment profile and immediately open it to see its configuration.

Profile Type: Business Components Service Interface

Deployment Profile Name: bcProfile1

Description: Creates a profile for deploying Business Components as a Service Interface to a target application server.

3. In the main menu, choose **Application > Deploy > *deployment profile*** for the deployment profile you created.
4. In the Deploy wizard, on the Deployment Action page, select **Deploy to Application Server** and click **Next**.
5. On the Select Server page, select the application server connection.
6. Click **OK**.

Accessing Remote Data Over the Service-Enabled Application Module

ADF Application Modules publish Service Data Objects (SDOs). You can create service-backed entity objects to utilize SDOs to expose business services in SOAP services.

ADF Business Components application modules offer built-in support for web services and for publishing rows of view object data as service data objects (SDOs). Entity objects that you create in your local data model project can utilize the SDO services that the service-enabled application module exposes on its service interface. By creating service-backed entity objects in your local project, you avoid having to work directly with the service proxy and SDOs programmatically for all common web service data access tasks.

The Create Entity Object wizard makes it easy for you to choose between a local database and the ADF Business Components web service when you create the entity object, as described in How to Use Service-Enabled Entity Objects and View Objects. In this way, service-enabled application modules provide an alternative way to access data that is not available locally in the database.

Once you create the service-backed entity object, you will be able to create view objects, view links, and view criteria to filter the data at runtime. You will also be able to utilize these view objects in your data model as though you were working with locally available data accessed from database tables.

The following sections describe how to augment your data model project using a service-enabled ADF application module.

How to Use Service-Enabled Entity Objects and View Objects

You will want to use the service-backed components as part of your application design strategy when one of the following conditions is true:

- The client data model project needs to work with data from a service-enabled application that is part of a separate business process.
- The client data model project needs to work with data from a pluggable, external service.

In the first case, you provide both sides of the service. In the second case, you may not know what the external service looks like and you may need to perform the following:

1. Even though you might not need a Fusion implementation of the service, since the service-enabled application module's service interface is the supported unit of pluggability and the supported way of creating service-backed entity objects and view objects, you create an application module with a service interface that describes the shape you want your "canonical" pluggable service to have.
2. After generating the service-enabled application module, as described in How to Enable the Application Module Service Interface, you then build service-back entity objects and view objects.
3. Finally, you can create an EJB session bean (or an SCA composite) that supports the same service interface as the "canonical" service-enabled application module

that you created in Step 2 and configure the `connections.xml` file of the client project containing the service-enabled business components based on this service interface to use this "plugged" version instead.

For details about how to expose an application module as a web service, see Publishing Service-Enabled Application Modules.

Creating Entity Objects Backed by SDO Services

You create the service-backed entity object using the Create Entity Object wizard by supplying the URL for the WSDL document that describes the deployed service already running on an application server. You may locate the WSDL either from a UDDI registry or, when the URL endpoint is not accessible, from the WSDL document file that you have downloaded. The wizard uses the WSDL service description to display the list of available service view instances. In the wizard, you select among the displayed view instances to specify the entity object's data source. At the time you run the wizard, the service endpoint must be accessible in order to locate the WSDL document.

Only unsecured (HTTP) service endpoints may be used to create the service-backed entity object; the Create Entity Object wizard displays an error message when you attempt to access a secured (HTTPS) service endpoint.

Before you begin:

It may be helpful to have an understanding of how to access ADF Business Components services in the client Fusion web application. For more information, see Accessing Remote Data Over the Service-Enabled Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Obtain the URL for the WSDL document that describes the deployed service. If the unsecured HTTP URL is not accessible, download the WSDL file for the service and use the downloaded WSDL to obtain the service from the local file system.
2. Expose an application module as a web service, as described in How to Enable the Application Module Service Interface.
3. Service-enable specific view object as needed, as described in How to Service-Enable Individual View Objects.
4. Define a complex type (one that includes currency codes or a unit of measure) for attributes of the service-enabled view object as needed, as described in Associating Related SDO Properties Using Complex Data Types.

To create the entity object that uses a service view instance as its data source:

1. In the Applications window, right-click the project in which you want to create the entity object and choose **New** and then **Entity Object**.
2. On the Name page of the Create Entity Object wizard, do the following to create the entity object:
   a. Enter the package name in which the entity object will be created and enter the entity object name.

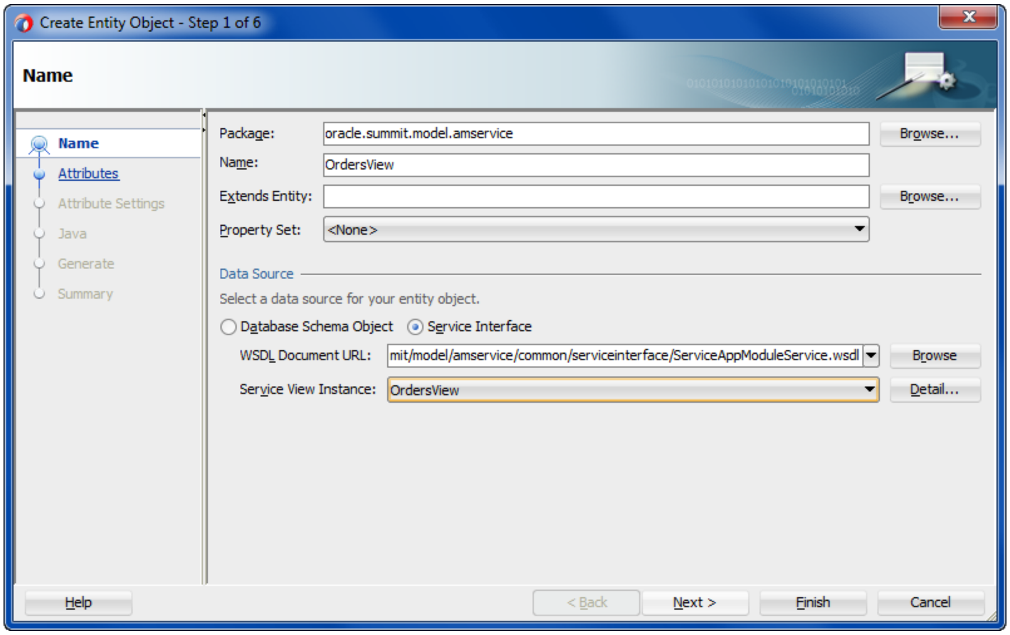
b. Select **Service Interface** as the data source for which you want to create the entity object.

c. Enter the WSDL document URL for the published web service, or click **Browse** and choose **UDDI Registry** to use the Find Web Services wizard to locate the web service from a UDDI registry. If the URL endpoint is not accessible, copy the WSDL file to the local file system and then click **Browse** and choose **File System** to navigate to the file.

   JDeveloper will attempt to connect with the service endpoint and populate the list of service view instances from the WSDL service description. If the endpoint is unavailable, the list will remain empty.

d. From the **Service View Instance** dropdown, choose the appropriate service view instance as the data source, as shown in Figure 15-15.

Figure 15-15 Service Interface as Data Source in the Create Entity Object Wizard



Create Entity Object - Step 1 of 6

Name

Package: oracle.summit.model.amservice

Name: OrdersView

Extends Entity:

Property Set: <None>

Data Source

Select a data source for your entity object.

○ Database Schema Object ● Service Interface

WSDL Document URL: mit/model/amservice/common/serviceinterface/ServiceAppModuleService.wsdl

Service View Instance: OrdersView

3. Click **Next** and modify the attributes settings of the entity object before you complete the wizard.

   For example, on the Attributes Settings page, you can enable the **Refresh After Insert** and **Refresh After Update** options for attributes that you anticipate will be modified whenever the entity is modified. Typical candidates include a version number column or an updated date column in the row.

4. Click **Finish**.

Using Complex Data Types with Service-Backed Entity Object Attributes

As a result of creating a service-backed entity object, JDeveloper automatically exposes attributes that were defined by the SDO properties of the base service-enabled view object. When your entity object contains attributes with complex types, you will need to select the complex type's related attribute from the entity object. For example, suppose that your service-backed entity object defines the `OrderTotal` attribute and a `CurrencyCode` attribute to specify the currency code of allowed countries. You will need to map the related attribute CurrencyCode to the SDO property type specified by the service-enabled view object. Complex types support these service types:

- AmountType service type, for use with any property that defines a currency code
- MeasureType service type, for use with any property that defines a unit of measure

You use the Attributes page of the overview editor to select the entity object attribute defined as a complex type. You use the Details tab that you display from the Attributes page of the overview editor to map the complex type of the selected attribute to a related attribute of the appropriate type.

Before you begin:

It may be helpful to have an understanding of how to access ADF Business Components services in the client Fusion web application. For more information, see Accessing Remote Data Over the Service-Enabled Application Module.

It may be helpful to have an understanding of complex types and SDO properties. For more information, see Associating Related SDO Properties Using Complex Data Types.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Expose an application module as a web service, as described in How to Enable the Application Module Service Interface.
2. Service-enable the desired view object, as described in How to Service-Enable Individual View Objects.
3. Specify a complex type for individual attributes of the service-enabled view object, as described in Associating Related SDO Properties Using Complex Data Types.
4. Create the service-backed entity object from the service-enabled view object, as described in Creating Entity Objects Backed by SDO Services.

To associate attributes using a complex type in the service-backed entity object:

1. In the Applications window, double-click the service-backed entity object.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute backed by an attribute defined as a complex type in the service-enabled view object.

   The attribute you select will be defined as a numeric type by the SDO property of the service-enabled view object.
4. With the attribute selected, click the **Details** tab and then in the **Service** section, in the **currencyCode** or **unitCode** dropdown list, select the entity object attribute that you want to associate with the complex type.

   The dropdown list displays all String attributes that the entity object defines. Select the attribute that is appropriate to map as the related attribute in the complex type definition. For example, to associate a currency code with the OrderTotal attribute that displays the amount paid by a customer, you might select the CurrencyCode attribute in the Orders service-backed entity object.

The SDO framework supports related service attribute values **currencyCode** and **unitCode**. When the editor displays **currencyCode**, the attribute you associate must specify currency information. When the editor displays **unitCode**, the attribute you associate must specify a unit of measure.

Creating View Objects Backed by SDO Services

After you add the service-backed entity object to your project, you can create service-backed view objects to query and optionally filter the data from the web service for use in the user interface. A service-backed view object is a view object whose single entity usage references an entity object that is backed an SDO service. You cannot make existing view objects service-backed. Instead, when you create the view object, the new view object will automatically be service-backed if its entity usage is a service-backed entity object.

Before you begin:

It may be helpful to have an understanding of how to access ADF Business Components services in the client Fusion web application. For more information, see Accessing Remote Data Over the Service-Enabled Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete this task:

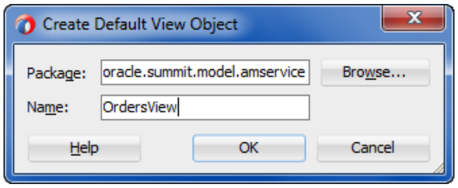
Create the service-backed entity object, as described in Creating Entity Objects Backed by SDO Services.

To create a view object from the service-backed entity object:

1. In the Applications window, right-click the service-backed entity object and choose **New Default View Object**.
2. In the Create Default View Object dialog, enter the package name in which the view object will be created and enter the view object name, as shown in Figure 15-16.

   The generated view object will contain the same attributes as the entity object. You can optionally edit the view object in the overview editor to customize the query. You can also define view criteria for the view object when you want to filter the data from the web service. For details about filtering query results, see Working with Named View Criteria.

Figure 15-16 View Object Can Be Created from Service-Backed Entity Object



Package: oracle.summit.model.amservice
Name: OrdersView

What Happens When You Create Service-Backed Business Components

The service-backed entity object is an entity object that encapsulates the details of accessing and, if necessary, modifying a row of data from an ADF Business Components web service. After you use the Create Entity Object wizard to create the service-backed entity object, JDeveloper saves additional service-related metadata in the `<Datasource>` element of the entity component definition. The entity component definition includes all the attributes that you selected from the service-enabled view object instance, including attributes with a complex type definition, as shown in the following example.

The service-backed view object references the single, service-backed entity object in its metadata just as any entity-based view object does. You can use the service-backed view object just as you would use any other view object. For details about working with view objects, see Defining SQL Queries Using View Objects. The ADF runtime handles the interaction with the ADF Business Components web service.

```

```

How to Update the Data Model for Service-Backed Business Components

Because the service interface exposes individual view instances, you are responsible for defining hierarchical relationships between service-backed entity objects (through associations) and service-backed view objects (through view links) in your consuming project. View links and associations are not automatically created when you create the service-backed business component. For example, if the application module of the published ADF Business Components service defines a master-detail relationship that you want to utilize, then you must define a view link for the corresponding view objects in your own project to preserve this hierarchy.

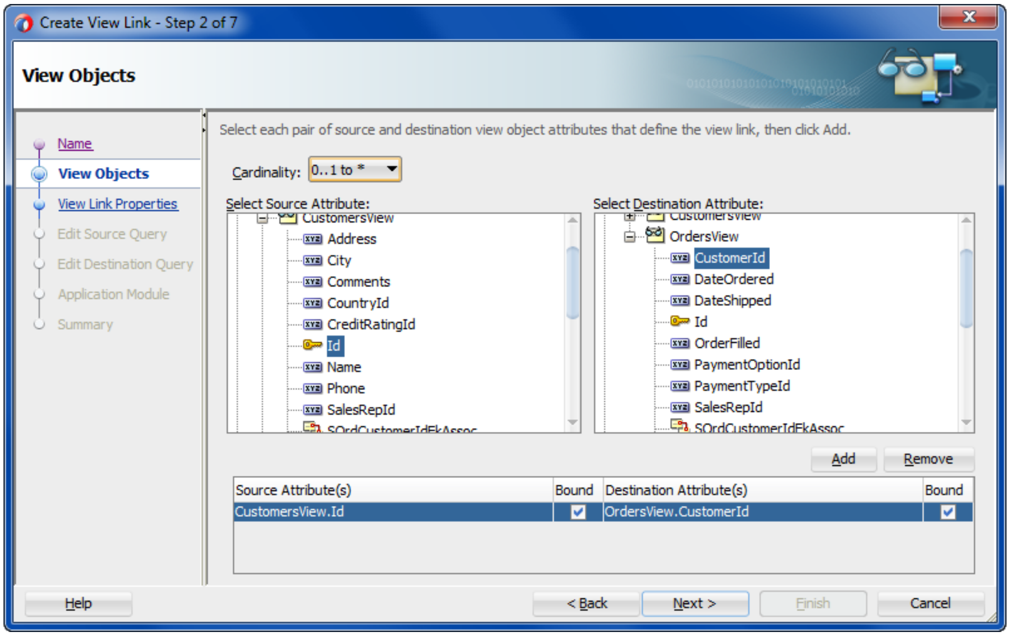
Furthermore, while you can create view links between view objects that query their data locally and service-backed view objects (and the other way around), once you define the view link, you will not be able to create entity-based view objects with the following entity object usages:

- The view object will not be able to reference a secondary entity usage that is a service-backed entity object.
- The view object will not be able to reference a primary entity usage that is a service-backed entity object with secondary entity usages.

The same restrictions apply to associations in the client project between regular entity objects and service-backed entity objects: while you can create the associations, you will not be able to create view objects.

You use the Create View Link wizard to specify relationships between the view objects that your project defines, as shown in Figure 15-17. For details about creating view links, see How to Create a Master-Detail Hierarchy Based on Entity Associations.

Figure 15-17   One to Many Relationship Defined in Create View Link Wizard



Select each pair of source and destination view object attributes that define the view link, then click Add.

Cardinality: 0..1 to *

Source Attribute(s)	Bound	Destination Attribute(s)	Bound
CustomersView.Id	☑	OrdersView.CustomerId	☑

View links you create may define relationships between service-backed view objects and view objects that query locally accessed database tables. For example, you might choose to drive a database-derived detail view object with a service-backed master view object. You can create view links with the combinations shown in Table 15-3.

Table 15-3   Supported View Link Combinations Involving Service-Backed View Objects

Use Case	Master View Object Type	View Linked Detail View Object Type	View Link Cardinality
Local master rows with remote details	Query-based	Service-backed	One-to-many
Remote master rows with local details	Service-backed	Query-based	One-to-many
Local master rows with remote reference information	Query-based	Service-backed	Many-to-one
Remote master rows with local reference information	Service-backed	Query-based	Many-to-one

Once you have defined the desired view hierarchy, using the Create View Link wizard, you use the overview editor for your project's application module to define new view instances on the data model, as shown in Figure 15-18. The updated data model allows you to expose the view objects as ADF data controls that enable databinding with the user interface components of the Fusion web application. For details about updating the data model, see Adding Master-Detail View Object Instances to an Application Module.

How to Configure the Service-Backed Business Components Runtime

Before you can run your application and interact with the published service-enabled ADF application module to invoke service operations, you need to describe the published service, including the service's endpoint provider type and other configuration information. The ADF Business Components `ServiceFactory` class (`oracle.jbo.client.svc.ServiceFactory`) returns a proxy for the service, then uses the service proxy to invoke the service operations. The service factory can return proxies for three different service endpoint providers, to support these transport protocols:

- When the service endpoint provider is ADF Business Component, the transport protocol is EJB RMI.
- When the service endpoint provider is SOA Fabric, the transport protocol is SOA Fabric SDO binding.
- When the service endpoint provider is SOAP (for JAX-WS clients), the transport protocol is SOAP.

To configure the consuming application to invoke published service operations:

1. Add the *`bcProfileName`*`_Common.jar` file for the SDO's generated classes to the client project's classpath.
2. Update the `connections.xml` file in the client project's `.adf/META-INF` folder to describe the published ADF Business Components service.

   The updates you make to the file will depend on the transport protocol your application uses: EJB RMI protocol, SOA Fabric SDO binding, or SOAP protocol (for JAX-WS clients).

Adding the SDO Client Library to the Classpath

Before your application can access the published service, the service consuming project must have access to the generated SDO classes and their schema definitions. These files are packaged in the `*bcProfileName*_Common.jar` file generated by the development team responsible for publishing the service.

To make the SDO classes and their schema definitions available to your application, obtain the `*bcProfileName*_Common.jar` file from the service-provider team and place this JAR file in a folder of your local project. For example, you may copy the JAR file into your project's `deploy` folder. You can then use JDeveloper to add the JAR file to your project's classpath with a SDO client library you create. For steps to generate the SDO classes JAR file, see How to Deploy Web Services to Oracle WebLogic Server.

Before you begin:

It may be helpful to have an understanding of how to access ADF Business Components services in the client Fusion web application. For more information, see Accessing Remote Data Over the Service-Enabled Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

To add the SDO client library to the classpath:

1. In the Applications window, right-click the project that contains the SDO classes and choose **Project Properties**.
2. In the Project Properties dialog, select **Libraries and Classpath** and click **Add Libraries**.
3. In the Add Library dialog, click **New** to create the SDO client library.
4. In the Create Library dialog, click **Add Entry** to add a classpath entry.
5. In the Select Path Entry dialog, browse to the folder that contains the `*bcProfileName*_Common.jar` file and select the file to view it in the Create Library dialog.

   The Select Path Entry dialog lets you browse the file system or local area network to locate the JAR file. If you cannot browse the `deploy` folder of the service-provider's application workspace to obtain the JAR file, you must obtain the file and copy it into your own project's folder. For example, you may have copied the JAR file into your project's `deploy` folder.
6. Click **OK** in the dialogs to display the Project Properties dialog with the SDO client library selected. Click **OK** to add the library to the classpath.

   Figure 15-19 shows the SDO client library with the name `ServiceProvider_Common.jar` selected. In this case, the library name is the same as the JAR file name. Optionally, you can edit the library name in the Create Library dialog.

Registering the ADF Business Components Service in the Consuming Application's connections.xml for the EJB RMI Protocol

When the service endpoint provider is ADF Business Components, the service factory will return an EJB object proxy bound to a stateless session bean running in the EJB container. You must provide the JNDI context information to allow the consuming application to look up the published service.

Lookup information that you provide to register the published ADF Business Components service appears in the consuming Fusion web application's `connections.xml` file, located in the `.adf/META-INF` folder relative to the application. The ADF connection architecture uses this file to encapsulate the details of the service endpoint provider.

The JNDI lookup information you provide will depend on whether the published service runs locally (in the same JVM) with the consuming application or runs remotely on a separate server from the consuming application. Typically, the ADF Business Components service is in a different application from the consuming application and is therefore run remotely.

To register the published service with your client application, update the `connections.xml` file, as shown in the following example. When the ADF Business Components service runs local to the consuming application (as occurs when you run within JDeveloper), the service factory needs only the JNDI name to look up the service.

> **Note:**

```

When the ADF Business Components service runs remotely to the calling client, then remote JNDI context information needs to be added to the `connections.xml` file. You can edit these JNDI context properties in the `connections.xml` file, as shown the example:

- `jndiFactoryInitial` should be set to `weblogic.jndi.WLInitialContextFactory`.
- `jndiProviderURL` is the JNDI provider URL that indicates the location of the JNDI server. The URL should be composed as `t3://`*`<hostname>`*`:`*`<server port>`*.

  For example, specify a URL like: `t3://localhost:8888`, where `t3` is the Oracle WebLogic protocol, `localhost` is the host name that the remote Oracle WebLogic Server instance runs in, `8888` is the port number.
- `jndiSecurityPrincipal` specifies the principal (user name) with permission to access the remote JNDI.

  When you deploy the service to standalone Oracle WebLogic Server, the user name can be read from the file.
- `jndiSecurityCredentials` specifies the credentials (password) to be used for the security principal.

When you deploy the service to standalone Oracle WebLogic Server in a test environment, you can specify credentials in plain text for the JNDI provider. For example, you can specify `weblogic/weblogic1`, which are the default administrator user name/password credentials with sufficient privileges to access JNDI provider for Oracle WebLogic Server.

When you deploy the service to a production environment, you must remove the plain text password to avoid creating a security vulnerability. As the following example shows, the `connections.xml` file must contain `<SecureRefAddr addrType="jndiSecurityCredentials"/>` with no password. To configure the service password for standalone Oracle WebLogic Server, you must use Oracle Enterprise Manager, which will store the encrypted password in Oracle's credential store.

Registering the ADF Business Components Service in the Consuming Application's connections.xml for the SOAP Protocol

When the service endpoint provider is SOAP, the service factory will create a dynamic JAX-WS client proxy. You must provide the WSDL URL and port name to allow the consuming application to look up the published service. Additionally, for the SOAP client, OWSM client security policy can be attached as part of the SOAP header.

Lookup information that you provide to register the published ADF Business Components service appears in the consuming Fusion web application's `connections.xml` file, located in the `.adf/META-INF` folder relative to the application. The ADF connection architecture uses this file to encapsulate the details of the service endpoint provider.

> **Note:**
>
> When you deploy the calling application to standalone Oracle WebLogic Server, you will use Oracle Enterprise Manager to configure the JNDI context properties instead of editing the `connections.xml` file. For instructions, refer to the online documentation in Oracle Enterprise Manager.

To register the published service with your client application for the SOAP protocol, depending on whether your application uses identity propagation or identity switching, update the `connections.xml` file following the examples below. Identity propagation and switching are similar in that each process involves propagating an identity. In Fusion web applications, identity propagation involves propagating the identity that is currently executing code. Identity switching, on the other hand, involves propagating an application identity that is different from that currently executing code.

To register the published service with your client application so the user identity will be switched based on the credential key, specify the clientside policy `oracle/wss11_username_token_with_message_protection_client_policy` in the `connections.xml` file as the following example illustrates.

> **Note:**
>
> The `connections.xml` file supports OWSM security policy client overrides. When the security policy is `oracle/wss11_username_token_with_message_protection_client_policy`, the `csf-key` property can be overridden to specify the consuming application's credentials.

Registering the ADF Business Components Service in the Consuming Application's connections.xml for Fabric SDO Binding

When the service endpoint provider is Fabric, the service factory will return a SOA Fabric composite proxy and call the service running inside a Fabric composite through Fabric's SDO binding. You must provide the name of the Fabric composite to allow the consuming application to look up the published service.

Lookup information that you provide to register the published ADF Business Components service appears in the consuming Fusion web application's `connections.xml` file, located in the `.adf/META-INF` folder relative to the application. The ADF connection architecture uses this file to encapsulate the details of the service endpoint provider.

> **Note:**
>
> When you deploy the calling application to standalone Oracle WebLogic Server, you will use Oracle Enterprise Manager to configure the JNDI context properties instead of editing the `connections.xml` file. For instructions, refer to the online documentation in Oracle Enterprise Manager.

To register the published service with your client application for the Fabric protocol, update the `connections.xml` file, as the following example shows, where `fabricAddress` is the name of the Fabric composite for the published service.

```
<References xmlns="http://xmlns.oracle.com/adf/jndi">
  <Reference name="{www.globalcompany.com}ServiceAppModuleService"
             className="oracle.jbo.client.svc.Service" xmlns="">
     <Factory className="oracle.jbo.client.svc.ServiceFactory"/>
     <RefAddresses>
       <StringRefAddr addrType="serviceInterfaceName">
        <Contents>oracle.summit.model.amservice.common.
                                             serviceinterface.ServiceAppModuleService</Content
       </StringRefAddr>
       <StringRefAddr addrType="serviceEndpointProvider">
          <Contents>Fabric</Contents>
       </StringRefAddr>
       <StringRefAddr addrType="fabricAddress">
         <Contents>fabric_ServiceAppModuleService</Contents>
       <StringRefAddr addrType="serviceSchemaName">
          <Contents>ServiceAppModuleService.xsd</Contents>
       </StringRefAddr>
       <StringRefAddr addrType="serviceSchemaLocation">
          <Contents>oracle/summit/model/amservice/common/serviceinterface/</Contents>
       </StringRefAddr>
     </RefAddresses>
  </Reference>
  ...
</References>
```

How to Test the Service-Backed Components in the Oracle ADF Model Tester

Before you can launch the Oracle ADF Model Tester, your project must meet the runtime requirements, as described in How to Configure the Service-Backed Business Components Runtime. The Oracle ADF Model Tester will display the view objects you create from the remote web service and allow you to interact with the service to perform standard CRUD operations.

Because the application module that you run can access locally queried data and remotely queried data together, service-backed view objects and database-derived view objects will display in the same tester. If the endpoint is unavailable at the time you select the service-backed view object in the Oracle ADF Model Tester, you will get a runtime exception.

For details about running the Oracle ADF Model Tester, see How to Run the Oracle ADF Model Tester Using Configurations.

How to Invoke Operations of the Service-Backed Components in the Consuming Application

The ADF Business Components service interface requires that you return a service proxy to ensure that operations you invoke use the transport protocol specified by the published service.

Before you begin:

It may be helpful to have an understanding of how to access ADF Business Components services in the client Fusion web application. For more information, see Accessing Remote Data Over the Service-Enabled Application Module.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete this task:

- Ensure that the consuming application has the correct libraries on the classpath. In the Applications window, double-click the project and in the Project Properties dialog, select **Libraries and Classpath** and confirm the following libraries appear:
  - **Java EE 1.5**
  - **Oracle XML Parser v2**
  - **BC4J Service Client**
  - **JAX-WS Client**
  - The service's common JAR file

As the following example shows, when you invoke the operation, you perform the following tasks:

1. Import the `oracle.jbo.client.svc.ServiceFactory` class and published service class.
2. Call `getServiceProxy()` on the service factory object and pass in the service name in the form `<`*`serviceName`*`>.NAME`. The ADF service factory embeds a `SDOHelperContext` ID in the service proxy object returned by this method to ensure delivery of the latest ADF Business Component service schema metadata to the SDO.

   The schema (`.xsd` files) for the service object may be stored in MDS and may have been extended for example to add more business component attributes, extend existing types, or define new types. The local helper context allows customization of individual service's schema definitions without affecting other service's SDO metadata or requiring restarting the application.
3. Call `create()` on a data factory object, where the proxy object is obtained from the `getServiceProxy()` call.
4. Invoke the operation on the proxy object and return a data object.
5. Save the data object return as XML.

```
import commonj.sdo.DataObject;
import commonj.sdo.helper.DataFactory;
import commonj.sdo.helper.XMLHelper;
import hr.common.Dept;
import hr.common.serviceinterface.HRAppService;
import oracle.jbo.client.svc.ServiceFactory;
   ...
   {
      HRAppService proxy = (HRAppService)
ServiceFactory.getServiceProxy(HRAppService.NAME);

      Dept dept = (Dept)
               ServiceFactory.getDataFactory(proxy).create("http://example.com/hr/common/"
"Dept");
      dept.setDname("ENGINEERING");
      ...
      dept = proxy.createDept(dept);
      String xml = ServiceFactory.getXMLHelper(proxy).save((DataObject) dept,
                                   "http://example.com/hr/common/", "dept");
      out.print(xml);
   }
```

What You May Need to Know About Creating Service Data Objects in the Consuming Application

The ADF service interface framework defines a set of common data objects, such as `oracle.jbo.common.service.types.FindCriteria`, `oracle.jbo.common.service.types.FindControl`, `oracle.jbo.common.service.types.ProcessControl`, and so on. Those data objects are used in standard `findXxx()` method and `processXxx()` method calls. You can create these data objects in the consuming application and pass them to the standard service methods. As the following example shows, you can need to call the data factory class' `create()` method to construct those data objects before passing them into the `findXxx()` or `processXxx()` methods.

```
FindCriteria fc = (FindCriteria) ServiceFactory.getDataFactory(proxy).create
                       ("http://xmlns.oracle.com/adf/svc/types/",
"FindCriteria");
```

What You May Need to Know About Invoking Built-In Service Methods in the Consuming Application

The ADF service interface framework defines several built-in SOAP service methods that may be optionally enabled for the service view instances, including `getDftlObjAttrHints()`, `getServiceLastUpdateTime()`, and `getEntityList()`, as described in Table 15-2. These methods primarily support programmatic interaction with the service endpoint by the consuming application and are not supported at design time by data controls.

What Happens at Runtime: How the Application Accesses the Published Application Module

The ADF runtime obtains the data source information from the service-backed entity object XML definition to automate interactions with the service interface methods as needed. By using the service-backed entity object, you avoid having to work directly with the service proxy and service data objects programmatically for all common web service data access tasks. The ADF service factory looks up the service and then uses the service interface you specified in the `connections.xml` to invoke the service methods.

When your application accesses an ADF Business Components web service, each remote call is stateless, and the remote service will not participate in the same transaction as the business component that uses a service-enabled application module's service interface.

In the majority of the cases, calls to remote services will be informational in nature and will not make changes to remote objects. However, if you must use a remote service to make changes, then keep these points in mind:

- An exception thrown by the remote service will cause the local transaction to fail.
- If you successfully call a remote service that results in modifying data, and then subsequently your local transaction fails for any reason, then it is the responsibility of your error handling code to perform a compensating transaction against the remote service to "undo" the previous change made.

What You May Need to Know About Service-Backed Entity Objects and View Objects

You will use some web services to access reference information. However, other services you call may modify data. This data modification might be in your own company's database if the service was written by a member of your own or another team in your company. If the web service is outside your firewall, of course the database being modified will be managed by another company. In either of these situations, it is important to understand that any data modifications performed by a web service you invoke will occur in its own distinct transaction unrelated to the service-enabled application module's current unit of work. For example, if you have invoked a web service that modifies data and then you later call `rollback()` to cancel the pending changes in the application module's current unit of work, rolling back the changes has no effect on the changes performed by the web service you called in the process. You may need to invoke a corresponding web service method to perform a compensating change to account for your rollback of the application module's transaction.

At runtime, ADF handles the interaction with the ADF Business Components web service. However, you should be aware that service-backed business components have the following design time restrictions that may restrict your application's runtime behavior.

- View objects that you create cannot reference a service-backed entity object as a secondary entity object usage.
- View objects that you create cannot produce a flattened join from two or more related entity objects when at least one of those entity objects is a service-backed entity object.
- Service-backed view objects that you create from service-backed entity objects will not reference secondary entity usages.

For more details about how these restrictions apply at design time, see How to Update the Data Model for Service-Backed Business Components.

Accessing Polymorphic Collections in the Consuming Application

ADF Business Components allows Service Data Objects (SDOs) as an alternative approach to invoke polymorphic sub-type view object instances in the application module.

The ADF Model project may contain base view objects that define one or more subtype view objects derived from a common base view object. When the business components developer wants to expose the polymorphic usage of the base view object instance, they add the subtype to the ADF data model. However, when the developer creates the SDO service interface from application module view instances, the subtype SDO for the polymorphic subtype view objects are not directly referenced in the SDO service interface.

After generating the SDO interface from a ADF Model project that defines base view objects and subtype view objects, the generated XML schema (`.xsd`) will be strongly-typed for the base view object, but not for the polymorphic subtype. Therefore, web service clients that need to access polymorphic subtype view objects use an alternative approach to invoke exposed operations of the SDO interface.

> **Note:**
>
> The example in this section refers to the custom project `PolymorphicVO_WSClient` in the `SummitADF_Examples` application workspace. The client project access the SDO service interface created in the `oracle.summit.model.polymorphicvo` package in the Model project of the same workspace.

How to Generate Web Service Client Proxy Classes From the Service-Enabled Application Module

In JDeveloper, you can generate Java classes that act as a proxy to the remote service-enabled application module web service that you add to your web service client project. To accomplish this, you use the Create Web Service Client and Proxy wizard and supply a WSDL URL to the deployed service. The wizard creates a client file which uses the proxy classes and allows you to make Java method calls to access the web service.

Before you begin:

It may be helpful to have an understanding of how the SDO framework supports service-enabled ADF view objects and enables web service clients to access rows of data and perform service operations. For more information, see Publishing Service-Enabled Application Modules.

It may be helpful to understand how JDeveloper supports accessing web services in a Java applications by creating JAX-WS web service client and proxy classes. For more information, see the "Creating JAX-WS Web Services and Clients" section in *Developing Applications with Oracle JDeveloper*.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Service-Enabled Application Modules.

You will need to complete these tasks:

1. Create the desired subtype view objects and configure the polymorphic usages on the application module view instance using the subtypes, as described in Defining Polymorphic View Objects.
2. Enable the service interface for the application module, as described in How to Enable the Application Module Service Interface.
3. Create the client project that will contain the web service proxy classes that you will use to invoke service methods.

   Tip: If you have not already created a Java client project in JDeveloper, you create a custom project to contain the web service proxy classes, as described the "Creating Applications and Projects" section in *Developing Applications with Oracle JDeveloper*.
4. Run the web service in JDeveloper to obtain the service endpoint URL that you will use to specify the location of the WSDL document.

   Tip: You can run the service in Integrated WebLogic Server and obtain the service endpoint URL from the Log window, as described in How to Test the Web Service Using Integrated WebLogic Server.

To generate the service client and proxy files:

1. In the Applications window, select the client project that you want to contain the client proxy classes and choose **File > New Gallery** and from the **Categories** list, expand **Business Tier** and **Web Services**, and then select **Web Service Client and Proxy**.
2. In the Create Web Service Client and Proxy wizard, on the Select Web Service Description page, paste the service endpoint URL that you copy from Log window

into the **WSDL Document URL** field and append ?WSDL to the end of the URL, accept all defaults and click **Finish**.

For example, if the name of the ADF web service you deploy is ADFModuleService, the WSDL document URL with ?WSDL appended would like this:

```
http://<ipaddress>/ADFServiceDemo-ADFModel-context-root/
AppModuleService?WSDL
```

How to Invoke Operations of Polymorphic View Object Using Generated Proxy Classes

In JDeveloper, you can create a Java client that accesses web services through JAXB (Java Architecture for XML Binding), using generated classes from the web service schemas. To generate JAXB packages, proxy classes, and interfaces, the client developer runs a JAXB binding compiler against the ADF Business Components service schema (WSDL). The developer requires no knowledge of the service XML to work with the proxy classes.

Using the generated proxy classes, developers can access and manipulate polymorphic collections in method calls that you make in the Java class files of your client project. A sample of such a file is the generated SOAP service client Java class file. The generated client file is named for the deployed ADF web service that you supplied with the WSDL document URL. For example, if the name of the ADF web service you deploy is ADFModuleService, the SOAP service client Java class is named AppModuleServiceSoapHttpPortClient.java.

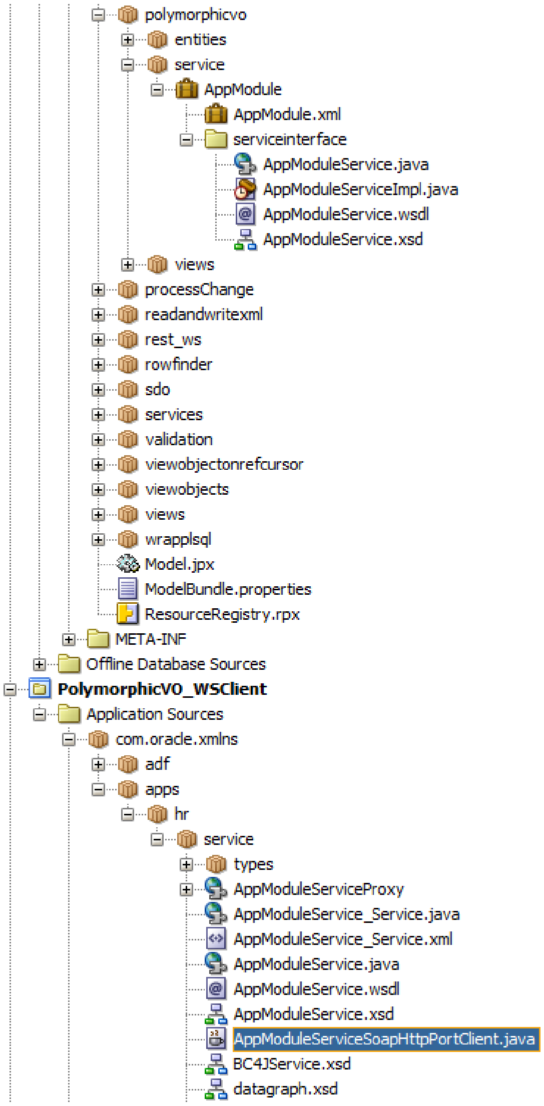
Before you begin:

It may be helpful to have an understanding of why polymorphic collections cannot be accessed as a remote service. For more information, see Accessing Polymorphic Collections in the Consuming Application.

You will need to complete these tasks:

- Create the Java client project that contains Java proxy classes for the service-enabled application module web service. For details, see How to Generate Web Service Client Proxy Classes From the Service-Enabled Application Module.
- In the Applications window, expand the client project and locate the SOAP service client file. As Figure 15-17 shows, the AppModuleServiceSoapHttpPortClient.java file is located in the com.oracle.xmlns package of the client project.

Figure 15-20   JAXB Generated SOAP Service Client File



You may proceed to edit the SOAP service client file to invoke the exposed operations of the base and subtype view objects. As the following example shows, factory objects are created for the subtype view object:

1. Create the collection using the factory method of the subtype view object.

   In this example, calling `createSalespersonViewExSDO()` on the service factory object creates an employee of subtype `Salesperson`.

2. Call the setters of the service factory object to set the required and optional attributes that the subtype's base view object defines.

   Note that optional attribute values must be cast as a special type `factory.create`*`ViewAttrName`* type, as described in What You May Need to Know About Invoking Service Methods in the Client Application.

3. Call the setters of the service factory object to set the required and optional attributes that the subtype view object defines.

In this example, the `Salesperson` subtype defines a single required attribute `CommissionPct` for the sales commission of sales department employees.

4. Invoke other operations on the collection.

   In this example, the `deleteSEmpView1()` deletes the created Salesperson row on the Employee collection and the `findSEmpView1ByDept()` finds the list of employees by their department.

```
package com.oracle.xmlns.apps.hr.service;

...

import oracle.summit.model.polymorphicvo.views.common.ObjectFactory;
import oracle.summit.model.polymorphicvo.views.common.SEmpViewSDO;

import oracle.summit.model.polymorphicvo.views.common.SalespersonViewExSDO;

...

public class AppModuleServiceSoapHttpPortClient {
    public static void main(String[] args) {
        AppModuleService_Service appModuleService_Service =
                                     new AppModuleService_Service();
        AppModuleService appModuleService =

appModuleService_Service.getAppModuleServiceSoapHttpPort();

        ...

        // Add your code to call the desired methods.
        try {
            SEmpViewSDO emp = testCreate(appModuleService);
            testFind(appModuleService);
            testDelete(appModuleService, emp);
            testFind(appModuleService);
        } catch (ServiceException e) {
        }

    }

...
    // 1. Create an employee of subtype Salesperson
    private static SEmpViewSDO testCreate(AppModuleService deptService) throws
                                ServiceException
    {
       oracle.summit.model.polymorphicvo.views.common.ObjectFactory factory = new
                oracle.summit.model.polymorphicvo.views.common.ObjectFactory();

       System.out.println("\n*** Testing createEmp ***\n");
       SalespersonViewExSDO salesperson = factory.createSalespersonViewExSDO();
       // 2. Set the attrs of the base SEmpView view object
       salesperson.setId(8001);
       salesperson.setFirstName(factory.createSEmpViewSDOFirstName("Lynn"));
       salesperson.setLastName("Munsinger");
       salesperson.setEmail(factory.createSEmpViewSDOEmail
                              ("lmunsing@summit.com"));
       salesperson.setTitleId(factory.createSEmpViewSDOTitleId
                              (new BigDecimal(2)));
       salesperson.setSalary(factory.createSEmpViewSDOSalary
                              (new BigDecimal(2000)));
       // 3. Set the attrs of the subtype SalespersonView view object
       salesperson.setCommissionPct
                            (factory.createSalespersonViewExSDOCommissionPct
                               (new BigDecimal(20)));
       salesperson.setDeptId(factory.createSEmpViewSDODeptId(31));

       return printEmp(deptService.createSEmpView1(salesperson));
    }

    // 4. Delete the employee of type Salesperson
    private static void testDelete(AppModuleService deptService, SEmpViewSDO emp)
                         throws ServiceException
    {
       System.out.println("\n*** Testing deleteEmp ***\n");
       deptService.deleteSEmpView1(emp);
    }

    // 5. Print
    private static SEmpViewSDO printEmp(SEmpViewSDO emp)
    {
       System.out.print(emp.getId() + "\t" + emp.getEmail().getValue() + "\t" +
             emp.getTitle().getValue() + "\t" +
                        "\t" + emp.getSalary().getValue());
       if (emp instanceof SalespersonViewExSDO)
       {
          System.out.print("\t" + ((SalespersonViewExSDO)
                             emp).getCommissionPct().getValue());
       }
       System.out.println();
       return emp;
    }

    // 6. Find employees by department
    private static void testFind(AppModuleService deptService) throws
                                                             ServiceException
    {
       com.oracle.xmlns.adf.svc.types.ObjectFactory factory = new
                        com.oracle.xmlns.adf.svc.types.ObjectFactory();

       System.out.println("\n*** Testing findEmpsByDept ***\n");
       FindCriteria fc = factory.createFindCriteria();
       fc.setFetchStart(0);
       fc.setFetchSize(-1);

       List<SEmpViewSDO> empList =
                          deptService.findSEmpView1ByDept(fc, "SALES", null);
       for (SEmpViewSDO emp : empList)
       {
          printEmp(emp);
       }
    }
}
```

Running `AppModuleServiceSoapHttpPortClient.java` client in JDeveloper produces the following output to the Log window. The `createEmp` method creates an employee in the sales department as a `Salesperson` subtype of the `EmpView` collection. The attribute value `20` is the `Commission` attribute of the new polymorphic view row. The `findEmpsByDept` method displays a mix of `EmpView` base view rows and `SalespersonView` subtype rows. The remaining methods delete the created salesperson from the `EmpView` collection and print the result.

```

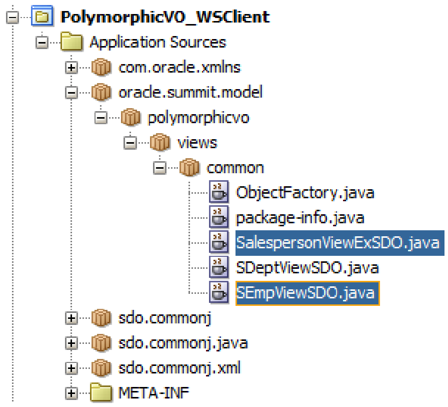
What Happens When You Generate Java Proxy Classes With the SDO Schema

The JAXB binding compiler generates Java proxy classes for the application module service and object factory classes for the various SDO view instances exposed by the service interface WSDL. Because the polymorphic view object is defined in the type hierarchy of the base view object, it also has a strongly-typed proxy class. As Figure 15-21 shows, the `SalespersonViewSDO.java` proxy class appears along with the proxy class `SEmpViewSDO.java` for the base view object `SEmpView`.

Figure 15-21 JAXB Generated SOAP Service Client Proxy Classes



- PolymorphicVO_WSClient
  - Application Sources
    - com.oracle.xmlns
    - oracle.summit.model
      - polymorphicvo
        - views
          - common
            - ObjectFactory.java
            - package-info.java
            - SalespersonViewExSDO.java
            - SDeptViewSDO.java
            - SEmpViewSDO.java
    - sdo.commonj
    - sdo.commonj.java
    - sdo.commonj.xml
    - META-INF

As the following example shows, when the `EmployeeView` view object has a subtype `SalespersonView` view object defined, the generated web service client contains the proxy class `SalespersonViewSDO.java` which extends the base proxy class (`SEmpViewSDO`) and defines the accessor methods for the `commissionPct` attribute.

```
@XmlAccessorType(XmlAccessType.FIELD)
@XmlType(name = "SalespersonViewExSDO", propOrder = { "commissionPct" })
public class SalespersonViewExSDO extends SEmpViewSDO {

    @XmlElementRef(name = "CommissionPct", namespace =
                   "/oracle/summit/model/polymorphicvo/views/common/",
                   type = JAXBElement.class, required = false)
    protected JAXBElement<BigDecimal> commissionPct;
    /**
     * Gets the value of the commissionPct property.
     *
     * @return
     *     possible object is
     *     {@link JAXBElement }{@code <}{@link BigDecimal }{@code >}
     *
     */
    public JAXBElement<BigDecimal> getCommissionPct() {
        return commissionPct;
    }

    /**
     * Sets the value of the commissionPct property.
     *
     * @param value
     *     allowed object is
     *     {@link JAXBElement }{@code <}{@link BigDecimal }{@code >}
     *
     */
    public void setCommissionPct(JAXBElement<BigDecimal> value)
{        this.commissionPct = value;
    }
}
```

What You May Need to Know About Invoking Service Methods in the Client Application

The generated service factory classes of the ADF Business Components service interface define the builtin methods that may be optionally enabled to create the service view instances. For example, for the polymorphic view object, the `createSalespersonView()` is enabled to create an instance of the polymorphic view object. When you use the create factory method to define the attributes of the view instance, the method signature for required attributes of the view object differs from attributes that may be optionally defined.

For example, when the `SalepersonViewSDO.java` defines setters for the required attributes of the view object, your client code can use a Java primitive value for the required attribute. However, setters for optional attributes must use a special type that indicates the XML element is missing and is not just an empty value. The factory object method supports the special type for optional view object attributes. As the following example shows, the method signature for `setFirstName` invokes `factory.createSEmpViewSDOFirstName`, whereas, the method signature for required attributes, like `setId` and `setLastName`, take an integer and String value.

```
private static SEmpViewSDO testCreate(AppModuleService deptService) throws
                                                              ServiceException
  {
    oracle.summit.model.polymorphicvo.views.common.ObjectFactory factory = new
            oracle.summit.model.polymorphicvo.views.common.ObjectFactory();
    System.out.println("\n*** Testing createEmp ***\n");
    SalespersonViewExSDO salesperson = factory.createSalespersonViewExSDO();
    salesperson.setId(8001);
    salesperson.setFirstName(factory.createSEmpViewSDOFirstName("Lynn"));
    salesperson.setLastName("Munsinger");
    salesperson.setEmail
            (factory.createSEmpViewSDOEmail("lmunsing@summit.com"));
    salesperson.setTitleId
            (factory.createSEmpViewSDOTitleId(new BigDecimal(2)));
    salesperson.setSalary
            (factory.createSEmpViewSDOSalary(new BigDecimal(2000)));
    salesperson.setCommissionPct
            (factory.createSalespersonViewExSDOCommissionPct(new
BigDecimal(20)));
    salesperson.setDeptId(factory.createSEmpViewSDODeptId(31));

    return printEmp(deptService.createSEmpView1(salesperson));
}
```

Working with the Find Method Filter Model in the Consuming Application

ADF Business Components defines a hierarchical filter model for the `FindCriteria` object that allows SOAP clients to control the behavior of find methods invoked as a SOAP request or in client code, programmatically.

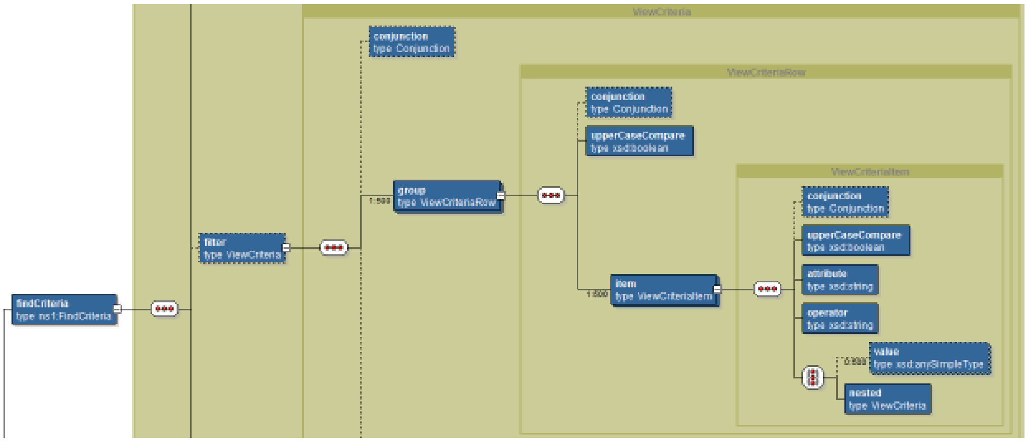
filter —>group—>item

The filter contains all runtime conditions and corresponds to a view criteria in ADF. View criteria restrict returned data to those rows matching the defined filters. At runtime, the filters will be converted to SQL WHERE clauses for the purpose of providing a data filter to a view object. Within the filter, the group contains a set of runtime filter conditions for one or more attributes of the SDO.

> **Note:**
>
> Attributes that participate in find method queries must be defined as queriable by the backing view object. The item defines one filter condition for a specific attribute.

The XSD diagram for the FindCriteria object shows in detail how the arguments for the find method are constructed.

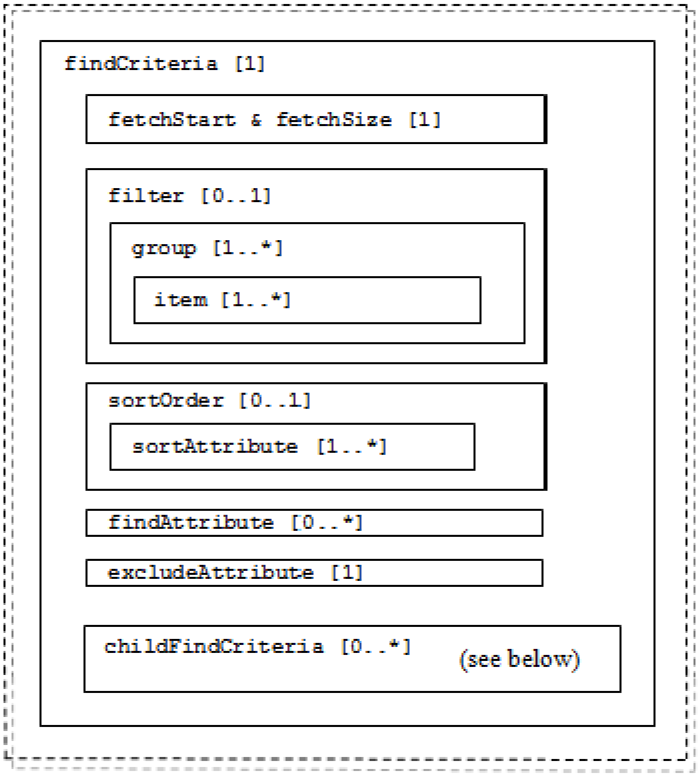
Figure 15-22   FindCriteria XSD Diagram



Conjunctions (And, Or, Not, AndNot, OrNot) may be specified to define multiple items in a group and define filter conditions are evaluated in relation to each other. For example, an And conjunction specifies that the query results meet both joined conditions. An Or conjunction specifies that the query results meet either or both joined conditions. When a conjunction is omitted, And behavior is assumed.

The following block diagram is another way to represent the containment model of the FindCriteria object.

Figure 15-23   FindCriteria Containment Hierarchy



To specify the filter `item` for the FindCriteria, the client must define the following:

- `Attribute` is a case-sensitive attribute name to be filtered by the filter condition.
- `Operator` is applied to the filter condition. Operators are appropriate to the attribute type and are defined by `oracle.jbo.common.JboCompOper`. See note below for exceptions.
- `Value` specifies the attribute filter criteria, which can include non-leading `%` wildcard.

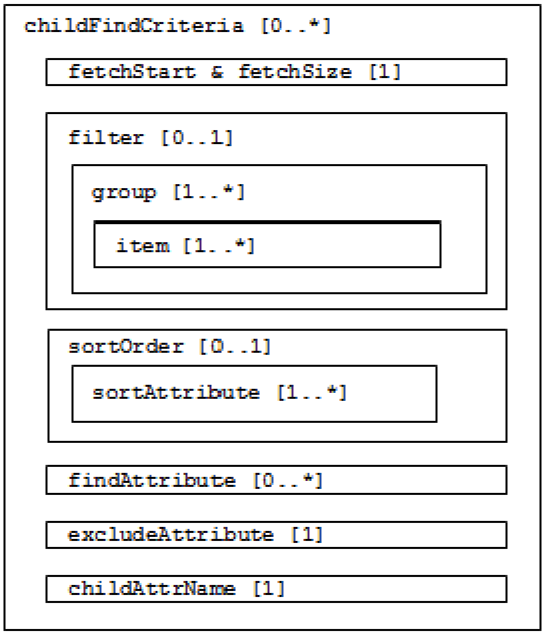
> **Note:**
>
> SOAP services clients may specify conditions using all operators defined by `oracle.jbo.common.JboCompOper`, with the exception of LIKE (use CONTAINS instead), IN, and NOTIN. The operators IN and NOTIN have runtime support and may therefore be applied programmatically. The operators CONTAINSALL and CONTAINSDELIMITEDID are supported for multi-select attributes.

Additionally, the client may specify the following FindCriteria elements to format the result set response:

- `FetchStart` (required) specifies the zero-based row index to start with. The default is 0 (first row).
- `FetchSize` (required) specifies the maximum number of rows to retrieve.
- `SortOrder` (optional) contains directive for sorting the result set in ascending or descending order.
- `FindAttribute` (optional) specifies the subset of attributes to retrieve when the filter criteria is satisfied. When none is satisfied, all attributes are fetched.
- `ExcludeAttribute` (optional) a boolean flag that when set to `True`, attributes specified by `FindAttribute` are not returned.

When attributes of a child object need to be conditionally evaluated and/or returned in the payload, a `childFindCriteria` structure may be added within the FindCriteria structure. The elements of the `childFindCriteria` are the same as used in the FindCriteria structure, with one addition: `childAttrName` specifies which child object to apply the filter criteria to, as the following block diagram illustrates for a single child object.

Figure 15-24 FindCriteria Containment Hierarchy with Child Find Criteria



How to Control Find Method Behavior Using a SOAP Request

To construct a find request payload for a SDO, it is necessary to understand the containment hierarchy of the find method filter model. Payload building blocks are derived from the elements defined by the find method XSD. For details about the containment hierarchy, see Working with the Find Method Filter Model in the Consuming Application.

To define a SOAP request for a FindCriteria, follow this process:

1. Specify the number of rows in the result set, and on which row to start (required).
2. Define the filter condition on the parent object, specifying one or more view criteria items (required).
3. Specify the sort order for the result, if desired (optional). Default is descending order.
4. Specify one or more attributes to retrieve when the filter criteria is satisfied (optional).
5. Specify filter conditions on child objects, if any (optional). See Figure 15-25.

The following request is designed to return a result set matching this description on the parent object:
Find up to 50 Locations where the Country attribute value is US or IE. Return only the Country, State, Province, and City attributes. Sort the result set in descending Country order. Do not return any translated values.

   </typ:findCriteria>
  </typ:findLocation>
</soapenv:Body>
```

How to Control Find Method Behavior Using a Java Client

The standard find method API provides control over the query behavior. To work with the API, it is necessary to understand the object containment hierarchy of the find method filter model. For details about the containment hierarchy, see Working with the Find Method Filter Model in the Consuming Application,

The following sample illustrates the process for programmatically creating a `FindCriteria` object:

1. Create a new `FindCriteria` (the Filter).
2. Create a new `ViewCriteriaItem` (the Item).
3. Create a new `ViewCriteriaRow` (the Group).
4. Add the created items and groups to the `FindCriteria`.

```
//1. Create FindCriteria
     final FindCriteria findCriteria =
(FindCriteria)DataFactory.INSTANCE.create(FindCriteria.class);
     findCriteria.setFetchStart(0);
     findCriteria.setFetchSize(-1);
     findCriteria.setExcludeAttribute(false);

//2. Create ViewCriteriaItem
     final ViewCriteriaItem viewCriteriaItem =
(ViewCriteriaItem)DataFactory.INSTANCE.create(ViewCriteriaItem.class);
     viewCriteriaItem.setConjunction("AND"); //Can also be OR
     viewCriteriaItem.setUpperCaseCompare(true);
     viewCriteriaItem.setAttribute("EmpName");
     viewCriteriaItem.setOperator("LIKE"); //LIKE used for WILDCARD comparison
      final List<Object> item_values = new ArrayList<Object>(5);
     item_values.add(viewCriteriaItem);
      viewCriteriaItem.setValue(item_values);

//3. Create ViewCriteriaRow.
//4. Further add ViewCriteriaItem into ViewCriteriaRow and ViewCriteriaRow into
FindCriteria.
     final ViewCriteriaRow viewCriteriaRow =
(ViewCriteriaRow)DataFactory.INSTANCE.create(ViewCriteriaRow.class);
     viewCriteriaRow.setConjunction("AND");
     viewCriteriaRow.setUpperCaseCompare(true);
     final List<Object> item = new ArrayList<Object>(5);
     item.add(viewCriteriaItem);
     viewCriteriaRow.setItem(item);
     findCriteria.getFilter().getGroup().add(viewCriteriaRow);
```

When you want to query with a list of partial attributes list

By default, the find operation returns all the attributes including all details. When you only need some attributes, you should set the partial attributes on the `FindCriteria` parameter of the find method. Do this in the following situations:

- SDO contains LOB, which can be very expensive to retrieve and transfer.
- SDO contains details that are not needed, such as translations. Querying detail is also expensive.

Note: The standard `getXXX` function does not take a `FindCriteria`, so this function always returns everything. You should use `findXXX` to trim your return attributes.

The following example shows how to set the partial attributes to include only `Dname`, `Loc` from `Dept`, and exclude `Empno` from `Emp`.

```
FindCriteria fc = (FindCriteria)datafactory.create(FindCriteria.class);
List l = new ArrayList();
l.add("Dname");
l.add("Loc");
l.add("Emp");
fc.setFindAttribute(l);
List cfcl = new ArrayList();
ChildFindCriteria cfc =
(ChildFindCriteria)datafactory.create(ChildFindCriteria.class);
cfc.setChildAttrName("Emp");
List cl = new ArrayList();
cl.add("Empno");
cfc.setFindAttribute(cl);
cfc.setExcludeAttribute(true);
cfcl.add(cfc);
fc.setChildFindCriteria(cfcl);
DeptResult res = svc.findDept(fc, null);
```

The following example shows how to set the partial attributes to exclude `PurchaseOrderLine` from `PurchaseOrder`.

```
FindCriteria fc = (FindCriteria)datafactory.create(FindCriteria.class);
List l = new ArrayList();
fc.setExcludeAttribute(true);
l.add("PurchaseOrderLine");
fc.setFindAttribute(l);
PchaseOrderResult res = svc.findPurchaseOrder(fc, null);
```

When you want to filter the result using a view criteria

The find API allows you to specify the WHERE clause of your query. The WHERE clause can be set on any level of the SDO.

The following example shows how to retrieve only the departments with a department number greater than 10 and child employees whose names start with "A".

```
FindCriteria fc = (FindCriteria)datafactory.create(FindCriteria.class);
//create the view criteria item
List value = new ArrayList();
value.add(new Integer(10));
ViewCriteriaItem vci =
(ViewCriteriaItem)datafactory.create(ViewCriteriaItem.class);
vci.setValue(value);
vci.setAttribute("Deptno");
List<ViewCriteriaItem> items = new ArrayList(1);
items.add(vci);
//create view criteria row
ViewCriteriaRow vcr = (ViewCriteriaRow)
datafactory.create(ViewCriteriaRow.class);
vcr.setItem(items);
//create the view criteria
List group = new ArrayList();
group.add(vcr);
ViewCriteria vc = (ViewCriteria)datafactory.create(ViewCriteria.class);
vc.setGroup(group);
//set filter
fc.setFilter(vc);

List cfcl = new ArrayList();
//create the child find criteria
ChildFindCriteria cfc =
(ChildFindCriteria)datafactory.create(ChildFindCriteria.class);
cfc.setChildAttrName("Emp");
//create the child view criteira
ViewCriteria cvc = (ViewCriteria)datafactory.create(ViewCriteria.class);
cfc.setFilter(cvc);
//create the view criteria item
List cvalue = new ArrayList();
cvalue.add("A%");
```

```
ViewCriteriaItem cvci =
(ViewCriteriaItem)datafactory.create(ViewCriteriaItem.class);
cvci.setValue(value);
cvci.setAttribute("Dname");
cvci.setOperator("LIKE");
List<ViewCriteriaItem> citems = new ArrayList(1);
citems.add(cvci);
//create child view criteria row
ViewCriteriaRow cvcr = (ViewCriteriaRow)
datafactory.create(ViewCriteriaRow.class);
cvcr.setItem(citems);
List cgroup = new ArrayList();
cgroup.add(cvcr);
cvc.setGroup(cgroup);

DeptResult dres = svc.findDept(fc, null);
```

You can also query the parents with the children that satisfy certain criteria. For example, the following sample retrieves the departments with employees whose salary is greater than $10,000.

```
//create the view criteria item on the employees
List nvalue = new ArrayList();
nvalue.add(new BigDecimal(10000));
ViewCriteriaItem nvci =
(ViewCriteriaItem)datafactory.create(ViewCriteriaItem.class);
nvci.setValue(nvalue);
nvci.setAttribute("Salary");
nvci.setOperation(">");
List<ViewCriteriaItem> nitems = new ArrayList(1);
nitems.add(nvci);
//create view criteria row
ViewCriteriaRow nvcr = (ViewCriteriaRow)
datafactory.create(ViewCriteriaRow.class);
nvcr.setItem(nitems);
//create the nested view criteria
List ngroup = new ArrayList();
ngroup.add(nvcr);
ViewCriteria nvc = (ViewCriteria)datafactory.create(ViewCriteria.class);
nvc.setGroup(ngroup);

//create the view criteria item on the department
ViewCriteriaItem vci =
(ViewCriteriaItem)datafactory.create(ViewCriteriaItem.class);
vci.setAttribute("Emp");
vci.setNested(nvc);
List<ViewCriteriaItem> items = new ArrayList(1);
items.add(vci);
//create view criteria row
ViewCriteriaRow vcr = (ViewCriteriaRow)
datafactory.create(ViewCriteriaRow.class);
vcr.setItem(items);
//create view criteria on department
ViewCriteria vc = (ViewCriteria)datafactory.create(ViewCriteria.class);
List group = new ArrayList();
group.add(vcr);
vc.setGroup(group);
//set filter
FindCriteria fc = (FindCriteria)datafactory.create(FindCriteria.class);
fc.setFilter(vc);
```

```
DeptResult dres = svc.findDept(fc, null);
```

When you want to page the result

If you know that your query might return a large amount of data, you should make multiple service invocations, and use `setFetchStart` and `setFetchSize` to control the amount of the data that you want to retrieve.

The following sample shows how to retrieve only the second employee and the employee's department.

```
FindCriteria fc = (FindCriteria)datafactory.create(FindCriteria.class);
List cfcl = new ArrayList();
ChildFindCriteria cfc =
(ChildFindCriteria)datafactory.create(ChildFindCriteria.class);
cfc.setChildAttrName("Emp");
cfc.setFetchStart(1);
cfc.setFetchSize(1);
cfcl.add(cfc);
fc.setChildFindCriteria(cfcl);
DeptResult dres = svc.findDept(fc, null);
```

16

Creating ADF RESTful Web Services with Application Modules

This chapter describes how to create ADF REST resources based on view object instances of the ADF application module to make these resources available as ADF RESTful web services in a Fusion web application.
This chapter includes the following sections:

About RESTful Web Services and ADF Business Components

ADF Business Components view object instances can be exposed as web services using REST. Client developers interact with these resources through the REST API enabled by the ADF REST runtime.

REpresentational State Transfer (REST) supports a stateless client-server architecture in which the web services are viewed as resources identified by their URL. HTTP Request methods such as GET and POST are the verbs that the developer can use in a web service client request message to describe the necessary create, read, update, and delete (CRUD) actions to be performed on the resource represented by the HTTP URL. REST prescribes the use of standards such as HTTP, URL, URI, XML, HTML, as well as Resource Types and MIME Types. Therefore, REST is not a standard but a proposed architectural style for web services.

Web services conforming to the REST design constraints are referred to as being RESTful. This type of web service allows the HTTP client and the HTTP server to exchange information about resources identified by using a URL. The request and response contain a representation of the resource, in a specific format, which defines the state of the actual resource.

In the Fusion web application, ADF REST resources acted on by RESTful web services are backed by view object instances exposed in the data model of the ADF Business Components Model project. ADF Business Components developers working in the ADF Model project can decide on the set of attributes to expose from backing view objects, the actions to make available CRUD operations, and the view link relationships to preserve for the resulting resource.

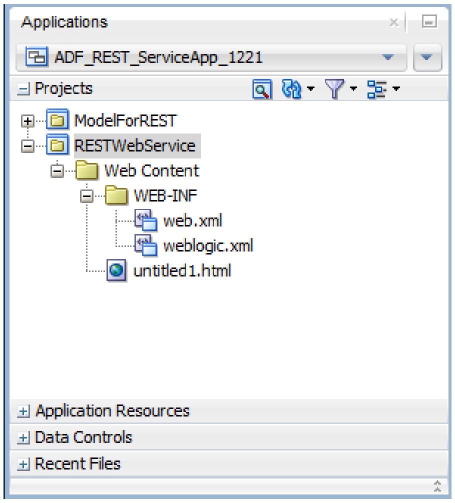
Note:

When you create view objects that you intend to expose as ADF REST resources, use the **Declarative** option on the Query page of the Create View Object wizard to create view objects with declarative SQL mode option enabled. View objects created in declarative SQL mode at design time support an ADF REST framework runtime optimization that allows resource collections to be efficiently filtered by client requests made with the URL query parameter `fields`.

The design-time choices made by ADF Business Components developers are captured in REST resource definition XML files. Web service client developers may interact with these resource definitions through the REST API enabled by the ADF REST runtime. As a result, the consuming service client may invoke CRUD operations to interact with the REST resources and ADF business objects. The data is shaped by the resource's backing view object instance, with the parent-child relationships intact.

When you create the first REST resource in the ADF Business Components project, JDeveloper also generates a separate RESTful web service project to register the ADF REST servlet. Figure 16-1 shows the `web.xml` file that JDeveloper generates. You use this project to run and deploy the RESTful web service.

Figure 16-1 Applications Window Displays RESTful Web Service Project



Security for ADF REST resources is enforced in RESTful web services similar to the way you secure the Fusion web application. In JDeveloper, you run the Configure ADF Security wizard to enforce security on the ADF Model project. After you run the wizard, the REST resources of the deployed RESTful web service will be protected by default and will require that you grant access to the operations of the service.

You can test security in JDeveloper by creating test users and granting them access privileges to the resources. The security policies that confer these access rights, may then be migrated from the application level to a domain-level security policy store, where enterprise users are provisioned with access rights.

RESTful Web Services Use Cases and Examples

Any development team can publish an ADF REST resource to contribute to the Fusion web application. ADF REST application developers can manage the functionality that they expose to the service client using these version features:

- Registering REST resources with an application-specific resource version name (or number) to support versioning of REST resources.
- Declaring a default ADF REST framework version for REST resources allows service clients to utilize new features and enhancements at runtime, such as the advanced query capabilities offered in version 2 of the ADF REST runtime framework. By declaring a default framework version to process requests, REST application developers may opt into the features introduced by a specific ADF REST framework when they are ready. In JDeveloper starting with release 12.2.1.2.0, versions 1, 2, and 3 exist. In the release 12.2.1.4.0 and later, versions 1, 2, 3, 4, 5, 6, and 7 exist.

Specific runtime features of the ADF REST framework that support the exchange of resource information by client and server include:

- Interacting with the REST resource is supported by separate JSON-based media type structures for the resource, action execution, and the results of action execution.
- Passing a custom header to specify the version of the ADF REST runtime framework that will be used to process requests. The version header allows service clients to override the default version declaration defined by the REST application. In JDeveloper starting with release 12.2.1.2.0, versions 1, 2, and 3 exist. In the release 12.2.1.4.0 and later, versions 1, 2, 3, 4, 5, 6, and 7 exist.
- Interacting with the REST resource using standard HTTP request methods, including GET, POST, PATCH, and DELETE.
- Executing an HTTP method using an `X-HTTP-Method-Override` header on a POST request method when client restrictions prevent the use of standard HTTP methods to interact with the REST resource.
- Merging payload content with the REST resource using a POST method in combination with a header `Upsert-Mode` set to true. This action implements create if the record does not exist or update if the record exists.
- Locating a REST resource item (such as a specific employee) or REST resource collection (such as an collection of all employees) is supported by REST-compliant URI path names based on resource names defined in the ADF Business Components Model project.
- Obtaining a description of the REST resource, including the resource attributes and available actions, is supported by a specific media type and describe action.
- Obtaining a error responses in the form of a JSON payload with exception detail when ADF REST framework version 4 or later is enabled. Alternatively, with framework version 3 or earlier, error responses are in the form of a simple message string.

- Linking to a canonical REST resource is supported when a resource with a super set of updatable entities is defined. The canonical link supports alternate links for the backing view object.
- Filtering of the REST resource is supported by query string parameters on the URI specified by the client to access the specific resource.
- Encoding formats are supported on the REST resource to enable compression and decompression.
- Content streaming of BLOB and CLOB attributes exposed by the REST resource is supported by the ADF REST framework.
- Performing data consistency checks while invoking the RESTful web service is supported by the ADF REST framework. This capability uses version history in the database to enable clients to manage HTTP payloads according to updates in the resource itself.
- Authorizing users to access the REST resource is enabled by ADF Security permission grants.

Additional Functionality for RESTful Web Services

You may find it helpful to understand other Oracle ADF features before you start working with RESTful web services. Following are links to supporting functionality that may be of interest.

- For details about creating view objects with the recommended declarative SQL mode enabled to support efficient resource collection filtering at runtime, see Working with View Objects in Declarative SQL Mode,
- For details about enabling change indicator attributes to entity objects when you want to support data consistency checking on the service client, see How to Protect Against Losing Simultaneously Updated Data.
- For details about creating row finders on view object when you want to expose finders in ADF REST resource, see Working with Row Finders.
- For details about creating LOV-enabled view object attributes when you want to expose LOV links in the ADF REST resource, see Working with List of Values (LOV) in View Object Attributes.
- For information about creating polymorphic view objects to expose subtype view rows in the ADF REST resource, see Working with Polymorphic View Rows.
- For information about the ADF REST framework that enables runtime access to ADF REST resources using a REST API, see Consuming ADF RESTful Web Services.
- For details about using the ADF REST data control to design the user interface, see Creating ADF REST Data Controls from ADF RESTful Web Services.
- For information about creating ADF REST resources using Create Business Components from Tables wizard, see How to Create a Data Model Project for ADF REST Web Applications.

Creating ADF REST Resources Using the Application Module

You can use view object instances that you expose on the ADF application module to create the ADF REST resource.

The application module is an ADF Business Components framework component that encapsulates business logic as a set of related business functions exposed as view object instances. You may map one or more view object instances that appear in the application module data model to ADF REST resources. You use the overview editor for your application module to create the ADF REST resource. The REST resource that you add to the ADF Model project may be published as a web service that follows the REST architectural style.

> **Note:**
>
> When you create view objects that you intend to expose as ADF REST resources, use the **Declarative** option on the Query page of the Create View Object wizard to create view objects with declarative SQL mode option enabled. View objects created in declarative SQL mode at design time support an ADF REST framework runtime optimization that allows resource collections to be efficiently filtered by client requests made with the URL query parameter `fields`.

How to Create ADF REST Resources Using the Create Business Components from Tables Wizard

In the New Gallery, in the **ADF Business Components** category, JDeveloper offers a wizard to create each kind of business component. Each wizard allows you to specify the component name for the new component and to select the package into which you'd like to organize the component. If the package does not yet exist, the new component becomes the first component in that new package.

The Create Business Components from Tables wizard is particularly useful in JDeveloper because it is the only wizard that combines generating the various business components along with creating REST resources in a single end to end process. This wizard lets you create REST resources quickly and easily. You can create entity objects based on an online or offline database, then you can create either entity-based view objects or query-based view objects, and an application module to contain the view instances of the data model, and then create the ADF REST resources.

Before you begin:

It may be helpful to have an understanding of the various ADF business components. For more information, see About ADF Business Components.

You will need to complete this task:

Create the data model project that will contain the business components, as described in How to Create a Data Model Project for ADF REST Web Applications.

To create REST resources from **Business Components from Tables** wizard in one pass:

1. In the Applications window, right-click the project in which you want to create the entity objects and choose **New**.
2. In the New Gallery, expand **Business Tier**, select **ADF Business Components** and then **Business Components from Tables**, and click **OK**.

   If this is the first component you are creating in the project, the Initialize Business Components Project dialog appears to allow you to select a database connection. Complete the dialog, as described in How to Initialize the Data Model Project With a Database Connection.
3. In the Create Business Components from Tables wizard, on the Entity Objects page, filter the database schema to display available database objects and select those database objects for which you want to create entity objects. Click **Next**.

   Note that if you change a default package name, you must not use reserved words like `rest` in the package name. For details about package naming, see What You May Need to Know About Package Naming Conventions.
4. On the Entity-based View Objects page, select among the available entity objects to create updatable view object definitions for your entity object definitions. Click **Next**.

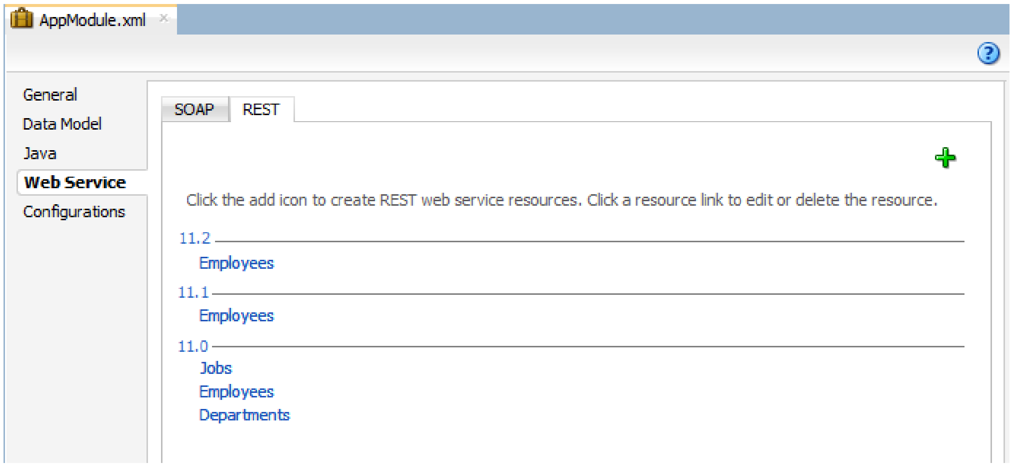
   Note that the view object definitions you create in this wizard will contain a single usage of an entity object, and will expose all the attributes in that object.
5. On the Query-based View Objects page, select among the available database objects to create read-only view object definitions. Click **Next**.
6. On the Application Module page, select the **Add to Application Module** checkbox and leave the other default selections unchanged. Click **Next**.
7. On the REST Resources page, choose an existing Release Version from the dropdown list or click the **Create New Release Version** icon. Select among the available view objects to add as view instances and create REST resources. Click **Next**.
8. You can optionally specify attributes to hide in the resource payload and also shape it in the Attribute Settings page. Click **Next**.
9. On the Summary page, review the list of business components that the wizard will create with REST resources, and click **Finish**.
10. You may create additional ADF REST resources using the overview editor for application modules. For details, see How to Create ADF REST Resources from View Object Instances.

How to Create ADF REST Resources from View Object Instances

View object instances are the business objects on which the Fusion web application operates. The ADF application module exposes these business objects in the data model it defines to specify the data that the service client can display and manipulate. After you have created the Model project, optionally using the application template for ADF REST, you may create additional ADF REST resources using the overview editor for the application module. In this case, any view object instance that the application module defines may have an ADF REST resource defined.

Adding an ADF REST resource is an option that appears in the Web Service page of the application module overview editor. Figure 16-2 shows how the editor displays the REST resources that have been created for view object instances on the AppModule application module. Notice that the editor organizes REST resources on the application module by their assigned release-specific version names (in this example, named 11.0, 11.1, and 11.2).

Figure 16-2 ADF REST Resources Defined on the Application Module



Click the add icon to create REST web service resources. Click a resource link to edit or delete the resource.

11.2
- Employees

11.1
- Employees

11.0
- Jobs
- Employees
- Departments

Note:

When you create an ADF REST resource JDeveloper prompts you to specify a version release name for the resource. The version is an alphanumeric identifier that helps you to manage the current and subsequent versions of resources that you add to the ADF Model project across multiple releases.

After you select the view object instance, name the REST resource, and select a version, JDeveloper opens the resource in the overview editor for the REST resource. You use the overview editor to edit the REST resource representation by exposing view object accessors and available operations as payload objects and actions of RESTful web services. JDeveloper saves the REST resource definition files as subpackages of the ADF application module organized by their assigned release version names.

For details about customizing the REST resource, see How to Edit the ADF REST Resource Definition.

Before you begin:

It may be helpful to have an understanding of how the ADF REST framework supports application modules and enables web service clients to access rows of data and perform service operations. For more information, see About RESTful Web Services and ADF Business Components.

You may also find it helpful to understand other Oracle ADF features that depend on ADF REST resources. For more information, see Additional Functionality for RESTful Web Services.

You will need to complete these tasks:

- Create the application module data model that contains the view object instances that you want the REST resource to expose, as described in How to Create an Application Module.
- Create a release version identifier in the `adf-config.xml` file to associate ADF REST resources you create with a specific version. Each REST resource must be associated with a release version to help manage the current and subsequent versions of ADF REST resources that you add to the ADF Model project, as described in Versioning the ADF REST Resource.

To create the ADF REST resource:

1. In the Applications window, double-click the application module that contains the view instance for which you want to create the ADF REST resource.
2. In the overview editor, click the **Web Service** navigation tab, then click the **REST** tab, and then click the **Enable Support for REST Service** add icon.

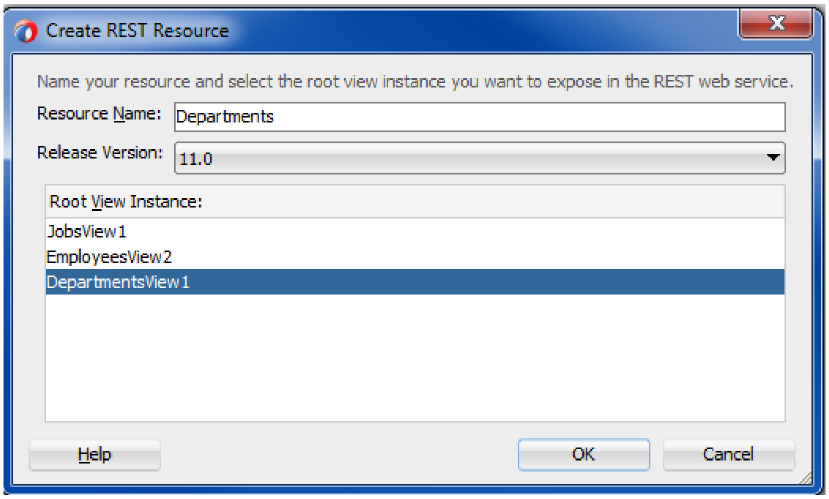
   When you create the first REST resource, JDeveloper also generates a separate RESTful web service project to register the ADF REST servlet.
3. In Create REST Resource dialog, select the root view instance to expose in a RESTful web service.

   The dialog displays view instances defined in the application module data model. Only the root view instance of a master-detail hierarchy may be selected.
4. Enter the **Resource Name** of the REST resource collection and select a release version from the dropdown list, and then click **OK**.

   The resource name is the identifier that service clients use to interact with view instance. For example, as the following figure shows, to name a collection based on a `DeptView1` view instance, you might name enter `Departments` to indicate the full collection name. For more information about naming, see What You May Need to Know About Naming ADF REST Resources.

   The release version is an identifier that you must create in the `adf-config.xml` file to manage the creation of resources in JDeveloper. The version will be part of the URL that service clients use to invoke operations on a specific REST resource, as described in Versioning the ADF REST Resource.

Figure 16-3 Assigning the ADF REST Resource to a Release Version



Create REST Resource

Name your resource and select the root view instance you want to expose in the REST web service.

Resource Name: Departments

Release Version: 11.0

Root View Instance:

JobsView1
EmployeesView2
DepartmentsView1

5. In the overview editor for the REST resource, you can proceed to edit the resource and its structure by performing any of the following tasks:

   a. Add and remove child resources defined by view link accessors. For details, see How to Edit the ADF REST Resource Definition.

   b. Add and remove resources defined by the same backing view instance. For details, see How to Add and Remove Resources Based on the Same View Instance.

   c. Add and remove attributes. For details, see How to Hide and Expose Attributes in the ADF REST Resource.

   d. Modify access to standard operations defined by HTTP methods, canonical links, row finder filters, and subtype view usages. For details, see Customizing the ADF REST Resource Representation and Methods.

6. Click **File** and then **Save All** to save the selections on this resource.

   JDeveloper saves the REST resource selections that you make in the overview editor in the resource definition file for the resource, as described in What Happens When You Create REST Resources in the ADF Business Components Project.

What Happens When You Create REST Resources in the ADF Business Components Project

JDeveloper generates the REST resources and displays them in the Applications window organized in the model project by their version release names, as shown in Figure 16-4.

JDeveloper also generates a separate RESTful web service project (**RESTWebService**) to register the ADF REST servlet. Figure 16-4 shows the `web.xml` file that JDeveloper generates. You use this project to run and deploy the RESTful web service.

The `ResourceRegistry.rpx` file that appears in the model project uses metadata annotations to specifies the list of REST resources that will be exposed as a RESTful web service.
