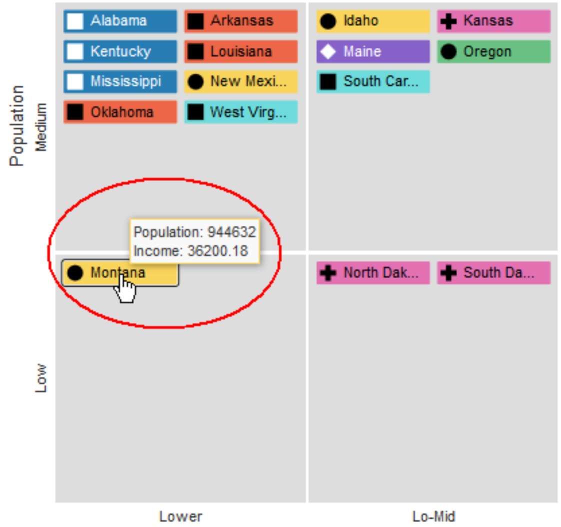
Attributes that were not specified in the Create NBox dialog during creation will not be included in the binding. If you need to reference another attribute in the data collection, you must add it manually to the binding. For example, the sample in this section displays a tooltip showing the state's income and population when the user hovers over a node.

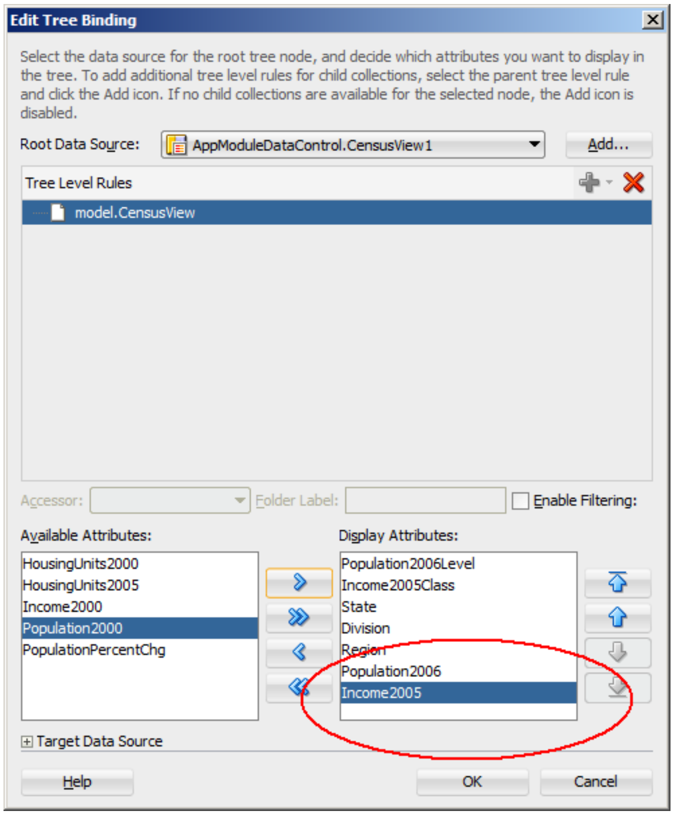
Figure 39-6 NBox Tooltip



For the tooltip to evaluate properly, you must add the `Population2006 and Income2005` attributes to the binding definition for the NBox. To add the binding, in the Structure window, right-click the **dvt:nBox** component and choose **Go to Binding**. Choose **Edit** in the **Binding** section to add the `Population2006` and `Income 2005` attributes.

Figure 39-7 shows the completed Edit Tree Binding with `Population2006 and Income2005` added to the display attributes.

Figure 39-7   Edit Tree Binding Dialog for NBox Sample



Edit Tree Binding
Select the data source for the root tree node, and decide which attributes you want to display in the tree. To add additional tree level rules for child collections, select the parent tree level rule and click the Add icon. If no child collections are available for the selected node, the Add icon is disabled.
Root Data Source:
AppModuleDataControl.CensusView1
Add...
Tree Level Rules
model.CensusView
Accessor:

OK
Cancel

After you click **OK**, the binding will be updated with the added attributes. The following code sample shows the revised binding for the `CensusView10` node definition.

```
<nodeDefinition DefName="model.CensusView" Name="CensusView10">
  <AttrNames>
    <Item Value="Population2006Level"/>
    <Item Value="Income2005Class"/>
    <Item Value="State"/>
    <Item Value="Division"/>
    <Item Value="Region"/>
    <Item Value="Population2006"/>
    <Item Value="Income2005"/>
  </AttrNames>
</nodeDefinition>
```

Code on the JSF page for an NBox Component

The following example shows the code that is generated on the JSF page for the NBox:

```
<dvt:nBox id="nb1" var="ent" rowsTitle="#{viewcontrollerBundle.POPULATION}"
          value="#{bindings.CensusView1.collectionModel}"
          columnsTitle="#{viewcontrollerBundle.INCOME}">
  <f:facet name="rows">
    <af:group id="g1">
      <dvt:nBoxRow label="#{viewcontrollerBundle.LOW}" id="nbr1" value="low"/>
      <dvt:nBoxRow label="#{viewcontrollerBundle.MEDIUM}" id="nbr2"
value="medium"/>
```

```
      <dvt:nBoxRow label="#{viewcontrollerBundle.HIGH}" id="nbr3" value="high"/>
    </af:group>
  </f:facet>
  <f:facet name="columns">
    <af:group id="g2">
      <dvt:nBoxColumn label="#{viewcontrollerBundle.LOWER}" id="nbc1"
value="lower"/>
      <dvt:nBoxColumn label="#{viewcontrollerBundle.LO_MID}" id="nbc2" value="lo-
mid"/>
      <dvt:nBoxColumn label="#{viewcontrollerBundle.HI_MID}" id="nbc3" value="hi-
mid"/>
      <dvt:nBoxColumn label="#{viewcontrollerBundle.UPPER}" id="nbc4"
value="upper"/>
    </af:group>
  </f:facet>
  <dvt:nBoxNode column="#{ent.Income2005Class}" row="#{ent.Population2006Level}"
                label="#{ent.State}" id="nbn1">
    <dvt:attributeGroups value="#{ent.Division}" type="color"
                         label="#{ent.Division}"
                         sectionLabel="#{viewcontrollerBundle.DIVISION}"
id="ag1"/>
    <f:facet name="icon">
      <dvt:marker id="m1">
        <dvt:attributeGroups value="#{ent.Region}" type="shape"
                             label="#{ent.Region}"
                             sectionLabel="#{viewcontrollerBundle.REGION}"
                             id="ag2"/>
      </dvt:marker>
    </f:facet>
  </dvt:nBoxNode>
</dvt:nBox>
```

Modifying NBox Properties and Layout

After you create your NBox, you can modify the layout of the component or add additional elements, such as a label, using the Create NBox dialog. To open the dialog, use the **Edit** icon in the Properties window for the nBox component. You can also customize the layout of the Nbox directly in the code, in the visual editor, or by setting values in the Properties window.

For example, to add the tooltip shown in Figure 39-6 to your NBox, you can enter a value for the NBox node's shortDesc attribute in the Properties window or in the code editor.

```
<dvt:nBoxNode column="#{ent.Income2005Class}" row="#{ent.Population2006Level}"
              label="#{ent.State}" id="nbn1"
              shortDesc="Population: #{ent.Population2006}&lt;br/>Income:
#{ent.Income2005}">
    ... contents omitted
</dvt:nBoxNode>
```

For additional information and examples for customizing your NBox, see Using NBox Componentsin *Developing Web User Interfaces with Oracle ADF Faces*.

Creating Databound Pivot Table and Pivot Filter Bar Components

This chapter describes how to create pivot tables from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization `pivotTable` and `pivotFilterBar` components to create pivot tables that visually represent business data. It describes how to use ADF data controls to create a pivot table with data-first development.
If you are designing your page using simple UI-first development, then you can add the pivot table to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the pivot table components, see the Using Pivot Table Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

This chapter includes the following sections:

About ADF Data Visualization Pivot Table and Pivot Filter Bar Components

Pivot tables display data in a grid layout with unlimited layers of hierarchically nested row header cells and column header cells. Similar to spreadsheets, pivot tables provide the option of automatically generating subtotals and totals for grid data. Pivot filter bars enhance the Pivot table by selectively displaying data according to the user's requirements.

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

The pivot table component produces a grid that supports multiple layers of data labels on the row edge or the column edge of the grid. An optional pivot filter bar represents a page edge that filters the available pivot table data. This component also provides the option of automatically generating subtotals and totals for grid data. Pivot tables let you pivot data layers from one edge to another to obtain different views of your data. For example, a pivot table might initially display total sales data for products within regions on the row edge, broken out by years on the column edge. If you pivot region and year at runtime, then you end up with total sales data for products within years, broken out by region. At runtime, end users can click buttons that appear in the inner column labels to sort rows in ascending or descending order.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

Data Visualization Components Use Cases and Examples

For detailed descriptions of each data visualization use cases and examples, see the Pivot Table and Pivot Filter Bar Component Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.

End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the End User and Presentation Features of Pivot Table Components section in *Developing Web User Interfaces with Oracle ADF Faces*.

Additional Functionality for Data Visualization Components

You may find it helpful to understand other **Oracle ADF** features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the Rerendering Partial Page Content chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the Allowing User Customization on JSF Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: By default, data visualization components are accessible. You can make your application pages accessible for screen readers. For more information, see the Developing Accessible ADF Faces Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls.

Creating Databound Pivot Tables

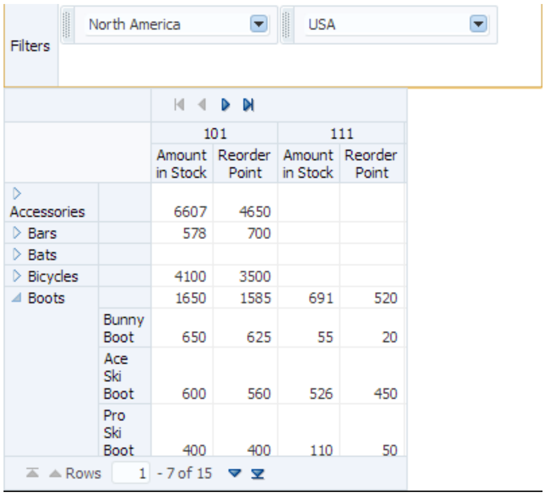
DVT Pivot Table components can be created and bound to a data collection with a data-first development approach. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

The ADF pivot table displays data in a grid layout with unlimited layers of hierarchically nested row header cells and column header cells. The pivot table supports an optional pivot filter bar, representing a page edge that filters the available pivot table data. The pivot table has the following structure:

- Column edge: The horizontal axis above the pivot table containing one or more layers of information in the pivot table.
- Row edge: The vertical axis to the side of the pivot table containing one or more layers of information in the pivot table.
- Page edge: The optional pivot filter bar containing zero or more layers of information for filtering the display of data in the pivot table.
- Data body: One or more measures, or data values, displayed in the cells of the pivot table.

Figure 40-1 shows a Product Inventory pivot table that displays data values for the amount in stock and reorder point in the data body, a warehouse ID data layer on the column edge, and product category and product data layers on the row edge. A pivot filter bar displays a world region and region filter on the page edge.

Figure 40-1 Product Inventory Pivot Table



Filters: North America | USA

		101		111	
		Amount in Stock	Reorder Point	Amount in Stock	Reorder Point
Accessories		6607	4650		
Bars		578	700		
Bats					
Bicycles		4100	3500		
Boots		1650	1585	691	520
	Bunny Boot	650	625	55	20
	Ace Ski Boot	600	560	526	450
	Pro Ski Boot	400	400	110	50

Rows 1 - 7 of 15

A Create Pivot Table wizard provides declarative support for data-binding and configuring the pivot table. In the wizard pages you can:

- Specify the initial layout of the pivot table
- Associate and configure a pivot filter bar
- Specify alternative labels for the data layers

- Configure insert or filter drilling
- Define aggregation of data values
- Configure category and data sorting

As you lay out the pivot table in the first page of the wizard, corresponding entries are initialized in the following wizard pages. You can use the **Back** and **Next** buttons to adjust the pivot table as you go through the wizard pages. You can also skip configuration options in later wizard pages by clicking **Finish**.

For information about customizing a pivot table after data binding is completed, see the Using Pivot Table Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Pivot Table Using ADF Data Controls

To create a pivot table using a data control, you bind the pivot table component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

> **Tip:**
>
> You can also create a pivot table by dragging a pivot table component from the Components window. This approach allows you the option of designing the pivot table user interface before binding the component to data.

Before you begin:

It may be helpful to have an understanding of databound pivot tables and pivot filter bars. For more information, see Creating Databound Pivot Tables.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an **application module** that contains instances of the **view objects** that you want in your data model for the pivot table, as described in Creating and Modifying an Application Module.

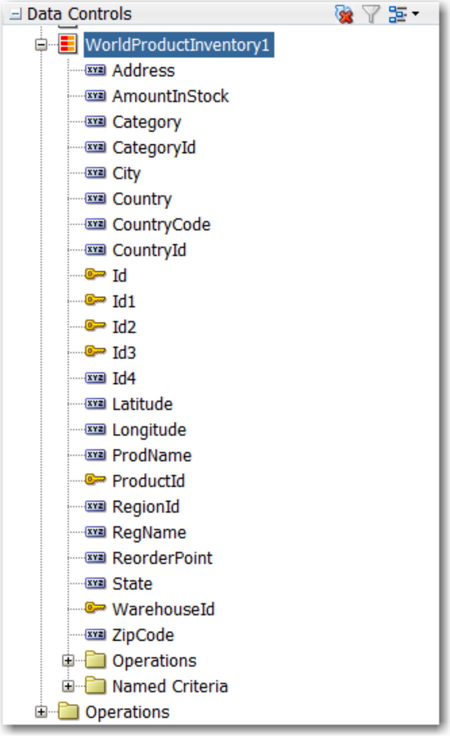
  For example, the data source for Product Inventory pivot table shown in Figure 40-1 comes from a view object created for the Summit sample application for ADF DVT components.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound pivot table:

1. From the Data Controls panel, select a collection.

   For example, to create a pivot table and pivot filter bar that displays product inventory levels in warehouses throughout the World, you could select the `WorldProductInventory1` collection in the Data Controls panel, as shown in Figure 40-2.

Figure 40-2 Data Collection for Product Inventory Levels



2. Drag the data collection onto a JSF page and, from the context menu, choose **Tables/List View** > **ADF Pivot Table**.

3. In the Select Display Attributes page of the Create Pivot Table wizard, specify the initial layout of the pivot table by doing the following:

   a. If you want to associate a pivot filter bar with your pivot table, select **Create Pivot Filter Bar**. Optionally, you can drag attributes from the **Available Attributes** list to the page edge to configure the initial display of filters; otherwise, an empty pivot filter bar is created.

   > **Note:**
   >
   > You can add a pivot filter bar after completing the wizard by right-clicking the `pivotTable` node in the Structure window, and choosing **Insert Before Pivot Table** > **ADF Data Visualizations** > **Pivot Filter Bar**.
   >
   > To remove a pivot filter bar, in the Structure window, right-click the `pivotFilterBar` node and choose **Delete**.

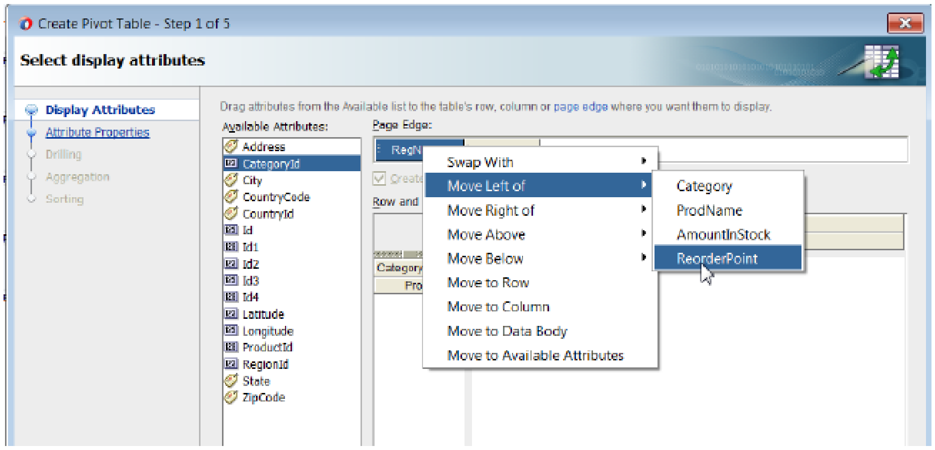
   b. For the initial layout, select the attributes for the pivot table's columns, rows, page edge, and data body by dragging the attributes from the **Available Attributes** list to the pivot table layout.

      In the pivot table layout, **Data Labels** refers to a layer of the pivot table that identifies the data in the cells (data values), and also appears as header labels in the row, column, or page edge. Labels for attributes that you drag to the data body of the pivot table appear in the data labels layer.

You can drag data labels to any location on the row, column, or page edge. You can also drag attributes to different locations on the same edge or on another edge.

As an alternative to using a drag operation to place or move attributes in the layout, you can right-click the attribute or use Shift+F10 to display a context menu of options. Figure 40-3 shows the context menu options for the RegName attribute.

Figure 40-3 Display Attributes Context Menu



Create Pivot Table - Step 1 of 5

Select display attributes

Drag attributes from the Available list to the table's row, column or page edge where you want them to display.

> **Note:**
>
> Potential drill paths between attributes are defined as you lay out multiple attributes on the row, column, and page edges. These drill paths can later be enabled to support pivot table drilling at runtime.

c. If you want to change from the default selection of **Typed Attributes** to **Name-Value Pairs** to configure how data points are stored in a collection, then click the **Change Data Shape** button. A dialog appears that presents you with the following options:

- **Typed Attributes**

  Each kind of data point in the collection is represented by a different attribute. This option is also valid when there is only a single kind of data point in the pivot table.

  For example, if you have data points for **Estimated Value** and **Actual Value**, then select **Typed Attributes** only if you have one attribute for the estimated value and a second attribute for the actual value.

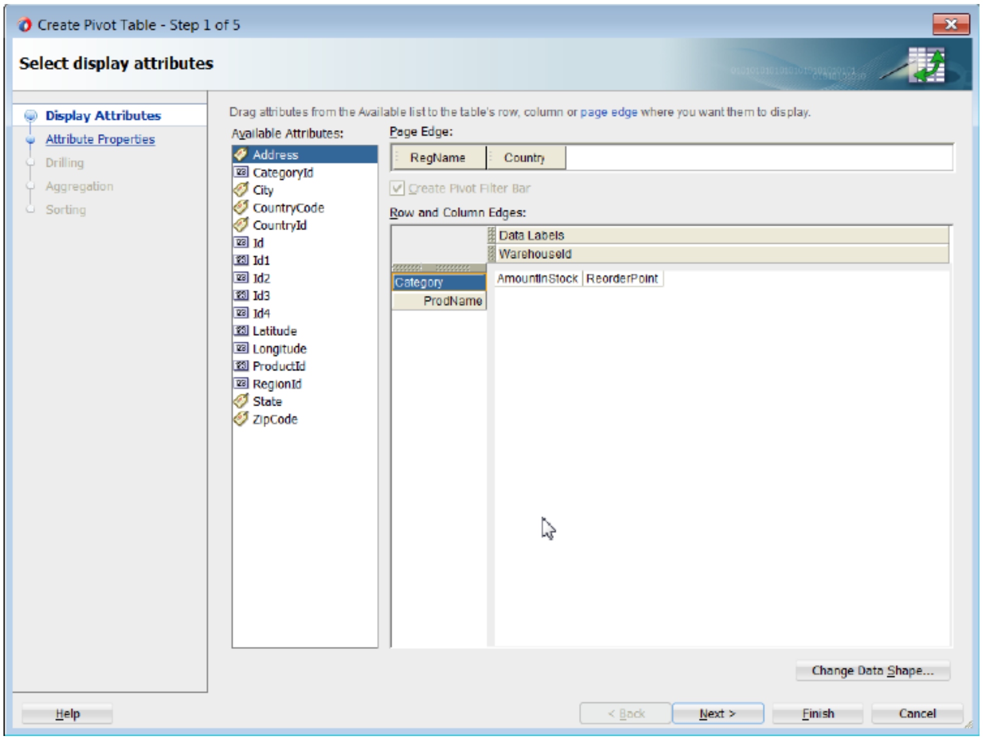
- **Name-Value Pairs**

  Indicates that there are two or more kinds of data points represented by exactly two attributes; a `Name` attribute that specifies the kind of data point, and a `Value` attribute that specifies the data value.

For example, the `Name` attribute might have the value `EST` for a `Value` attribute that represents an estimated value, or the `Name` attribute might have a value `ACT` for a `Value` attribute that represents an actual value.

For example, to specify the initial layout of the Product Inventory pivot table shown in Figure 40-1, you would drag the RegName and Country attributes to the page edge, Category and ProdName attributes to the row edge, AmountinStock and ReorderPoint attributes to the data body (Data Labels), WarehouseID to the column edge, and select **Create Pivot Filter Bar**, as shown in Figure 40-4.

Figure 40-4 Select Display Attributes Page of Create Pivot Table Wizard



Drag attributes from the Available list to the table's row, column or page edge where you want them to display.

Page Edge: RegName | Country

☑ Create Pivot Filter Bar

4. If you want to specify alternative values or labels for the attributes laid out in the Select Display Attributes page of the wizard, click **Next**, and use the Specify Attribute Properties page to do the following:

   a. By default, the data cells in a pivot table are not editable. An `af:outputText` component is automatically stamped for each data cell. If you wish to create a pivot table with editable data cells, deselect **Read-Only Pivot Table** and an `af:inputText` component option will be available for each data cell attribute in the **Component** column. You can then specify zero or more data values as editable by selecting the `af:inputText` component, and the tag and its corresponding `f:validator` tag will be stamped for that pivot table data cell. For more information, see What You May Need to Know About Configuring Editable Data Cells.

   b. To specify alternative labels for data values in the **Data Values** area, change the default `Use Data Attribute Name` text label stamped in the header cell for the attribute at runtime. You can enter the text directly, select `No Label` to suppress the header cell as in the case of using a single data value for the pivot table, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime.

c. To specify alternative labels for attribute categories in the **Categories** area, change the default `Use Attribute Name` text label stamped in the header cell for the attribute at runtime in the **Attribute Display Name** column. You can enter the text directly, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime. The label displays in the pivot handle at runtime.

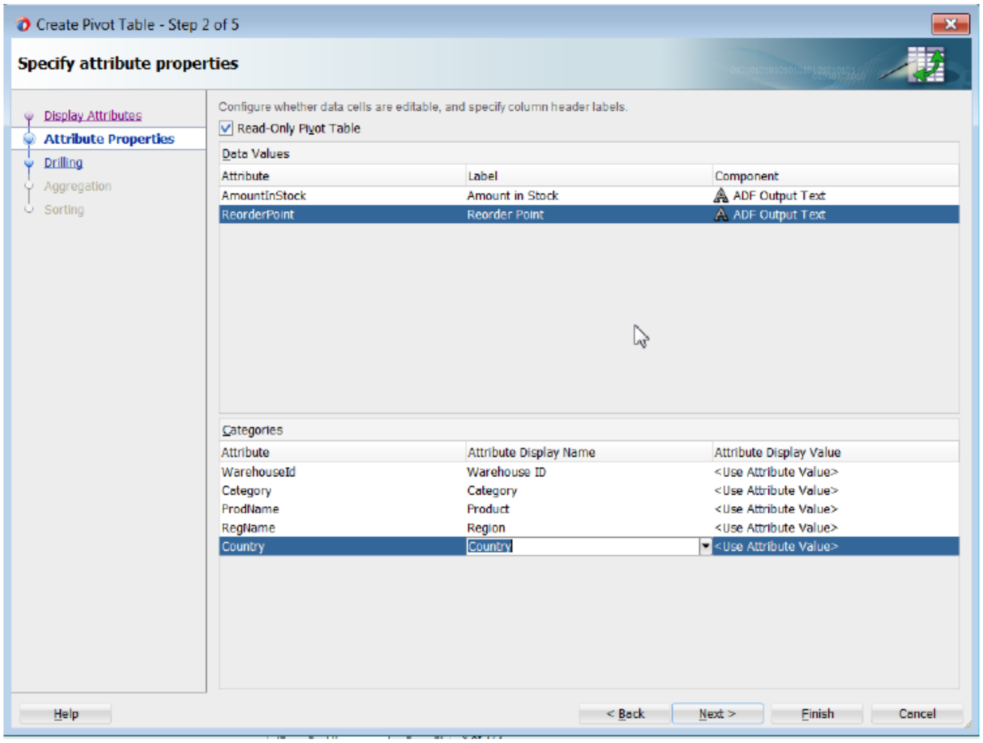
   You can also specify an alternative value for an attribute category by selecting a different attribute in the **Attribute Display Value** column. For example, you might use a `RegionId` attribute in the data collection to lay out the pivot table, but you want the `RegionName` attribute values to appear in the pivot table header at runtime to make the information more readable.

Setting a text resource enables your JSF page or application to display the correct language for the language setting of a user's browser. Choose the **Select Text Resource** option for the **Data Values** labels and the **Categories** attribute display name fields to set a translatable text resource.

> **Note:**
>
> If you configured **Project Properties** > **Resource Bundle** page to **Automatically Synchronize Bundle**, then you can type an alternate label string, and the design time code will create a translatable text resource for you.

For example, to set the Product Inventory pivot table shown in Figure 40-1 to use text resources for labels and display names, complete the Specify Attributes Properties page of the wizard as shown in Figure 40-5.

Figure 40-5 Specify Attribute Properties Page of Create Pivot Table Wizard



Create Pivot Table - Step 2 of 5

Specify attribute properties

Configure whether data cells are editable, and specify column header labels.

☑ Read-Only Pivot Table

Data Values

Attribute	Label	Component
AmountInStock	Amount in Stock	ADF Output Text
ReorderPoint	Reorder Point	ADF Output Text

Categories

Attribute	Attribute Display Name	Attribute Display Value
WarehouseId	Warehouse ID	<Use Attribute Value>
Category	Category	<Use Attribute Value>
ProdName	Product	<Use Attribute Value>
RegName	Region	<Use Attribute Value>
Country	Country	<Use Attribute Value>

5. If you want to expose drill operations in the pivot table at runtime, click **Next**, and use the Configure Drilling page of the Create Pivot Table wizard to enable one of the following options:

   - Select **Insert Drilling** to provide a collapsed or expanded view of the detail data while preserving the sibling and aggregate data. At runtime, a drill icon is displayed in the parent attribute display label.

     Use **Insert Parent Row** to specify whether the aggregate total for the parent attribute will be displayed before or after the child attributes in the expanded view.

     To enable insert drilling you must also:

     – Select the drill paths to enable. Drill paths are configured based upon the layout of the attributes in the Select Display Attributes page of the wizard.

     – Configure aggregation in the Configure Aggregation page of the wizard.

     For example, Figure 40-6 shows a pivot table using insert drilling to expand the view for the Year data layer. The aggregated value of Sales (52,500 in 2007, 544,150 in 2006) and Units (410 in 2007, 507 in 2006) for each year is displayed in the row above the products.

Figure 40-6 Pivot Table with Insert Drilling Enabled

	Sales	Units
TOTAL	128,172	1,135
▷ 2007	52,500	410
▷ 2006	54,150	
▷ 2005	21,522	

		Sales	Units
TOTAL		128,172	1,135
▽ 2007		52,500	410
	Tents	25,500	275
	Canoes	27,000	135
▽ 2006		54,150	507
	Tents	30,750	375
	Canoes	23,400	132
▷ 2005		21,522	218

- Select **Filter Drilling** to provide a collapsed or expanded view of the detail data without preserving the sibling or aggregate data. At runtime, a drill icon is enabled in the parent attribute display label.

  Filter drilling focuses the view on the details of the data layer attribute. For example, Figure 40-7 shows a pivot table using filter drilling to expand the view of the Year (2007) data layer, displaying the total Sales (52,500) and Units (410), while filtering out both the data for the other years and the aggregated total for all the years.

Figure 40-7 Pivot Table with Filter Drilling Enabled

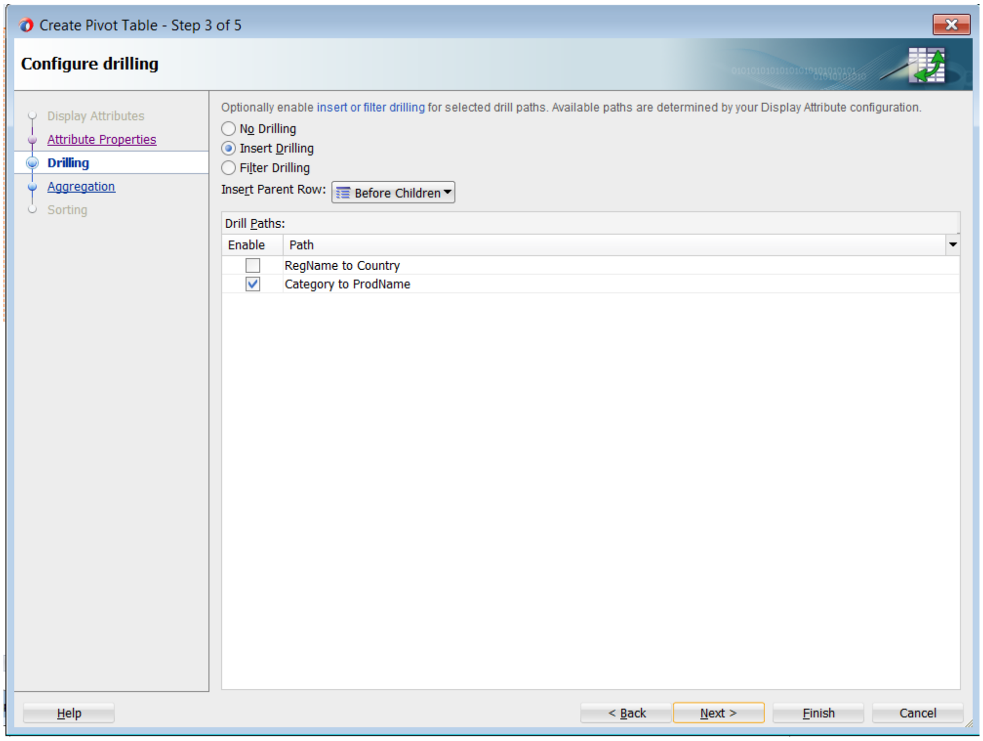
	Sales	Units
TOTAL	128,172	1,135
▷ 2007	52,500	410
▷ 2006	54,150	
▷ 2005	21,522	

		Sales	Units
TOTAL		52,500	410
▽ 2007	Tents	25,500	275
	Canoes	27,000	135

  To enable filter drilling you must select the drill paths to enable. Drill paths are configured based upon the layout of the attributes in the Select Display Attributes page of the wizard.

For example, to enable the insert drilling for the Product Inventory pivot table shown in Figure 40-1, complete the Configure Drilling page of the wizard, as shown in Figure 40-8.

Figure 40-8 Configure Drilling Page of Create Pivot Table Wizard



Create Pivot Table - Step 3 of 5

Configure drilling

Optionally enable insert or filter drilling for selected drill paths. Available paths are determined by your Display Attribute configuration.

○ No Drilling
● Insert Drilling
○ Filter Drilling

Insert Parent Row: Before Children

Drill Paths:

Enable	Path
□	RegName to Country
☑	Category to ProdName

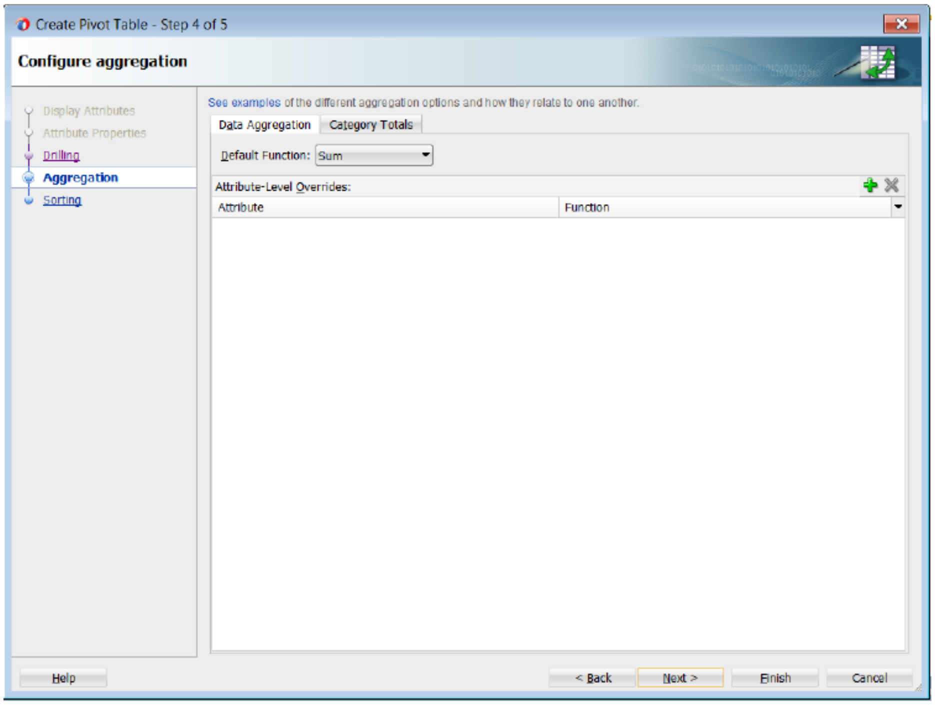
6. If you want to define how data is aggregated in totals and subtotals for the pivot table, click **Next**, and use one or both of the Configure Aggregation pages of the Create Pivot Table wizard.

   By default, if the attributes displayed in the pivot table do not uniquely identify each row in the data collection, the data from duplicate rows is aggregated to collapse that data into a single pivot table cell. You can also override the default aggregate type for a particular data item.

   - If you want to specify how data is aggregated in the pivot table, in the Data Aggregation page, do the following:
     - If you want to change the default aggregation method for handling duplicate rows, use the **Default Function** dropdown list to specify the value. Valid values are `Sum`, `Average`, `Count`, `Maximum`, `Minimum`, `Standard Deviation`, `Median`, and `Variance`.
     - If you want to override the default aggregate type for a specific data value, click the **Add** icon to insert a row for the available attributes. Then, in the **Function** column for each attribute, select the mathematical operation that you want to use for the aggregation. Available options are `Sum`, `Average`, `Count`, `Maximum`, `Minimum`, `Standard Deviation`, `Median`, and `Variance`. This attribute is useful only when you have multiple data values (such as Sales and Units) bound to your pivot table.

     For example, to override the default aggregation type for the Units data value in the Sales pivot table shown in Figure 40-1, use the **Add** icon to add the Units attribute and select Average in the **Function** column in the Data Aggregation page, as shown in Figure 40-9.

Figure 40-9   Data Aggregation Page of Create Pivot Table Wizard



Create Pivot Table - Step 4 of 5

Configure aggregation

See examples of the different aggregation options and how they relate to one another.

Default Function: Sum

- You can also define totals and subtotals for attribute categories added to the column, row, or page edges in the pivot table. In the Categories Totals page, use the **Add** icon to insert each attribute or select **Aggregate All** to add all available attributes, and do the following:
  - In the **Attribute** column, select the attribute that you want to total.
  - In the **Function** column, select the mathematical operation that you want to use for the aggregation. Available options are `Sum`, `Average`, `Count`, `Maximum`, `Minimum`, `Standard Deviation`, `Median`, and `Variance`.
  - In the **Insert Total** column, select the value that indicates where you want the aggregate display to appear relative to the item referenced in the **Attribute** column. Valid values are: `Before`, `After`, or `Replace`.
  - In the **Total Label** column, enter the text that you want to use as a label for the aggregation. You can enter the text directly, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime.

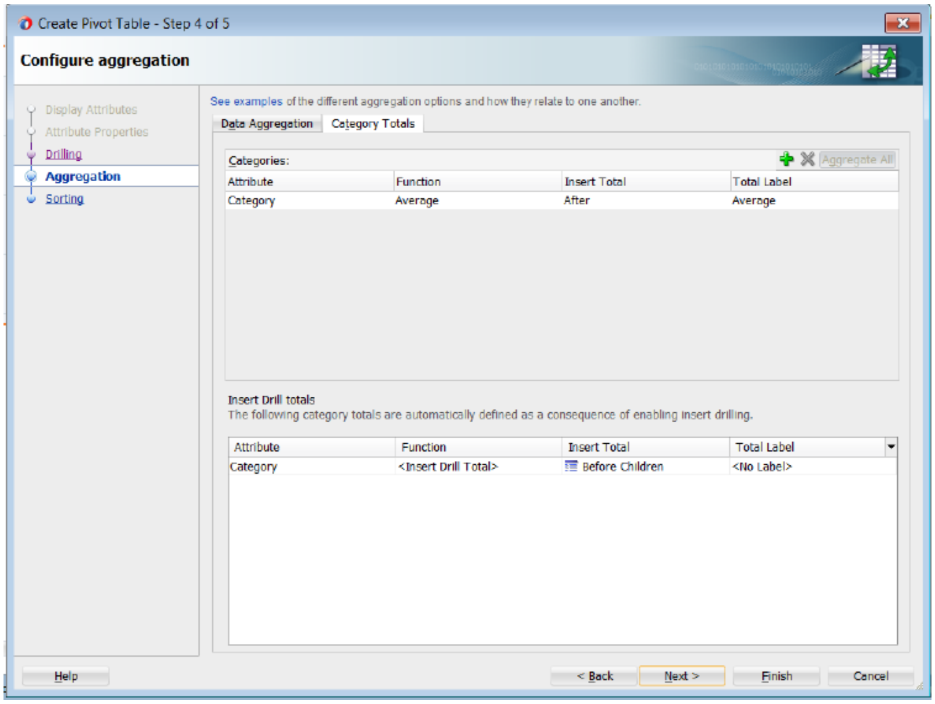
> **Note:**
>
> The read-only **Insert Drill Totals** table displays the category totals automatically defined as a consequence of enabling insert drilling on the pivot table.

For example, to define totals for the Geography and Year data layers in the Sales pivot table shown in Figure 40-1, select `Sum` in the **Function** column and `After` in the **Insert Total** column, and enter text (Total Geography and

Total Year) in the **Total Labels** column respectively for each attribute in the Categories Totals page, as shown in Figure 40-10.

In the resulting pivot table at runtime, expanding a particular Year value will automatically preserve the aggregate total computed from its child value based on the layout and configuration of the insert drill option in the previous wizard page.

Figure 40-10 Categories Totals Page of the Create Pivot Table Wizard



Create Pivot Table - Step 4 of 5

Configure aggregation

See examples of the different aggregation options and how they relate to one another.

Categories:

Attribute	Function	Insert Total	Total Label
Category	Average	After	Average

Insert Drill totals
The following category totals are automatically defined as a consequence of enabling insert drilling.

Attribute	Function	Insert Total	Total Label
Category	<Insert Drill Total>	Before Children	<No Label>

7. If you want to configure sorting in the pivot table, click **Next**, and use one or both of the Configure Sorting pages in the Create Pivot Table wizard.

   By default, a pivot table initially sorts data based on values in the outer row data layer. You can specify sort order on the data layer of any row, column, or page edge, called a category sort. At runtime, when the data layer is pivoted to a different edge, the specified category sort order is honored.

   You cannot specify a category sort of data labels (data values), although you can order the attributes mapped to the data body in the Select Display Attributes page of the wizard. For example, Figure 40-4 shows a pivot table layout with data values for Sales and Units. While you cannot specify a category sort of these measures, you can specify the order in which the values will appear in the data body of the pivot table at runtime, shown in Figure 40-1.

   You can also specify an initial sort order of the data values in the data body when the pivot table is rendered, called a data sort.

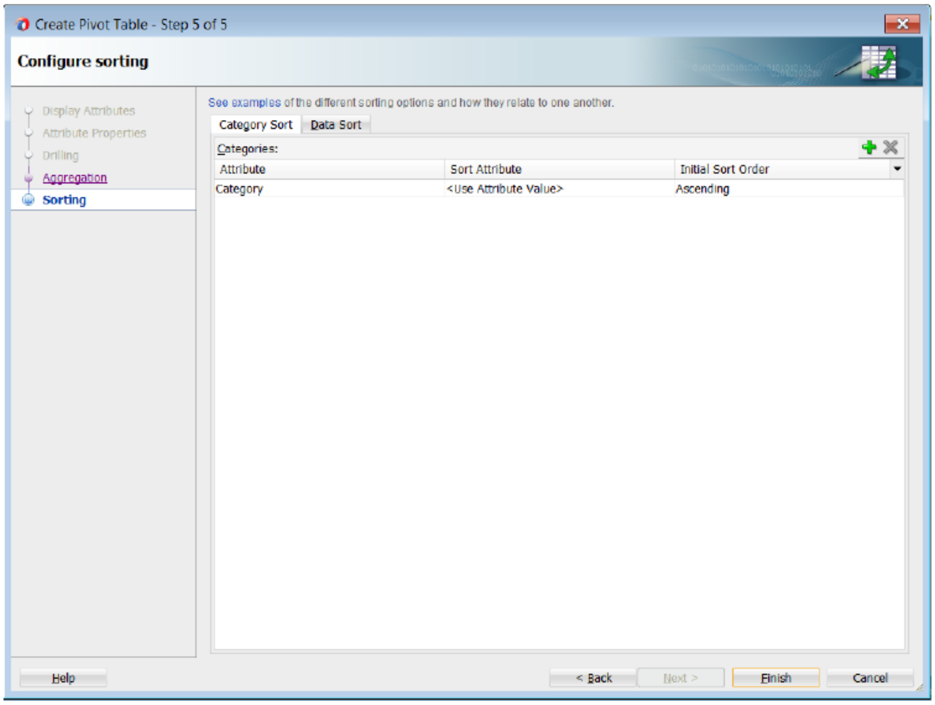
   - To configure sorting by category, in the Category Sort page, use the **Add** icon to add the attribute for each row, column, or page edge you wish to configure, and do the following:
     – In the **Sort Attribute** column, accept the default `Use Attribute Value` to specify an alphabetical sort based on the actual values in the pivot table header, or customize the sort order by specifying an alternate sort

order attribute from the dropdown list. For example, if the underlying query included a rank calculation for ranking products by profitability, you could choose to see products ordered by (ProductRank, Descending).

- In the **Initial Sort Order** column, select the initial direction of the sort. Valid values are `ASCENDING` or `DESCENDING`.

For example, Figure 40-11 shows the Category Sort page of the wizard configured to display the Category data layer ascending on the column edge.

Figure 40-11 Category Sort Page of Create Pivot Table Wizard



See examples of the different sorting options and how they relate to one another.

Categories:

Attribute	Sort Attribute	Initial Sort Order
Category	<Use Attribute Value>	Ascending

At runtime, the pivot table displays as shown in Figure 40-12.

Figure 40-12 Category Sort Example

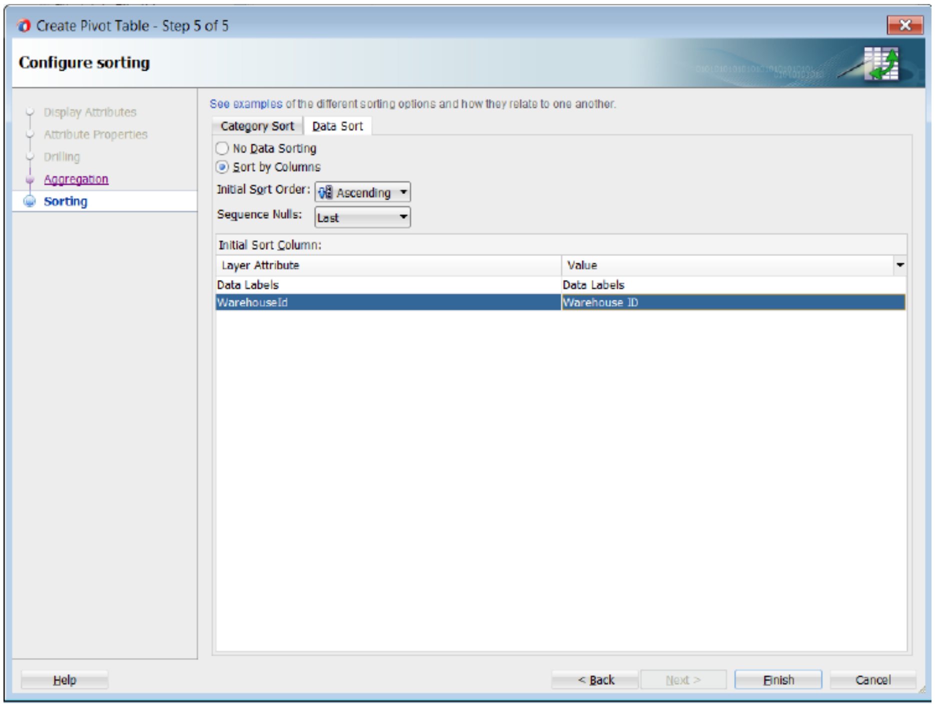
	Sales		Units	
	Indirect	Direct	Indirect	Direct
2005	12272	9250	131	87
2006	35650	18500	338	169
2007	36600	15900	333	77

- To configure data sorting, in the Data Sort page, do the following:
  - Select **Sort by Columns** to specify an initial sort order of the data when the pivot table is rendered.
  - In the **Initial Sort Order** dropdown list select the initial direction of the sort. Valid values are `ASCENDING` and `DESCENDING`.
  - In the **Sequence Nulls** dropdown list, select `First` if you want the null values to appear at the beginning of a sort and select `Last` if you want the null values to appear at the end of the sort.

– In the **Initial Sort Column** table, specify a data value in the **Value** column for each data layer displayed in the **Layer Attribute** column.

For example, Figure 40-13 shows the Data Sort page configured to sort the Channel data layer grouped by Year, based upon Units/World/Canoes data values.

Figure 40-13 Data Sort Page of the Create Pivot Table Wizard



Create Pivot Table - Step 5 of 5

Configure sorting

See examples of the different sorting options and how they relate to one another.

Category Sort | Data Sort

○ No Data Sorting
● Sort by Columns

Initial Sort Order: Ascending

Sequence Nulls: Last

Initial Sort Column:

Layer Attribute	Value
Data Labels	Data Labels
WarehouseId	Warehouse ID

At runtime, the pivot table initially renders as shown in Figure 40-14.

Figure 40-14 Data Sort Example

		Units			
		World		Boston	
		Tents	Canoes △▼	Tents	Canoes
2007	Indirect	200	75	50	8
	Direct	5	50	20	2
2006	Indirect	200	80	50	8
	Direct	100	40	25	4
2005	Direct	50	20	15	2
	Indirect	100	10	20	1

8. Click **Finish** to complete the creation of your databound pivot table.

   After completing the wizard to create the pivot table, use the tools in JDeveloper to customize the look and feel of the pivot table. For example, you can configure word wrapping for labels that do not fit into the default size of the header cell and add a page control as an alternative to scrollbars for the data set in the pivot table in Figure 40-1.

9. To customize pivot table display elements, perform the following tasks.

   a. In the Structure window, right-click the `dvt:pivotTable` node and choose **Go to Properties**.

b. In the Properties window, expand the **Common** section and set the **ScrollPolicy** property to `page` to configure a page control as an alternative to the default scrollbars.

c. In the Structure window, right-click the `dvt:headerCell` node and choose **Go to Properties**.

d. In the Properties window, expand the **Behavior** section and set the **WhiteSpace** attribute to `normal` to configure word wrapping in the pivot table headers.

For additional information about customizing a pivot table after data binding is completed, see the Using Pivot Table Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Use the Data Controls Panel to Create a Pivot Table

Dropping a pivot table from the Data Controls panel has the following effect:

- Creates the bindings for the pivot table and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

When you create a pivot table from the Data Controls panel, the page definition file is updated with the bindings. The code sample below shows the row set bindings that were generated for the pivot table that displays product sales and units sold within geography by year. The pivot table data map contains the following elements:

- `<columns>`: Defines each column item in the appropriate sequence
- `<rows>`: Defines each row item in the appropriate sequence
- `<pages>`: Defines the items to be included in the pivot filter bar
- `<aggregatedItems>`: Defines the totals and subtotals of items
- `<hierarchies>`: Defines the potential drill paths between two items
- `<sorts>`: Defines category sorts and the initial sort order of pivot table data

The default data aggregation method for duplicate rows is specified in the `<data>` element. For more information about aggregating duplicates, see What You May Need to Know About Aggregating Attributes in the Pivot Table.

For more information about sorting operations, see What You May Need to Know About Specifying an Initial Sort for a Pivot Table.

```
<pivotTable IterBinding="WorldProductInventory1Iterator"
            id="WorldProductInventory1"
            xmlns="http://xmlns.oracle.com/adfm/dvt" ChangeEventPolicy="ppr">
  <pivotTableDataMap convert="false">
    <columns>
      <data aggregateDuplicates="true" defaultAggregateType="SUM">
        <item label="${adfBundle['view.ViewControllerBundle'].AMOUNT_IN_STOCK}"
              value="AmountInStock"/>
        <item label="${adfBundle['view.ViewControllerBundle'].REORDER_POINT}"
              value="ReorderPoint"/>
      </data>
        <item value="WarehouseId"
              itemLabel="$
```

```
{adfBundle['view.ViewControllerBundle'].WAREHOUSE_ID}"/>
    </columns>
    <rows>
      <item value="Category"
            itemLabel="${adfBundle['view.ViewControllerBundle'].CATEGORY}"/>
    </rows>
    <pages>
      <item value="RegName"
            itemLabel="${adfBundle['view.ViewControllerBundle'].REGION}"/>
      <item value="Country"
            itemLabel="${adfBundle['view.ViewControllerBundle'].COUNTRY}"/>
    </pages>
    <aggregatedItems>
      <item aggregateLocation="AFTER" aggregateType="AVERAGE" value="Category"
            aggregateLabel="${adfBundle['view.ViewControllerBundle'].AVERAGE}"/>
    </aggregatedItems>
    <drills type="INSERT"/>
    <hierarchies>
      <item value="Category" location="BEFORE">
        <child value="ProdName"
               itemLabel="${adfBundle['view.ViewControllerBundle'].PRODUCT}"/>
      </item>
    </hierarchies>
    <sorts>
      <categorySort item="Category" direction="ASCENDING"/>
    </sorts>
  </pivotTableDataMap>
</pivotTable>
```

When the pivot table is created using the Data Controls panel, the necessary code is added to the page. The example below shows the code generated on the JSF page for the sales pivot table and associated pivot filter bar.

```
<dvt:pivotFilterBar id="pfb1"

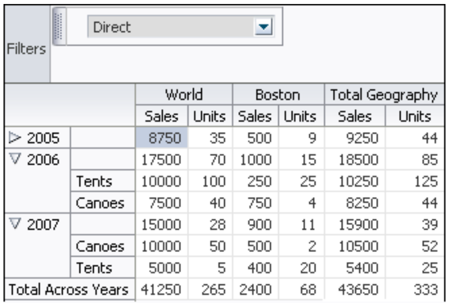
value="#{bindings.WorldProductInventory1.pivotFilterBarModel}"
                    modelName="pt1Model"/>
<dvt:pivotTable id="pt1"
                value="#{bindings.WorldProductInventory1.pivotTableModel}"
                modelName="pt1Model"
                var="cellData" varStatus="cellStatus"
                summary="#{viewcontrollerBundle.WorldProductInventoryPivotTable}"
                scrollPolicy="page">
  <dvt:headerCell whiteSpace="normal">
    <af:switcher facetName="#{cellData.layerName}" defaultFacet="Default"
id="s1">
      <f:facet name="DataLayer">
        <af:outputText value="#{cellData.label}" id="ot1"/>
      </f:facet>
      <f:facet name="WarehouseId">
        <af:outputText value="#{cellData.dataValue}" id="ot2">
          <af:convertNumber groupingUsed="false"
                            pattern="#{bindings.WorldProductInventory1.
                                     hints.WarehouseId.format}"/>
        </af:outputText>
      </f:facet>
      <f:facet name="Category">
        <af:outputText value="#{cellData.dataValue}" id="ot3"/>
      </f:facet>
      <f:facet name="ProdName">
        <af:outputText value="#{cellData.dataValue}" id="ot4"/>
      </f:facet>
      <f:facet name="RegName">
        <af:outputText value="#{cellData.dataValue}" id="ot5"/>
      </f:facet>
      <f:facet name="Country">
        <af:outputText value="#{cellData.dataValue}" id="ot6"/>
      </f:facet>
      <f:facet name="Default">
        <af:outputText value="#{cellData.dataValue}" id="ot7"/>
      </f:facet>
    </af:switcher>
  </dvt:headerCell>
  <dvt:dataCell>
    <af:switcher facetName="#{cellStatus.members.DataLayer.value}"
                 defaultFacet="Default" id="s2">
      <f:facet name="AmountInStock">
        <af:outputText value="#{cellData.dataValue}" id="ot8">
          <af:convertNumber groupingUsed="false"
                            pattern="#{bindings.WorldProductInventory1.
                                     hints.AmountInStock.format}"/>
        </af:outputText>
      </f:facet>
      <f:facet name="ReorderPoint">
        <af:outputText value="#{cellData.dataValue}" id="ot9">
          <af:convertNumber groupingUsed="false"
                            pattern="#{bindings.WorldProductInventory1.
                                    hints.ReorderPoint.format}"/>
        </af:outputText>
      </f:facet>
      <f:facet name="Default">
        <af:outputText value="#{cellData.dataValue}" id="ot10"/>
      </f:facet>
    </af:switcher>
  </dvt:dataCell>
</dvt:pivotTable
```

What You May Need to Know About Aggregating Attributes in the Pivot Table

If the attributes that you choose to display in your pivot table do not uniquely identify each row in your data collection, then you can aggregate the data from duplicate rows to collapse that data into a single pivot table cell.

For example, if the rows in the data collection shown in Figure 40-15 also contained a store identification, then the data rows from all stores in a given combination of Product, Channel, and Geography would have to be collapsed into a single cell in the pivot table.

Figure 40-15   Sales Pivot Table



Filters: Direct ▾

		World		Boston		Total Geography	
		Sales	Units	Sales	Units	Sales	Units
▷ 2005		8750	35	500	9	9250	44
▽ 2006		17500	70	1000	15	18500	85
	Tents	10000	100	250	25	10250	125
	Canoes	7500	40	750	4	8250	44
▽ 2007		15000	28	900	11	15900	39
	Canoes	10000	50	500	2	10500	52
	Tents	5000	5	400	20	5400	25
Total Across Years		41250	265	2400	68	43650	333

The pivot table has the following optional data binding attributes available for controlling the calculation of duplicate data rows:

- `aggregateDuplicates`: Boolean property of the `<data>` element that determines whether special processing is enabled at binding runtime to aggregate data values in duplicate rows. If this attribute is not specified, then `false` is assumed.
- `defaultAggregateType`: String property of the `<data>` element that specifies a default aggregation method for handling duplicates. Valid values are `SUM`, `AVERAGE`, `COUNT`, `MIN`, `MAX`, `STDDEV`, `MEDIAN`, `VARIANCE`. If `aggregateDuplicates` is `true` and `defaultAggregateType` is unspecified, then `SUM` is assumed.
- `aggregateType`: String property of an `<item>` element that enables you to override the default aggregate type for a particular data item. This attribute is useful only when you have multiple data values (such as Sales and Units) bound to your pivot table.

Default Aggregation of Duplicate Data Rows

By default, the pivot table uses the SUM operation to aggregate the data values of duplicate data rows in a data collection to produce a single cell value in the pivot table. This means that the `aggregateDuplicates` attribute is set to `true` and the `defaultAggregateType` is assumed to be `SUM`.

The `<data>` element shown in the example below is an example of such default aggregation.

```
<pivotTable IterBinding="ptExampleDataIterator" id="ptExampleData"
            xmlns="http://xmlns.oracle.com/adfm/dvt"
            ChangeEventPolicy="ppr">
  <pivotTableDataMap>
    <columns>
      <item value="Geography" itemLabel="Location"/>
        <data aggregateDuplicates="true" defaultAggregateType="SUM">
          <item value="Sales"/>
          <item value="Units" aggregateType="AVERAGE"/>
        </data>
    </columns>
    <rows>
      <item value="Year"/>
    </rows>
    <pages>
      <item value="Channel"/>
    </pages>
    <aggregatedItems>
```

```
      <item aggregateLocation="AFTER" aggregateType="SUM" value="Geography"
            aggregateLabel="Total Geography"/>
      <item aggregateLocation="AFTER" aggregateType="SUM" value="Year"
            aggregateLabel="Total Across Years"/>
    </aggregatedItems>
    <drills type="INSERT"/>
    <hierarchies>
      <item value="Year" location="BEFORE">
        <child value="Product" label="Product"/>
      </item>
    </hierarchies>
    <sorts>
      <categorySort item="Channel" direction="DESCENDING"/>
      <categorySort item="Year" direction="ASCENDING"/>
      <qdrSliceSort direction="DESCENDING" edge="rows" grouped="true"
                    nullsFirst="true">
        <item name="Geography" value="World"/>
      </qdrSliceSort>
    </sorts>
  </pivotTableDataMap>
</pivotTable>
```

Custom Aggregation of Duplicate Rows

If you want the pivot table to use a different mathematical operation to aggregate the data values of duplicate rows, then you set the defaultAggregateType to the desired operation.

The example below shows a data element with the defaultAggregateType set to SUM. This operation would be appropriate if you want to see the total of sales from all stores for each unique combination of Product, Channel, and State.

```
<pivotTable IterBinding="SalesPivotTable1Iterator" id="SalesPivotTable11"
            xmlns="http://xmlns.oracle.com/adfm/dvt">
  <pivotTableDataMap>
    <columns>
      <data aggregateDuplicates="true" defaultAggregateType="SUM">
        <item value="Sales"/>
      </data>
      <item value="Geography"/>
    </columns>
    <rows>
      <item value="Channel"/>
      <item value="Product"/>
    </rows>
    <aggregatedItems>
      <item aggregateLocation="After" aggregateType="AVERAGE"
            value="Product" aggregateLabel="Average"/>
    </aggregatedItems>
  </pivotTableDataMap>
</pivotTable>
```

If you have a pivot table with multiple data values (such as sales and the average size of a store in square feet) and you want to sum the sales data values in duplicate rows, but you want to average the square feet data values, then do the following:

- On the <data> element, set the defaultAggregateType to SUM.
- On the <item> element for the square feet attribute, set the aggregateType to AVERAGE.

The example below shows the <columns> elements wrapped by a PivotTableDataMap element. The <data> element contains the default attributes for aggregation. These apply to all data items that do not have a specific custom aggregateType attribute specified.

```
<columns>
   <data aggregateDuplicates="true" defaultAggregateType="SUM">
     <item value="Sales" label="Total Sales"/>
     <item value="StoreSqFeet" label="Avg Sq Feet" aggregateType="AVERAGE"/>
   </data>
   <item value="State"/>
</columns>
```

What You May Need to Know About Specifying an Initial Sort for a Pivot Table

By default, a pivot table initially sorts data based on values in the outer row data layer. You can specify sort order on the data layer of any row, column, or page item, called a category sort. At runtime, when the data layer is pivoted to a different edge, the specified category sort order is honored. Insert a categorySort element inside the sorts element and set values for the attributes as described in Table 40-1.

Table 40-1 Attribute Values for categorySort Element

Attribute	Description
item	Specify the column, row, or page item for which you are setting the category sort. A value for this attribute is required.
direction	Specify the initial direction of the sort. Valid values are ASCENDING and DESCENDING. A value for this attribute is required.

You can also specify the initial sort order of the data values in the data body when the pivot table is rendered, called a data sort. You can change the default behavior by inserting a sorts element inside the pivotTableDataMap element of a pivot table binding in the page definition file. Insert a qdrSliceSort element inside the sorts element and set values for the attributes as described in Table 40-2.

Table 40-2 Attribute Values for qdrSliceSort Element

Attribute	Description
direction	Specify the initial direction of the sort. Valid values are ASCENDING and DESCENDING. A value for this attribute is required.
edge	Specify columns or rows to determine which edge sorts data. A value for this attribute is required.
grouped	Specify true if you want to sort slices within their parent or false if you want to sort across the entire edge. A value for this attribute is optional. The default value is false.
nullsFirst	Specify true if you want null values to appear at the beginning of a sort and false if you want null values to appear at the end of a sort. The default value is false. A value for this attribute is optional.

Insert one or more `item` tags inside the `qdrSliceSort` tag. An item tag specifies the slice on the opposite edge from which the values to be sorted should be obtained. For example, if sorting rows based upon the data, then you must specify an item tag for each layer on the column edge. Set values for the attributes as described in Table 40-3.

Table 40-3   Attribute Values for item Tag

Attribute	Description
`name`	Specify the name of the layer to sort on. Typically, this is the column name in the row set. Specify `DataLayer` to identify the layer that contains the data columns in a row set (for example, Sales, Costs, and so on).
`value`	Specify the value of the specified layer on the desired slice.

What You May Need to Know About Configuring Editable Data Cells

By default, the data cells in a pivot table are not editable. When you create a pivot table using ADF data controls, an `af:outputText` component is automatically stamped for each data cell. You can also use the Create Pivot Table wizard to configure a data cell as editable by specifying an `af:inputText` component and the tag and its corresponding `f:validator` tag will be stamped in the data cell as illustrated in the example below.

```
<dvt:dataCell>
  <af:switcher facetName="#{cellStatus.members.DataLayer.value}"
           defaultFacet="Default" id="s2">
    <f:facet name="AmountInStock">
      <af:inputText value="#{cellData.dataValue}"
                    label="#{bindings.WorldProductInventory1.hints.
                          AmountInStock.label}"
                    required="#{bindings.WorldProductInventory1.hints.
                          AmountInStock.mandatory}"
                    columns="#{bindings.WorldProductInventory1.hints.
                          AmountInStock.displayWidth}"
                    maximumLength="#{bindings.WorldProductInventory1.hints.
                          AmountInStock.precision}"
                    shortDesc="#{bindings.WorldProductInventory1.hints.
                          AmountInStock.tooltip}"
                    id="it1">
        <f:validator binding="#{cellData.bindings.AmountInStock.validator}"/>
      </af:inputText>
    </f:facet>
    <f:facet name="ReorderPoint">
      <af:outputText value="#{cellData.dataValue}" id="ot8">
        <af:convertNumber groupingUsed="false"
                          pattern="#{bindings.WorldProductInventory1.hints.
                                   ReorderPoint.format}"/>
      </af:outputText>
    </f:facet>
    <f:facet name="Default">
      <af:outputText value="#{cellData.dataValue}" id="ot10"/>
    </f:facet>
  </af:switcher>
</dvt:dataCell>

<dvt:dataCell>
  <af:switcher facetName="#{cellStatus.members.DataLayer.value}"
```

```
               defaultFacet="Default" id="s2">
    <f:facet name="Sal">
      <af:inputText value="#{cellData.dataValue}" id="ot5"
                    label="#{bindings.EmpView1.hints.Sal.label}"
                    required="#{bindings.EmpView1.hints.Sal.mandatory}"
                    columns="#{bindings.EmpView1.hints.Sal.displayWidth}"
                    maximumLength="#{bindings.EmpView1.hints.Sal.precision}"
                    shortDesc="#{bindings.EmpView1.hints.Sal.tooltip}">
      <f:validator binding="#{cellData.bindings.Sal.validator}"/>
    </af:inputText>
  </f:facet>
  <f:facet name="Default">
    <af:inputText value="#{cellData.dataValue}" id="ot6"/>
  </f:facet>
    </af:switcher>
</dvt:dataCell>
```

You can also configure pivot table data cells to use most components that implement the `EditableValueHolder` or `ActionSource` interfaces as a child of the `dataCell` component, for example, `af:selectBooleanCheckbox` or `af:inputComboboxListofValues`. For more information, see the How to Configure Header and Data Cell Stamps section in the *Developing Web User Interfaces with Oracle ADF Faces*.

41
Creating Databound Geographic and Thematic Map Components

This chapter describes how to create geographic or thematic maps from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization `map` and `thematicMap` components to create geographic or thematic maps that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.
If you are designing your page using simple UI-first development, then you can add the geographic or thematic map to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the map components, see the Using Map Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

This chapter includes the following sections:

- About ADF Data Visualization Map Components
- Creating Databound Geographic Maps
- Creating Databound Thematic Maps

About ADF Data Visualization Map Components

The DVT Geographic Map and Thematic Map components allow users to present business data on a map. This is useful to represent patterns, trends, and comparative data within a region of interest.

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

The geographic map component represents business data spatially, enabling you to superimpose multiple layers, also referred to as themes, of information on a single map. For example, a map of the United States might use a color theme that provides varying color intensity to indicate the popularity of a product within each state, a pie chart theme that shows sales within product category, and a point theme that identifies the exact location of each warehouse. When all three themes are superimposed on the United States map, you can easily evaluate whether there is sufficient inventory to support the popularity level of a product in specific locations. Geographic maps require a connection to an Oracle MapViewer service, and optionally, a geocoder service to display geographical and political detail.

Thematic map components represents business data as patterns in stylized areas or associated markers and does not require a connection to an Oracle MapViewer service. Thematic maps focus on data without the geographic details in a geographic map. The thematic map is packaged with prebuilt base maps including a USA base map, a world base map, and base maps for continents and regions of the world including EMEA and APAC. Each base map includes several sets of regions and one fixed set of cities. A set of regions or cities is referred to as a layer. Each layer can be bound to a data collection and stylized to represent the data with color and pattern fills, or a data marker, or both. At runtime, only one map layer and its associated data can be displayed at a time, unless the thematic map has been enabled for drilling.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

Use Cases and Examples

For detailed descriptions of each data visualization use cases and examples, see the Map Component Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.

End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the End User and Presentation Features of Maps section in *Developing Web User Interfaces with Oracle ADF Faces*.

Additional Functionality for Data Visualization Components

You may find it helpful to understand other **Oracle ADF** features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the Rerendering Partial Page Content chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the Allowing User Customization on JSF Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: By default, data visualization components are accessible. You con configure your application pages for accessibility to screen readers. For more information, see the Developing Accessible ADF Faces Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls.

Creating Databound Geographic Maps

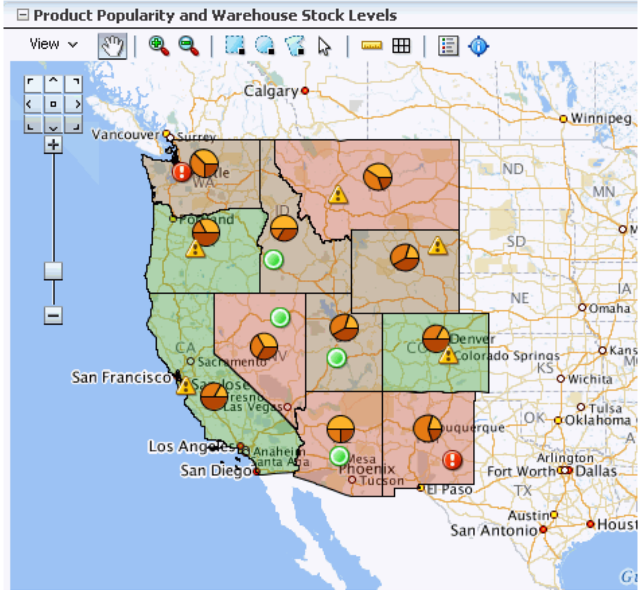
A geographic map is an ADF Data Visualization component that provides the functionality of Oracle Spatial within Oracle ADF. This component allows users to represent business data on a geographic map and to superimpose multiple layers of information (known as themes) on a single map.

These layers can be represented as any of the following themes: bar graph, pie graph, color, point, and predefined theme.

Figure 41-1 shows a geographic map component that uses a base map for a region in the United States with the following themes:

- Color theme: For the selected product, this theme colors states based on product popularity. The colors range from green, representing the highest popularity for that product, to red, representing the lowest popularity for that product.
- Pie graph theme: This theme displays a pie graph in each state to indicate the popular product categories in that state. In this example, the pie graph shows the product categories as pie slices for Media, Office, and Electronics.
- Point theme: This theme identifies warehouses as points. For each point, it displays an icon to indicate the inventory level at that warehouse for the selected product. A separate icon is displayed for each of the following ranges of inventory: low inventory, medium inventory, and high inventory.

Figure 41-1   Geographic Map with Color Theme, Pie Graph Theme, and Point Theme



A geographic map component differs from other ADF Data Visualization components as you do not need to put multiple maps on a page to display multiple sets of data. This contrasts to components such as graphs where you can put multiple graphs on a page. Instead, you show how multiple sets of data relate to each other spatially or, for a specific point, you display different attributes layered in separate themes.

The geographic map component itself is not bound to data. However, each map theme has its own data bindings.

A base map forms the background on which the ADF geographic map component layers the themes that developers create.

In Oracle Spatial, administrators create base maps that consist of one or more themes. The administrator controls the visibility of the base map themes. When you zoom in and out on a base map, various base map themes are hidden or displayed. At the ADF geographic map component level, you cannot use zoom factor to control the display of the themes created by the administrator on the base map.

When you overlay themes on the ADF geographic map, you can control the visibility of your themes by setting the `maxZoom` and `minZoom` properties of the components related to these themes. At runtime, you can also hide or display your custom themes by using the View menu of the Map toolbar or by using other ADF components that you create on the page.

For information about customizing a geographic map after data-binding is completed, see the Using Map Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Configure a Geographic Base Map

To create a geographic map, you first configure the map before you bind a point, pie or bar graph, or color theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel for the theme you want to create.

Before you begin:

It may be helpful to have an understanding of databound geographic maps. For more information, see Creating Databound Geographic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an **application module** that contains instances of the **view objects** that you want in your data model for the pivot table, as described in Creating and Modifying an Application Module.

  For example, the data source for Product Inventory pivot table shown in Figure 41-1 comes from a view object created for the Summit sample application for ADF DVT components.

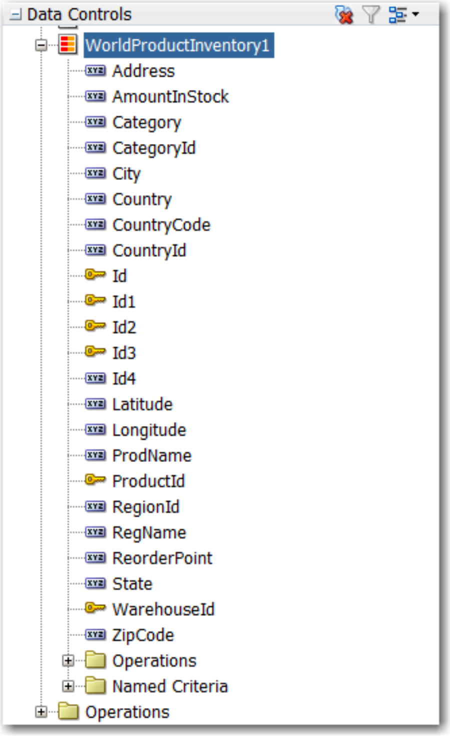
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To configure a geographic base map:

1. From the Data Controls panel, select a collection.

For example, to create a geographic map that displays product inventory levels in warehouses throughout the World, you could select the `WorldProductInventory1` collection in the Data Controls panel, as shown in Figure 41-2.

Figure 41-2 Data Collection for Product Inventory Levels



Data Controls

- WorldProductInventory1
  - Address
  - AmountInStock
  - Category
  - CategoryId
  - City
  - Country
  - CountryCode
  - CountryId
  - Id
  - Id1
  - Id2
  - Id3
  - Id4
  - Latitude
  - Longitude
  - ProdName
  - ProductId
  - RegionId
  - RegName
  - ReorderPoint
  - State
  - WarehouseId
  - ZipCode
  - Operations
  - Named Criteria
- Operations

2. Drag the data collection onto a JSF page and, from the context menu, choose **Geographic Map** > **Map and Point, Pie Graph, Color, or Bar Graph Theme**.

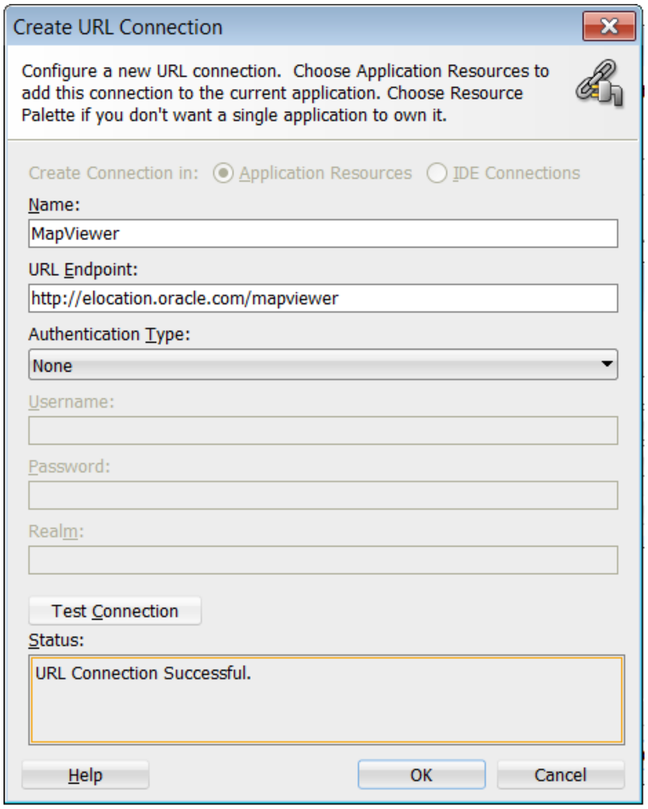
3. If you have not yet configured a map on the page, in the Create Geographic Map dialog, click the **New** icon to display the Create Geographic Map Configuration dialog and do the following:

   a. In the **Id** field enter the unique identifier for the map configuration. For example, `mapConfig1`.

   b. In the **MapViewer URL** field enter the URL for the Oracle MapViewer service.

      Use the dropdown list to select an existing connection, or click the Add icon to configure a new connection. In the Create URL Connection dialog use the address `http://elocation.oracle.com/mapviewer` for the URL endpoint and click **Test Connection** to confirm the connection. Figure 41-3 shows the completed Create URL dialog.

Figure 41-3 Create Map Viewer URL Connection



Create URL Connection

Configure a new URL connection. Choose Application Resources to add this connection to the current application. Choose Resource Palette if you don't want a single application to own it.

Create Connection in: ● Application Resources ○ IDE Connections

Name: MapViewer

URL Endpoint: http://elocation.oracle.com/mapviewer

Authentication Type: None

Username:

Password:

Realm:

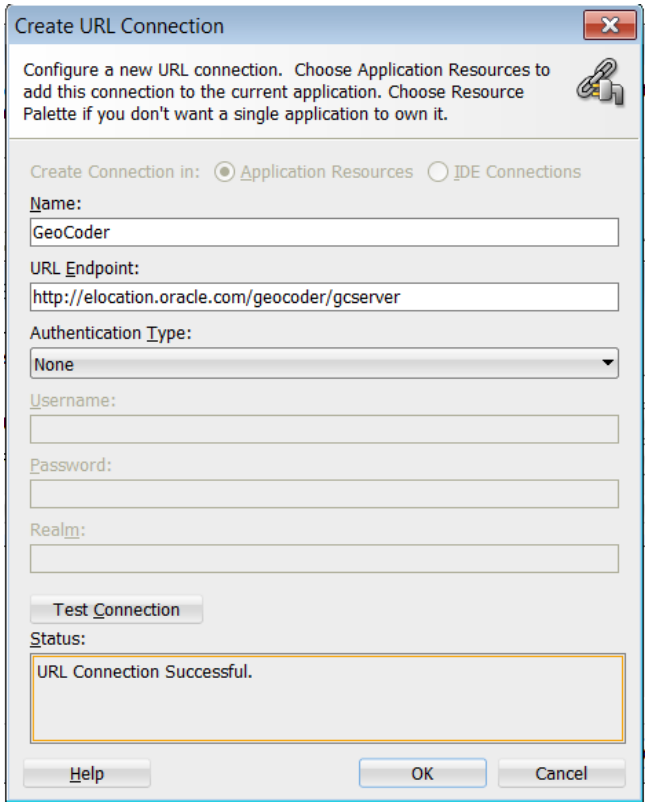
Status: URL Connection Successful.

c. In the **Geocoder URL** field enter the URL for the Geocoder web service that converts street addresses into latitude and longitude coordinates for mapping.

> **Note:**
>
> The Geocoder URL is needed only if you do *not* already have longitude and latitude information for addresses.

Use the dropdown list to select an existing connection, or click the Add icon to configure a new connection. In the Create URL Connection dialog use the address `http://elocation.oracle.com/geocoder/gcserver` for the URL endpoint and click **Test Connection** to confirm the connection. Figure 41-4 shows the completed Create URL dialog.

Figure 41-4 Create Geocoder URL Connection



Create URL Connection

Configure a new URL connection. Choose Application Resources to add this connection to the current application. Choose Resource Palette if you don't want a single application to own it.

Create Connection in: ● Application Resources ○ IDE Connections

Name: GeoCoder

URL Endpoint: http://elocation.oracle.com/geocoder/gcserver

Authentication Type: None

Username:

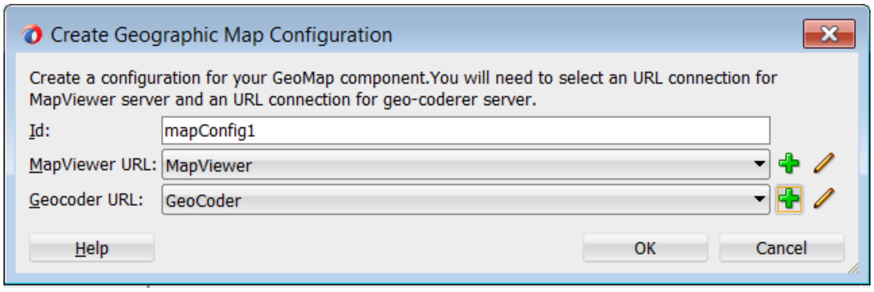
Password:

Realm:

Status: URL Connection Successful.

d. Click **OK**. Figure 41-5 shows the completed Create Geographic Map Configuration dialog.

Figure 41-5 Create Geographic Map Configuration Dialog



Create Geographic Map Configuration

Create a configuration for your GeoMap component.You will need to select an URL connection for MapViewer server and an URL connection for geo-coderer server.

Id: mapConfig1

MapViewer URL: MapViewer

Geocoder URL: GeoCoder

4. Click **OK**.

5. In the Create Geographic Map dialog, select the base map for the geographic map component and provide other settings to use with the map by doing the following:

   a. From the **Data Source** list select the collection of maps from which you will choose a base map.

   b. From the **Base Map** list select the map that will serve as the background for the geographic map component.

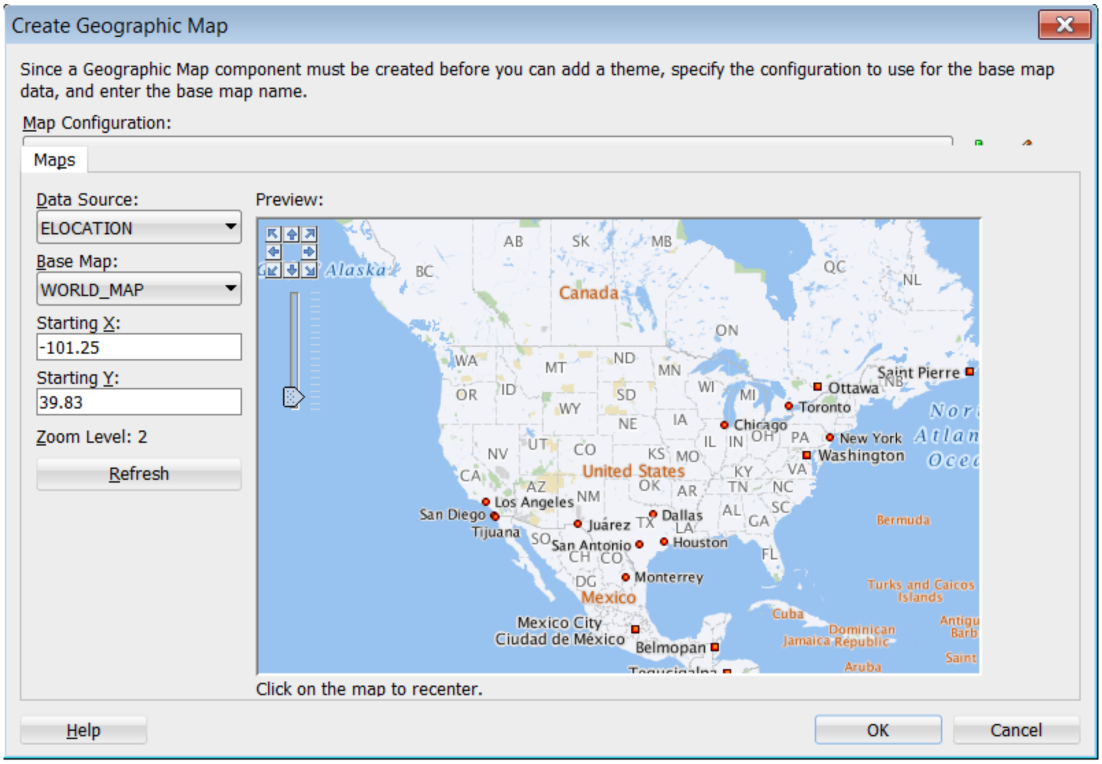
   c. To specify values for the **StartingX** field and the **StartingY** field click on the image of the map to center it within the Preview window.

You can use the arrows in the map navigator in the upper left-hand corner to move the map in the appropriate direction.

d. Optionally use the sliding arrow in the Preview window to adjust the zoom factor of the map.

e. Click **OK.** Figure 41-5 shows the completed Create Geographic Map dialog.

Figure 41-6 Create Geographic Map Dialog



Create Geographic Map

Since a Geographic Map component must be created before you can add a theme, specify the configuration to use for the base map data, and enter the base map name.

Map Configuration:

Maps

Data Source: ELOCATION

Base Map: WORLD_MAP

Starting X: -101.25

Starting Y: 39.83

Zoom Level: 2

Preview:

Click on the map to recenter.

6. Use the Create Theme dialog to data bind a map theme as follows:

   - Create a point theme to represent data on the base map. For more information, see How to Create a Geographic Map with a Point Theme.
   - Create a color theme to represent data on the base map. For more information, see How to Create a Geographic Map with a Color Theme.
   - Create a pie or bar graph theme to represent data on the base map. For more information, see How to Create a Geographic Map with a Pie or Bar Graph Theme.

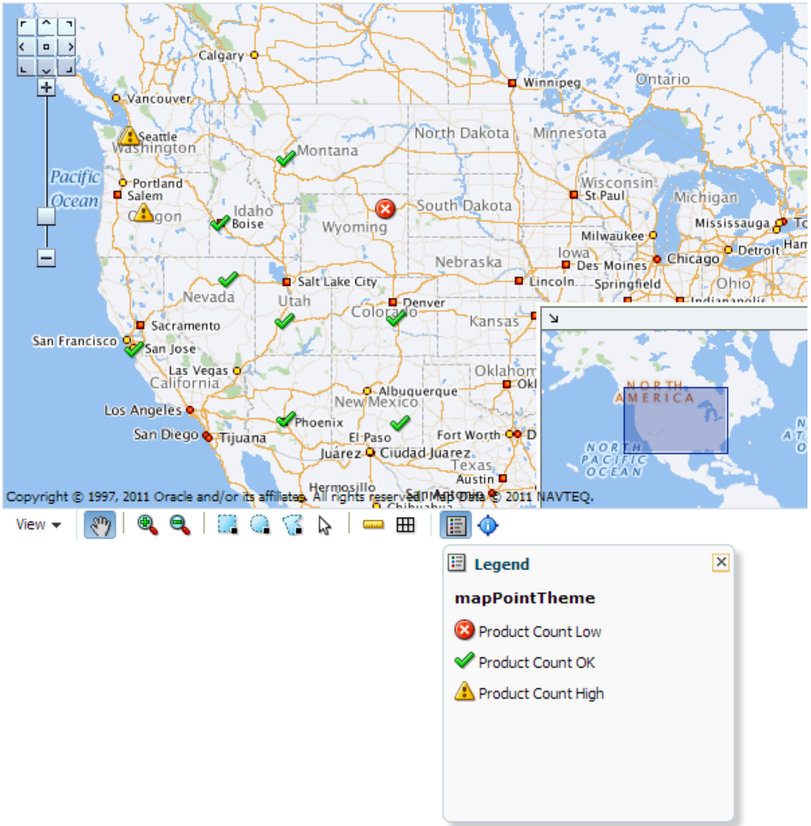
How to Create a Geographic Map with a Point Theme

You can create a geographic map with a point theme to display specific locations in a map, identified by latitude and longitude or address. For example, a point theme might identify the locations of warehouses in a map. If you customize the style of the point that is displayed, you could choose to use a different image for a warehouse product count (high, acceptable, low) in a set of warehouses to differentiate them from each other.

To create a geographic map with a point theme, you first configure the base map and then bind a point theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel. You can also layer a point theme on a base map that has already been configured and bound to another theme.

For example, the geographic map in Figure 41-7 has a point theme that identifies the location of warehouses and their product count levels in the United States.

Figure 41-7 Geographic Map with Point Theme



Before you begin:

It may be helpful to have an understanding of databound geographic maps. For more information, see Creating Databound Geographic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the geographic map with point theme, as described in Creating and Modifying an Application Module.

  For example, the data source for the geographic map point theme shown in Figure 41-7 comes from a view object created for the Summit ADF DVT sample application.

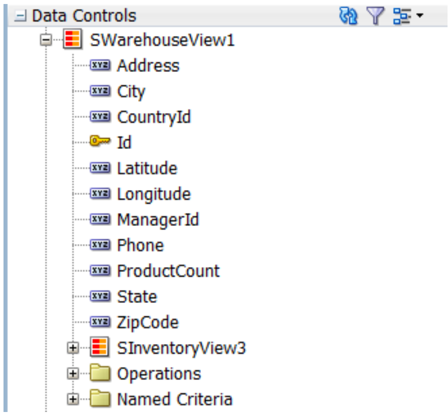
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a geographic map with a databound point theme:

1. From the Data Controls panel, select a collection.

   Figure 41-8 shows an example where you could select the `SWarehouseView1` collection in the Data Controls panel to create a geographic map with a point theme that displays an image to identify the location of each warehouse, styled to represent the product count level.

   Figure 41-8 Data Collection for Warehouse Location and Product Count



Data Controls
SWarehouseView1
Address
City
CountryId
Id
Latitude
Longitude
ManagerId
Phone
ProductCount
State
ZipCode
SInventoryView3
Operations
Named Criteria

2. Drag the collection onto a JSF page and, from the context menu, choose **Geographic Map** > **Map and Point Theme**.
3. If you have not yet configured a map on the page, complete the Create Geographic Map dialog. For more information, see How to Configure a Geographic Base Map. Otherwise, do one of the following:
   - Use the dropdown list to select the map configuration you wish to use
   - Click **OK** to accept the available map configuration
   - Click **New** to configure a new base map
   - Click **Edit** to modify the available map configuration
4. If you are layering a point theme on a base map that has already been configured and bound to another theme, in the Create dialog select Point Theme.
5. In the Create Point Map Theme dialog, in the **Theme Id** field, enter the unique identifier for the point map theme.
6. In the **Location** section, choose whether the point location is to be specified by **Address** or by a pair of *x* and *y* coordinates (Longitude and Latitude).

   The choice you select for location will determine which controls appear in the Location section.

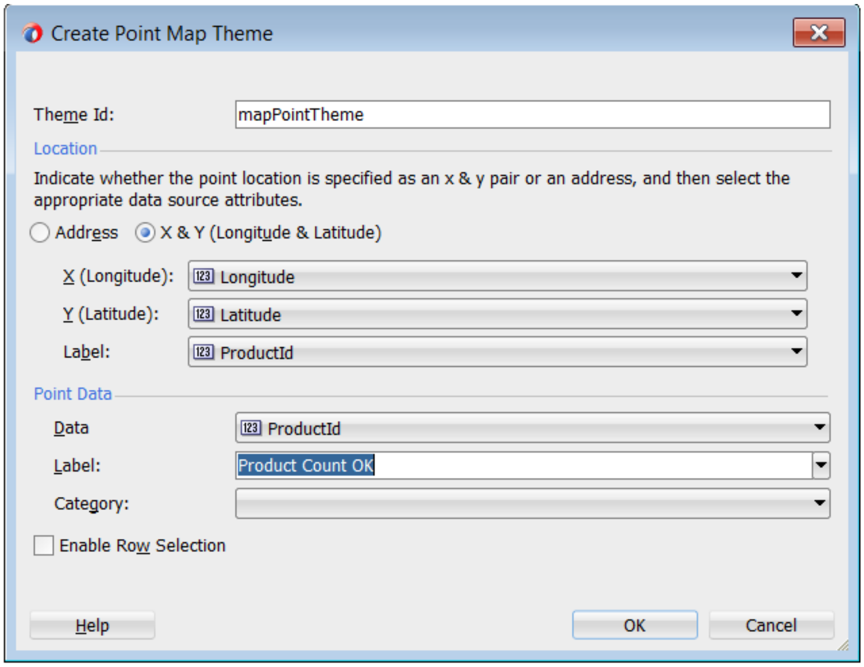
> **Tip:**
>
> Using *x* and *y* coordinates is a more efficient way to present data on the map rather than using the Address controls, which must be converted by a Geocoder to *x* and *y* coordinates. If the data collection has more than 100 rows, use *x* and *y* coordinates for better performance.

7. For the *x* and *y* point location, select attributes from the data collection that represents the following items:
   - X (Longitude): The horizontal location of the point on the map.
   - Y (Latitude): The vertical location of the point on the map.
   - Label: The labels for the points in the top section of the information window, which is displayed when you click a point.
8. In the Point Data section, provide the following information that identifies the data associated with the point, its label, and optionally the style for the point:
   - In the **Data** field, select the data column that is associated with the point, such as `ProductCount`.
   - In the **Label** field, enter the text that will appear in the information window before the data value when you click a point. You can enter a text resource to use for the label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.
   - Optionally, in the **Category** field, select a data column to use for finding the appropriate style for a point. If you select a value for Category, that value is stored in the binding for this point theme and then matched against the `itemValue` attribute of the `mapPointStyleItem` tags that you create for this point theme.

     > **Note:**
     >
     > If your data does not have a column that you want to use as a category for finding the style of a point, you can also use `mapPointStyleItem` tags to define styles related to data ranges (such as high, acceptable, and low) that are matched to the values in the column that you select in the Data field. For more information, see How to Create Point Style Items for a Point Theme.
9. Select the **Enable Row Selection** Select if you want to enable master-detail relationships. This is useful when the data collection for the geographic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. Selecting this options enables both `selectionListenter` and `clickListener` attributes.
10. Click **OK**.

Figure 41-9 shows the completed Create Point Map Theme dialog for a geographic map with a point theme that displays an image representing the location and product count levels for each warehouse point.

Figure 41-9 Create Point Map Theme Dialog for Warehouse Product Counts



Create Point Map Theme

Indicate whether the point location is specified as an x & y pair or an address, and then select the appropriate data source attributes.

○ Address ● X & Y (Longitude & Latitude)

X (Longitude): Longitude

Y (Latitude): Latitude

Label: ProductId

Point Data

Data: ProductId

Label: Product Count OK

Category:

□ Enable Row Selection

After you create a map point theme, you can further customize the style of the points that appear in the map to represent more detailed information. For example, the map point theme in Figure 41-7 uses a different image to represent the levels (high, acceptable, low) for the product count in each warehouse. For each different point style, use a `mapPointStyleItem` tag. For more information, see How to Create Point Style Items for a Point Theme.

How to Create Point Style Items for a Point Theme

There are a variety of options available for creating point style items for use in a given map point theme. These are:

- A single image for all data points
- Separate images for each data point category
- Images that represent low, medium, and high data value ranges

After you create the data binding for a map point theme, you have the option of selecting a single built-in image that should be used for all points in that map theme. In the Properties window, you can make this selection in the `builtInImage` attribute of the `mapPointTheme` tag. The default value for this attribute is an orange ball.

Alternatively, if you specify a value for Category in the Create Point Map Theme dialog, then you should also create a set of point style items to determine a separate image that represents data points in each category. In this case, you do not use the minimum and maximum values in the point style item tags. Instead, you set the `itemValue` attribute of point style item tags to a value that matches entries in the data column that you specified for Category.

In a point theme for a geographic map, if you do not specify a value for Category, you can still use the `mapPointStyleItem` child tags of the `mapPointTheme` tag to specify ranges of values (such as low, medium, and high) and the images that are to represent these ranges. If you do this, then each point will be represented by an image that identifies the range in which the data value for that point falls.

Before you begin:

It may be helpful to have an understanding of databound geographic maps. For more information, see Creating Databound Geographic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the geographic map with point theme, as described in Creating and Modifying an Application Module.

  For example, the data source for the geographic map point theme shown in Figure 41-7 comes from a view object created for the Summit ADF DVT sample application.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
- Add a geographic map with a point theme to your page. For more information, see How to Create a Geographic Map with a Point Theme.

To add point style items to a map point theme to represent data value ranges:

1. In the Structure window, right-click the **dvt:mapPointTheme** tag and choose **Insert inside the Point Theme** > **Point Style Item**.
2. In the Point Style Item Properties window, set values as described Table 41-1.

Table 41-1 Properties for Point Style Item

For this property	Set this value
`Id`	Specify a unique ID for the point style item.
`MinValue`	Specify the minimum value in a data range that you define.
`MaxValue`	Specify the maximum value in a data range that you define.
`ShortLabel`	Specify text to appear when a user hovers over the point item. For example, if you define a point item for low inventory, then enter `Low Inventory` as the value for this property.
`ImageURL`	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears on the map to represent the data range identified by the **MinValue** and **MaxValue** properties. Alternatively, you can select one of a number of predefined images referenced by the **BuiltInImage** dropdown list that appears in the **Other** section.
`HoverImageURL`	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears when a user hovers over the point item.

Table 41-1 (Cont.) Properties for Point Style Item

For this property	Set this value
`SelectedImageURL`	Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears when a user selects the point item.

3. If you defined a data value range for a low data value range in Steps 1 and 2, then repeat Steps 1 and 2 to define medium and high data value ranges with appropriate values.

> **Note:**
>
> The use of `mapPointStyleItem` child tags to customize the style of points is a declarative approach that lets you provide custom point images. For information about using a callback to provide not only custom images but also custom HTML, see What You May Need to Know About Adding Custom Point Style Items to a Map Point Theme.

What Happens When You Create a Geographic Map with a Point Theme

Creating a geographic map with a point theme from the Data Controls panel has the following effect:

- Creates the bindings for the point theme and adds the bindings to the page definition file
- Adds the necessary tags to the JSF page for the geographic map component
- Adds the necessary point theme child tags within the geographic map tag to the JSF page

The example below shows the row set bindings that were generated for the geographic map with a point theme.

```
<bindings>
    <mapTheme xmlns="http://xmlns.oracle.com/adfm/dvt"></mapTheme>
    <mapTheme IterBinding="WorldProductInventory1Iterator"
              id="WorldProductInventory1"
              xmlns="http://xmlns.oracle.com/adfm/dvt">
      <mapThemeDataMap convert="false" mapThemeType="point">
        <data>
          <item value="AmountInStock"
                label="${adfBundle['view.ViewControllerBundle'].AMOUNT_IN_
                       STOCK}"/>
        </data>
        <item type="us_form_2" street="Address" city="City" state="State"
                   zipCode="ZipCode" label="WarehouseId"/>
      </mapThemeDataMap>
    </mapTheme>
    <mapTheme IterBinding="SWarehouseView1Iterator" id="SWarehouseView1"
              xmlns="http://xmlns.oracle.com/adfm/dvt">
      <mapThemeDataMap convert="false" mapThemeType="point">
        <data>
```

```
          <item value="ProductCount"
                label="${adfBundle['view.ViewControllerBundle'].PRODUCT_COUNT}"/>
        </data>
        <item type="lat_long" longitude="Longitude" latitude="Latitude"
              label="ProductCount"/>
      </mapThemeDataMap>
    </mapTheme>
  </bindings>
```

The example below shows the XML code generated on the JSF page for the geographic map and its point theme.

```
<dvt:map id="map" startingX="-104.15" mapServerConfigId="mapConfig1"
            baseMapName="ELOCATION.WORLD_MAP" mapZoom="3"
         inlineStyle="width:600px; height:375px;" startingY="42.09">
  <dvt:mapPointTheme id="mapPointTheme"
                     value="#{bindings.SWarehouseView1.geoMapModel}">
    <dvt:mapPointStyleItem maxValue="5.0"
                           shortLabel="#{viewcontrollerBundle.PRODUCT_COUNT_LOW}"
                           imageURL="/images/error.png" minValue="0.0"/>
    <dvt:mapPointStyleItem minValue="6.0" maxValue="7.0"
                           shortLabel="#{viewcontrollerBundle.PRODUCT_COUNT_OK}"
                           imageURL="/images/checkmark.png"/>
    <dvt:mapPointStyleItem minValue="8.0"

shortLabel="#{viewcontrollerBundle.PRODUCT_COUNT_HIGH}"
                           imageURL="/images/warning.png"/>
  </dvt:mapPointTheme>
</dvt:map>
<dvt:mapToolbar mapId="map" id="mt1"/>
```

What You May Need to Know About Adding Custom Point Style Items to a Map Point Theme

If you want to provide custom HTML as well as custom images for map points, then you can use the `customPointCallback` attribute of the `mapPointTheme` tag to accomplish this customization.

> **Note:**
>
> If you set the `customPointCallback` attribute for a map point theme, the map ignores any `dvt:mapPointStyleItem` child tags because the callback overrides these tags.

To use a callback to customize the style of map points:

1. Write a method in Java to perform the desired point customization.
2. Store this method in a managed bean for the map.

   For more information about managed beans, see the Creating and Using Managed Beans section in *Developing Web User Interfaces with Oracle ADF Faces*.

3. After you finish data-binding the map point theme, use the Properties window to specify a reference to the managed bean method in the `customPointCallback` attribute of the `dvt:mapPointTheme` tag.

   For example, if the managed bean is named `MapSampleBean` and the method is named `setCustomPointStyle`, then the reference becomes `#{mapSampleBean.CustomPointStyle}`.

How to Create a Geographic Map with a Color Theme

You can create a geographic map with a color theme to display areas of the map in colors. For example, a color theme might identify the states with warehouses, styled with a range of color to represent stock levels in each state.

To create a geographic map with a color theme, you first configure the base map and then bind a color theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel. You can also layer a color theme on a base map that has already been configured and bound to another theme.

For example, the geographic map in Figure 41-10 has a color theme that identifies the states with warehouses styled to represent stock levels for each states.

Figure 41-10 Geographic Map with Color Theme

Before you begin:

It may be helpful to have an understanding of databound geographic maps. For more information, see Creating Databound Geographic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the geographic map with color theme, as described in Creating and Modifying an Application Module.

  For example, the data source for the geographic map with color theme shown in Figure 41-10 comes from a view object created for the Summit ADF DVT sample application.

- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a geographic map with a databound color theme:

1. From the Data Controls panel, select a collection.

   Figure 41-11 shows an example where you could select the `WorldProductInventory1` collection in the Data Controls panel to create a color map theme that shows product inventory levels by the color of regions, in this example, US States.

Figure 41-11 Data Collection for Product Inventory Levels

Operations
Named Criteria
Operations

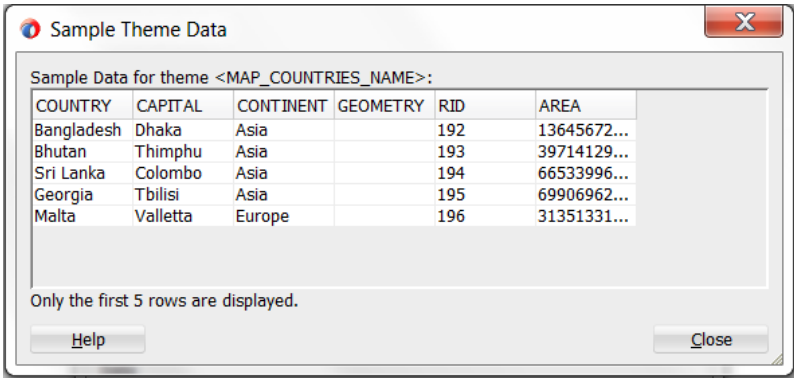
2. Drag the collection onto a JSF page which already contains a geographic map component and, from the context menu, choose **Geographic Map** > **Map and Color Theme**.

3. If you have not yet configured a map on the page, complete the Create Geographic Map dialog. For more information, see How to Configure a Geographic Base Map. Otherwise, do one of the following:
   - Use the dropdown list to select the map configuration you wish to use
   - Click **OK** to accept the available map configuration
   - Click **New** to configure a new base map
   - Click **Edit** to modify the available map configuration
4. If you are layering a color theme on a base map that has already been configured and bound to another theme, in the Create dialog select Color Theme.
5. In the Create Color Map Theme dialog, in the **Theme Id** field, enter a unique identifier for the map theme in the **Id** field.
6. In the **Base Map Theme** section, identify the base map color theme to use for the geographic map by doing the following:
   a. In the **Name** field, select the name of the base map theme.
   b. For **Location**, select the location column in the data collection that should be matched to the location column in the base map theme that you selected.
   c. Optionally, click **View Sample Theme Data** to display the Sample Theme Data dialog, in which you can examine the first several rows of the actual data so that you can identify the appropriate location column.

      For example, if you want to view the data for a region that consists of states in the United States map, you might select MAP_STATES_NAME as shown in Figure 41-12.

> **Note:**
>
> It is possible for an administrator of Oracle Spatial to disable the display of sample data. If this button is not available, then consult the administrator for guidance.

Figure 41-12 Sample Theme Data for Regions or States



Sample Data for theme <MAP_COUNTRIES_NAME>:

COUNTRY	CAPITAL	CONTINENT	GEOMETRY	RID	AREA
Bangladesh	Dhaka	Asia		192	13645672...
Bhutan	Thimphu	Asia		193	39714129...
Sri Lanka	Colombo	Asia		194	66533996...
Georgia	Tbilisi	Asia		195	69906962...
Malta	Valletta	Europe		196	31351331...

Only the first 5 rows are displayed.

7. In the **Appearance** section, specify the look of the color theme as follows:
   a. In **Data Bucket Count**, enter the number of groups for the data in this geographic map. Each group is coded with a color. After specifying this

number, you can provide colors for the minimum value and the maximum value. The colors for the other values are chosen automatically using an RGB algorithm.

b. In **Minimum Value Color**, select the color for the minimum value.

c. In **Maximum Value Color**, select the color for the maximum value.

> **Note:**
>
> If you want to specify an exact color for each data bucket, see What You May Need to Know About Customizing Colors in a Map Color Theme.

8. In the **Data** section, provide the following information about the data in the collection:

   a. For **Location**, select the column in the data collection that should match the values in the location column that you selected from the base map theme.

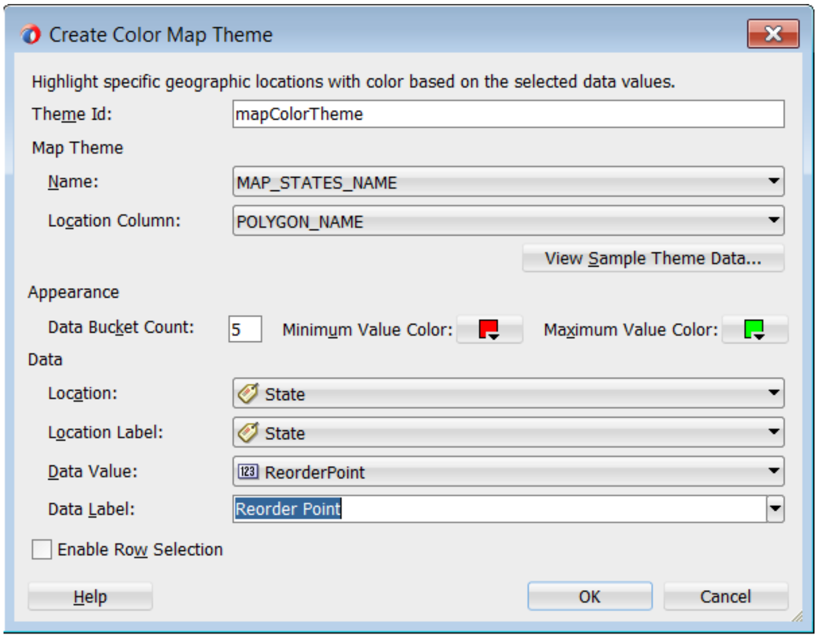
   b. For **Location Label**, select the column in the data collection that contains the labels associated with the values in the location column. These labels are shown in the information window that is displayed when you click or hover over a color.

   c. For **Data Label**, enter the label to use for describing the data in the information window and the tooltip that is displayed when you click or hover over a color. For example, the information window might include a label before the data value, such as **Product Popularity**. You can also enter a text resource to use for the data label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime for a dynamic label. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

9. Use **Enable Row Selection** only if you want to enable master-detail relationships. This is useful when the data collection for the map theme is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page.

Figure 41-13 shows the Create Color Map Theme dialog for the product popularity by state color theme.

Figure 41-13 Create Color Map Theme for Product Popularity By State



Create Color Map Theme

Highlight specific geographic locations with color based on the selected data values.

☐ Enable Row Selection

What Happens When You Add a Color Theme to a Geographic Map

Dropping a color theme from the Data Controls panel to an existing geographic map has the following effect:

- Creates the bindings for the color theme and adds the bindings to the page definition file
- Adds the necessary color theme child tags within the geographic map tag to the JSF page

The example below shows the row set bindings that were generated for the color theme of the geographic map.

```
<bindings>
    <mapTheme IterBinding="WorldProductInventory1Iterator"
              id="WorldProductInventory1"
              xmlns="http://xmlns.oracle.com/adfm/dvt">
      <mapThemeDataMap convert="false" mapThemeType="color">
        <item type="location" value="State" label="State"/>
        <data>
          <item value="AmountInStock"
                label="${adfBundle['view.ViewControllerBundle'].STOCK_LEVELS}"/>
        </data>
      </mapThemeDataMap>
    </mapTheme>
  </bindings>
```

The example below shows the XML code generated on the JSF page for a color theme that represents product popularity in different states on the United States map.

```
<dvt:map id="map" startingX="-102.39" mapServerConfigId="mapConfig1"
         baseMapName="ELOCATION_MERCATOR.WORLD_MAP"
         mapZoom="3" inlineStyle="width:600px; height:375px;" startingY="40.27"
```

```
           summary="Geographic map with color theme">
    <dvt:mapColorTheme id="mapColorTheme" themeName="MAP_STATES_ABBRV"
                       value="#{bindings.WorldProductInventory1.geoMapModel}"
                       bucketCount="5" minColor="#ff0000"
                       maxColor="#00ff00" locationColumn="STATE_ABRV"/>
        </dvt:map>
```

What You May Need to Know About Customizing Colors in a Map Color Theme

While you are data-binding a map color theme, you can specify only a minimum color and a maximum color for the data buckets. The map uses an algorithm to determine the colors of the buckets between the minimum and maximum. However, after the data-binding is finished, you have the option of specifying the exact color to be used for each data bucket.

In the Properties window, for the `dvt:mapColorTheme` tag you can use the `colorList` attribute to specify the color for each bucket. You can either bind a color array to this attribute or you can specify a string of colors using a semicolon separator.

For example, if the value of this attributes is set to: `#ff0000;#00ff00;#0000ff`, then the color of the first bucket is red, the second bucket is green, and the third bucket is blue.

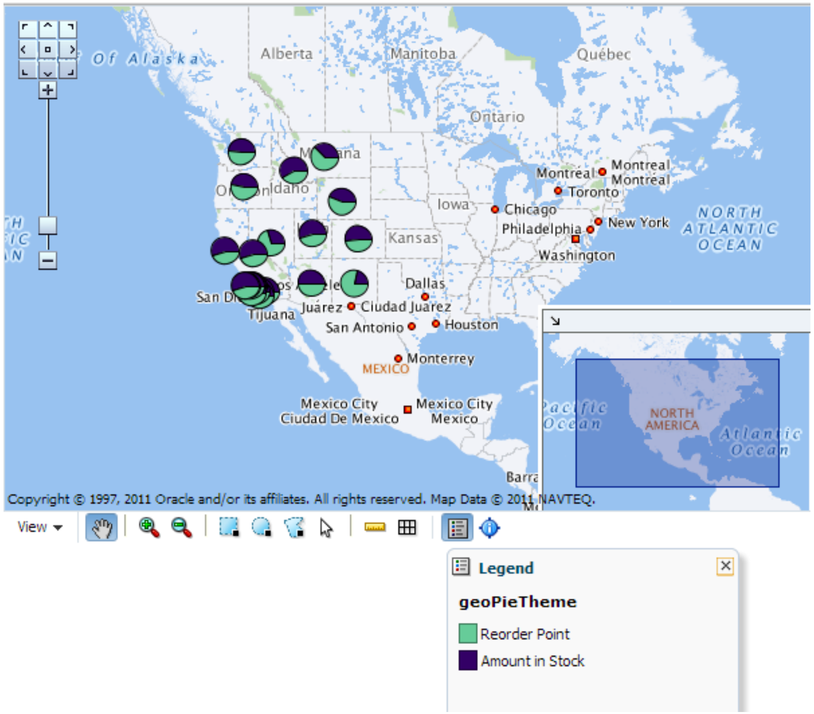
How to Create a Geographic Map with a Pie or Bar Graph Theme

You can create a geographic map with a pie or bar graph theme to display specific locations in a map, identified by latitude and longitude or address. For example, a point theme might identify the locations of warehouses in a map. If you customize the style of the point that is displayed, you could choose to use a different image for the warehouse product count (high, acceptable, low) in a set of warehouses to differentiate them from each other.

To create a geographic map with a pie or bar graph theme, you first configure the base map and then bind a pie or bar graph theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel. You can also layer a pie or bar graph theme on a base map that has already been configured and bound to another theme.

For example, the geographic map in Figure 41-14 has a point theme that identifies the location of warehouses and their product count levels in the United States.

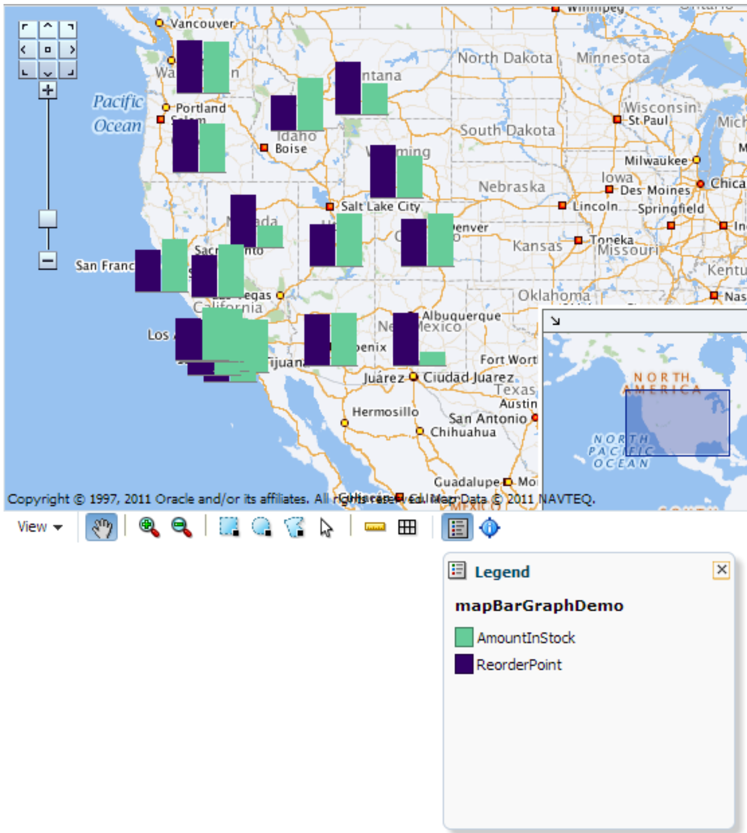
Figure 41-14   Geographic Map with Pie Graph Theme



Copyright © 1997, 2011 Oracle and/or its affiliates. All rights reserved. Map Data © 2011 NAVTEQ.

For example, the geographic map in Figure 41-14 has a point theme that identifies the location of warehouses and their product count levels in the United States.

Figure 41-15 Geographic Map with Bar Graph Theme



Before you begin:

It may be helpful to have an understanding of databound geographic maps. For more information, see Creating Databound Geographic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the geographic map with a pie or bar graph theme, as described in Creating and Modifying an Application Module.

  For example, the data source for the pie graph theme shown in Figure 41-14 and the bar graph theme shown in Figure 41-15 comes from a view object created for the Summit ADF DVT sample application.

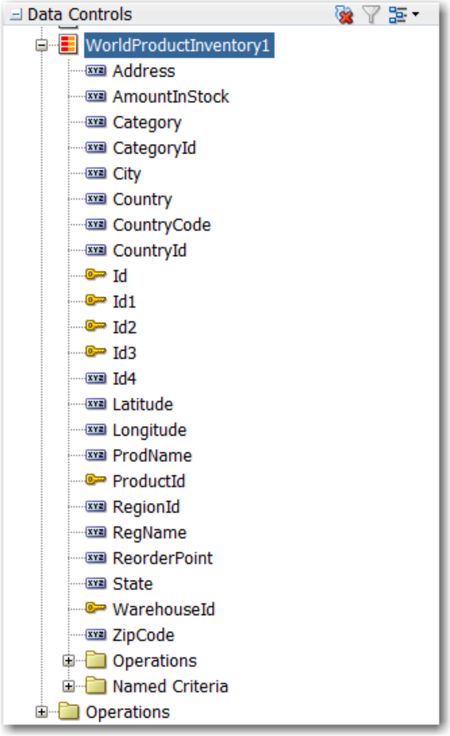
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a geographic map with databound pie or bar graph theme:

1. From the Data Controls panel, select a collection.

Figure 41-16 shows an example where you could select the `WorldProductInventory1` collection to create a pie or bar graph bar theme in an existing geographic map component to represent the popular product categories within a state.

Figure 41-16   Data Collection for Inventory Levels by Product



Data Controls
- WorldProductInventory1
  - Address
  - AmountInStock
  - Category
  - CategoryId
  - City
  - Country
  - CountryCode
  - CountryId
  - Id
  - Id1
  - Id2
  - Id3
  - Id4
  - Latitude
  - Longitude
  - ProdName
  - ProductId
  - RegionId
  - RegName
  - ReorderPoint
  - State
  - WarehouseId
  - ZipCode
  - Operations
  - Named Criteria
- Operations

2. Drag the collection onto a JSF page and, from the context menu, choose **Geographic Map** > **Map and Pie (or Bar) Graph Theme**.

3. If you have not yet configured a map on the page, complete the Create Geographic Map dialog. For more information, see How to Configure a Geographic Base Map. Otherwise, do one of the following:

   - Use the dropdown list to select the map configuration you wish to use
   - Click **OK** to accept the available map configuration
   - Click **New** to configure a new base map
   - Click **Edit** to modify the available map configuration

4. If you are layering a pie graph theme on a base map that has already been configured and bound to another theme, in the Create dialog select Pie Graph Theme.

5. In the Create Pie Graph Theme dialog, do the following to identify the new theme and the base map theme elements that you want to work with:

   a. For **Theme Id**, enter a unique identifier for the pie graph theme that you are creating.

   b. In the **Base Map Theme** section, select the name of the base map and the region in which you want to place the pie graphs.

6. In the **Appearance** section, under **Data**, do the following:
   a. For **Location**, select the location column in the data collection that should be matched to the location column in the base map theme that you selected.

      If needed, click **View Sample Theme Data** to examine the first several rows of the actual data so that you can identify the appropriate location column.
   b. For **Location Label**, select the column in the data collection that contains labels for the locations in the data collection.
   c. In the grid for the **Pie Slices Attributes** (for pie graph) or **Series Attributes** (for bar graph), enter each attribute that contains values that you want represented in the pie or bar graph that you are creating.
   d. Beside each pie slice or series attribute, enter text that should be used as a label for the data value in the attribute. You can enter the text directly, select `No Label` to suppress the label as in the case of using a single data value, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime.
7. Select **Enable Row Selection** only if you want to enable the selection of rows in a related component. You select this component when the page contains a component that is linked to a data collection that is related to the geographic map that you are creating.
8. Click **OK**.

Figure 41-17 shows the completed Create Pie Graph Map Theme dialog for the inventory levels by product.

Figure 41-17 Create Pie Graph Map Theme for Inventory Levels by Product

What Happens When You Add a Pie or Bar Graph Theme to a Geographic Map

Dropping a pie graph theme from the Data Controls panel to an existing geographic map has the following effect:

- Creates the bindings for the pie graph theme and adds the bindings to the page definition file
- Adds the necessary pie graph theme code to the JSF page within the map XML

The example below shows the row set bindings that were generated for the pie graph theme of the geographic map.

```
<mapTheme IterBinding="PopularCategoriesByState1Iterator"
        id="PopularCategoriesByState1"
        xmlns="http://xmlns.oracle.com/adfm/dvt">
  <mapThemeDataMap mapThemeType="pieChart">
    <item type="location" value="StateProvince" label="StateProvince"/>
    <data>
      <item value="AudioVideo"
            label="${adfBundle['view.ViewControllerBundle'].AUDIO_VIDEO}"/>
      <item value="CellPhones"
            label="${adfBundle['view.ViewControllerBundle'].CELL_PHONES}"/>
      <item value="Games"
            label="${adfBundle['view.ViewControllerBundle'].GAMES}"/>
    </data>
  </mapThemeDataMap>
</mapTheme>
```

The example below shows the XML code generated on the JSF page for the pie graph theme of the geographic map.

```
<dvt:mapPieGraphTheme id="mapPieGraphTheme1"
     themeName="MAP_STATES_NAME"
     shortLabel="#{viewcontrollerBundle.POPULAR_CATEGORIES}"
     pieRadius="10"
     styleName="comet"
     value="#{bindings.PopularCategoriesByState1.geoMapModel}"
     locationColumn="POLYGON_ID"/>
</dvt:mapPieGraphTheme>
```

Creating Databound Thematic Maps

A thematic map represents business data as patterns in stylized areas or associated markers and does not require a connection to a remote Oracle MapViewer service. Thematic maps focus on data without the geographic details in a geographic map.

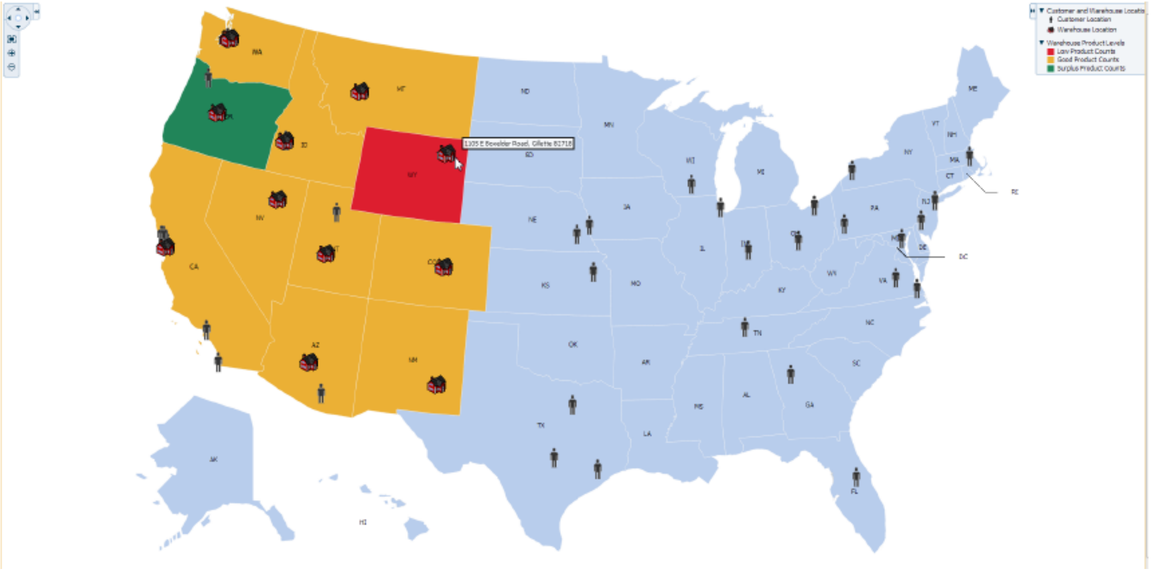
The thematic map is packaged with prebuilt base maps including a USA base map, a world base map, and base maps for continents and regions of the world including EMEA and APAC. Each base map includes several sets of regions and one fixed set of cities. A set of regions or cities is referred to as a layer. Each layer can be bound to a data collection and stylized to represent the data with color and pattern fills, or a data marker, or both. At runtime, only one map layer and its associated data can be displayed at a time, unless the thematic map has been enabled for drilling.

The data displayed in a thematic map is based on data collections. Using ADF data controls, JDeveloper makes data binding a declarative task. You drag and drop a collection from the Data Controls panel onto the JSF page and use a Component Gallery to select the base map and map layers on which to display the data. You can then use a Layer Browser and binding dialogs to bind data collection attributes to the data layers in the thematic map.

Stamping is used to associate map layers with a row of data in a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image. When you use stamping, child components are not created for every area, marker, or image in a thematic map. Rather, the content of the component is repeatedly rendered, or stamped, once per data attribute, such as the rows in a data collection.

Figure 41-19 shows a thematic map using a USA base map with a states map layer to display customer and warehouse locations, and the product inventory levels for states with warehouses in the Summit ADF DVT sample application. The example illustrates thematic map default features including a data bound legend and labels associated with the styled points and areas when you use the Data Controls panel and thematic map binding dialogs.

Figure 41-19   Thematic Map Displaying Customer and Warehouse Locations



For detailed information about thematic map end user and presentation features, use cases, tag structure, and adding special features to thematic maps, see the Using Thematic Map Components section in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Thematic Map Using ADF Data Controls

The `thematicMap` component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The data layer will automatically convert the instance into a `CollectionModel`.

Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Creating Databound Thematic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

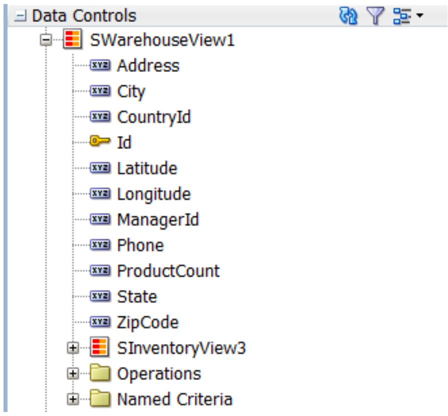
- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a thematic map using the Data Controls panel:

1. From the Data Controls panel, select a data collection.

Figure 41-20 shows the data collection for warehouse locations and product inventory levels.

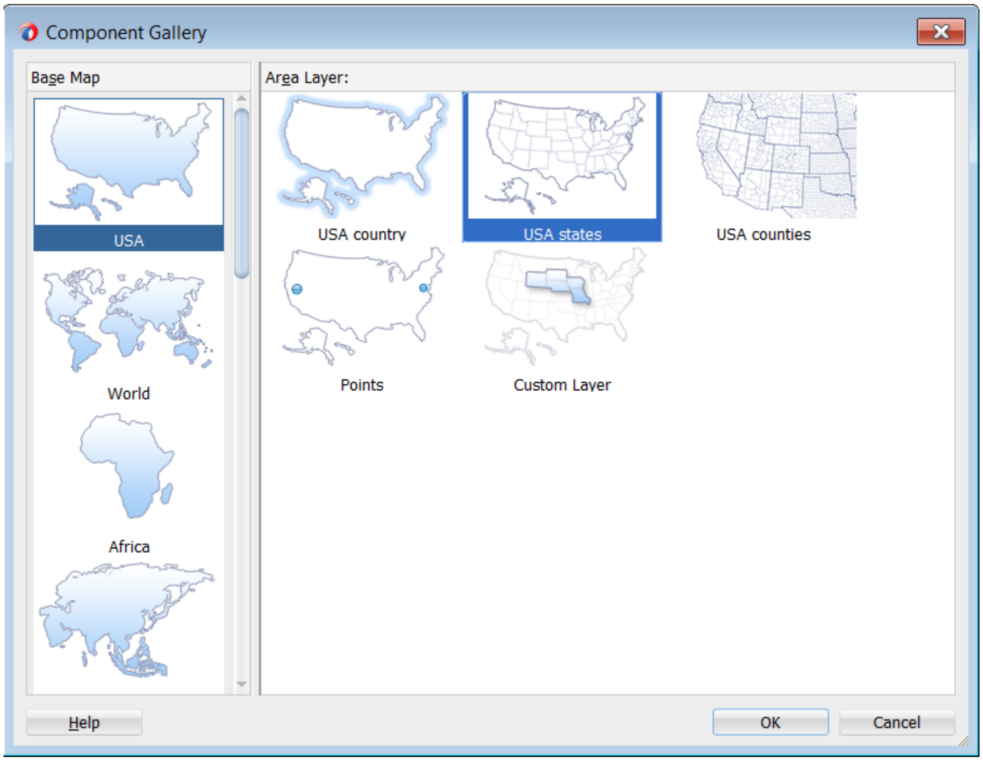
Figure 41-20 Data Collection for Warehouse Location and Inventory



Data Controls
- SWarehouseView1
  - Address
  - City
  - CountryId
  - Id
  - Latitude
  - Longitude
  - ManagerId
  - Phone
  - ProductCount
  - State
  - ZipCode
  - SInventoryView3
  - Operations
  - Named Criteria

2. Drag the collection onto a JSF page and, from the context menu, choose **Thematic Map**.
3. In the Component Gallery, select the map layer associated with the base map you want to configure for displaying data. In the example, a states map layer in the US base map is selected. Figure 41-21 shows the Component Gallery with the USA states map layer selected.

Figure 41-21 Thematic Map Component Gallery



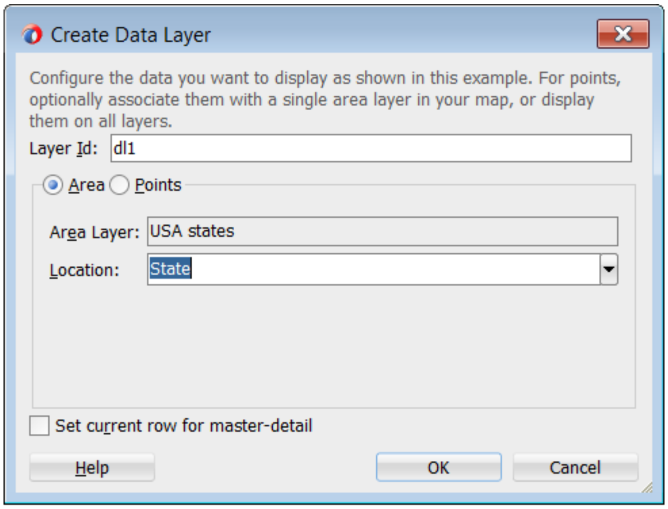
By default, the Create Data Layer dialog opens for adding an area or point data layer to the selected map layer. In the thematic map displayed in Figure 41-19, an area data layer is configured style USA states by warehouse product levels.

4. In the Create Data Layer dialog, enter the following:

   - **Layer Id**: Enter a unique name for the data layer you are defining. By default, a unique, consecutively numbered id is entered, `dl1`, `dl2`, and so on.
   - **Area**: Select to add an area data layer to the map layer.
   - **AreaLayer**: References the map layer to which you are adding a data layer. In the example, a **USA States** map layer.
   - **Location**: Select the attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. For more information, see What You May Need to Know About Base Map Location Ids.
   - **Set current row for master-detail**: Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see What You May Need to Know About Configuring Master-Detail Relationships.

   Figure 41-22 shows the completed Create Data Layer dialog.

Figure 41-22 Create Area Data Layer Dialog



Configure the data you want to display as shown in this example. For points, optionally associate them with a single area layer in your map, or display them on all layers.

Layer Id: dl1

● Area ○ Points

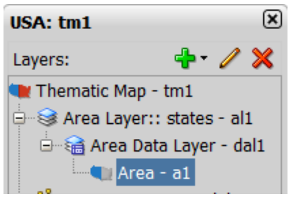
Area Layer: USA states

Location: State

□ Set current row for master-detail

An area data layer representing the `areaDataLayer` component, and an area, representing the `area` component is added in the Layer Browser hierarchy. Figure 41-23 shows the expanded Layer Browser after adding an area data layer and area to the map layer.

Figure 41-23 Thematic Map Layer Browser



USA: tm1

Layers:

Thematic Map - tm1
Area Layer:: states - al1
Area Data Layer - dal1
Area - a1

5. In the Layer Browser, expand the area data layer, select the area to be stylized, and click the **Edit** icon.

> **Note:**
>
> You configure an area with a default stamp across all areas in the thematic map layer, or you can you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the `area` tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence. For more information, see Styling Areas, Markers, and Images to Display Data.

6. In the Configure Area dialog, Attribute Groups page, enter the following:

   - **Grouping Rules**: Use this table to specify the styling of categorical groups of data in a data collection. Use the **Add** icon to add a row to the table for configuring rules for a categorical group and use the **Delete** icon to remove any row selected in the table. Each grouping rule is represented as a `attributeGroups` component, and assigned a unique, consecutively numbered Id, `ag1`, `ag2`, and so on.

     For each row added to the table, enter the following:

     – **Group by Value**: Enter or use the dropdown list to select the attribute representing the column in the data set by which you wish to group the data values. For example, `ProductCount` represents the warehouse product inventory levels by state.

     > **Note:**
     >
     > The selected attribute should consist of discrete values that can be categorized. For example, a range of numeric values between 40 and 45, are not automatically grouped.

     – **Area Properties**: Use the dropdown list to select the property to use for styling that area. Areas can be styled using **color**, **pattern**, **opacity**, or any combination of these valid values. Choose **Select multiple attributes** from the dropdown list for a dialog to specify any combination of values.

     The default style values that are generated for each property are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the skin, and these can be customized by setting the index-based properties to the desired values. For more information, see What You May Need to Know About Default Style Values for Attribute Groups.

  - **Legend Label**: Enter text or use the dropdown list to select the attribute representing the text to use for the categorical group in the thematic map legend. You can also select **Expression Builder** from the dropdown list to create an EL expression to specify the legend text. For more information, see Creating Databound Legends.

- **Value-Specific Rules**: Click to open the **Match Rules** and **Exception Rules** tables used to specify a finer detail for one or more data values in categorical groups in a data set. For example, use a match rule to style every state with a warehouse with a low product inventory level with a `#DD1E2F` color, instead of a predefined range of colors.

  > **Note:**
  >
  > Any match or exception rule specified in these tables will override the settings defined in the **Grouping Rules** table.

- **Match Rules**: Use to specify the style rule matched to one or more data values in a group of data in a data collection. Use the **Add** icon to add a row to the table for configuring a match rule for a categorical group and use the **Delete** icon to remove any row selected in the table. Each match rule is represented as a `attributeMatchRule` component, and assigned a unique, consecutively numbered Id, `amr1`, `amr2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

  ```
  <dvt:attributeMatchRule id="amrl" group="Mountain Dew">
    <f:attribute name="color" value="#ffff00"/>
  </dvt:attributeMatchRule>
  ```

  For each row added to the table, enter the following:

  - **Group Value**: Enter the exact value for a **Group By Value** attribute that will trigger this Match Rule to execute. In the example, warehouse product inventory level data collection attribute, values include `low`, `med`, and high.

  - **Property**: Use the dropdown list to select the property to use for styling that data value. Areas can be styled using **color**, **pattern**, or **opacity** values. The property selected here must match one of the property types listed in the **Area Properties** for the attribute **Grouping Rules**.

  - **Property Value**: Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

    Valid values for **color** are RGB hexidecimal colors.

    Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

    Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

- **Exception Rules**: Use to specify one or more exception to the style rules for categorical groups in the data set. Use the **Add** icon to add a row to the table for configuring an exception rule and use the **Delete** icon to remove any row selected in the table. Each exception rule is represented as an `attributeExceptionRule` component, and assigned a unique, consecutively numbered Id, `aer1`, `aer2`, and so on. The property and property value is defined in a child `f:attribute` tag.

  For each row added to the table, enter the following:

  – **Condition**: Enter an EL expression, or use the dropdown list to open an Expression Builder dialog to create an EL expression that replaces the style property value with another when certain conditions are met. For example:

    ```
    #{row.Sales gt 100000}
    ```

  – **Property**: Use the dropdown list to select the property to use for styling that data value. Areas can be styled using **color**, **pattern**, or **opacity** values. The property selected here must match one of the property types listed in the **Area Properties** for the attribute **Grouping Rules**.

  – **Property Value**: Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

    Valid values for **color** are RGB hexidecimal colors.

    Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

    Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

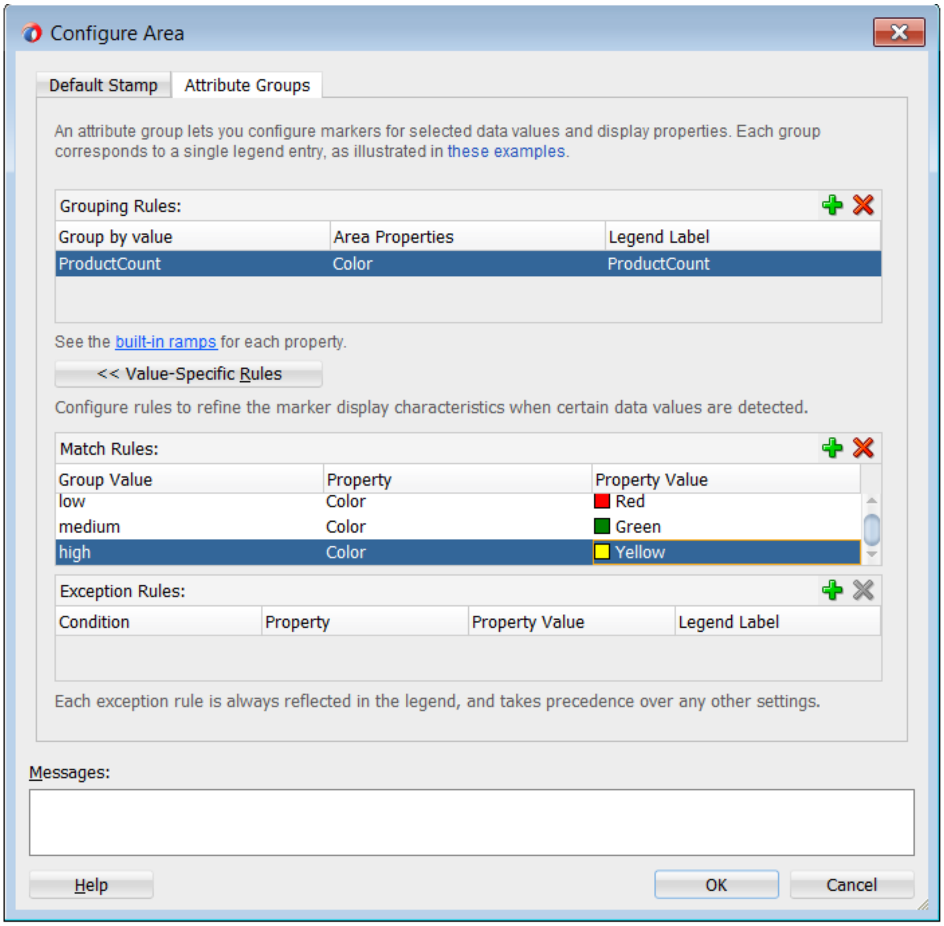
  – **Legend Label**: Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

    > **Note:**
    >
    > the text resource option is only available for a fixed area.
    > For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:
    >
    > ```
    > #{viewController.ResourceBundle[row.label]}
    > ```

- **Messages**: Review and clear as necessary any alerts related to the configuration of the area.

Figure 41-24 shows the completed Configure Area dialog. The warning in the message pane alerts the user that the default area color specified in the Default Stamp page of the dialog will be overwritten by the color specified in the Grouping Rules and any value-specific overrides specified in the Attribute Groups page.

Figure 41-24 Configure Area Dialog Attribute Groups Page



Configure Area

An attribute group lets you configure markers for selected data values and display properties. Each group corresponds to a single legend entry, as illustrated in these examples.

Grouping Rules:

Group by value	Area Properties	Legend Label
ProductCount	Color	ProductCount

See the built-in ramps for each property.

Configure rules to refine the marker display characteristics when certain data values are detected.

Match Rules:

Group Value	Property	Property Value
low	Color	🟥 Red
medium	Color	🟩 Green
high	Color	🟨 Yellow

Exception Rules:

Condition	Property	Property Value	Legend Label

Each exception rule is always reflected in the legend, and takes precedence over any other settings.

Messages:

7. Use the Layer Browser to add a global point data layer representing warehouse locations using the same data collection you used to create the thematic map. For detailed instructions, see How to Add Data Layers to Thematic Maps.

8. Use the Layer Browser to add a global point data layer representing customer addresses using a different data collection than the one you used to create the thematic map. For detailed instructions, see How to Add Data Layers to Thematic Maps. Figure 41-25 shows the data collection for customer locations.

10. Add and configure a data bound legend and labels associated with the styled points and areas. For detailed instructions, see Creating Databound Legends.

What Happens When You Use Data Controls to Create a Thematic Map

When you use ADF data controls to create a thematic map, JDeveloper:

- Defines the bindings for the thematic map in the page definition file of the JSF page, and
- Inserts code in the JSF page for the DVT thematic map components.

The example below shows the bindings defined in the page definition file of the JSF page for the example thematic map in Figure 41-19.

```
<bindings>
    <tree IterBinding="WorldProductInventory1Iterator"
id="WorldProductInventory1">
      <nodeDefinition DefName="model.WorldProductInventory"
Name="WorldProductInventory10">
        <AttrNames>
          <Item Value="Address"/>
          <Item Value="AmountInStock"/>
          <Item Value="Category"/>
          <Item Value="CategoryId"/>
          <Item Value="City"/>
          <Item Value="Country"/>
          <Item Value="CountryCode"/>
          <Item Value="CountryId"/>
          <Item Value="Id"/>
          <Item Value="Id1"/>
          <Item Value="Id2"/>
          <Item Value="Id3"/>
          <Item Value="Id4"/>
          <Item Value="Latitude"/>
          <Item Value="Longitude"/>
          <Item Value="ProdName"/>
          <Item Value="ProductId"/>
```

```
            <Item Value="RegName"/>
            <Item Value="RegionId"/>
            <Item Value="ReorderPoint"/>
            <Item Value="State"/>
            <Item Value="WarehouseId"/>
            <Item Value="ZipCode"/>
          </AttrNames>
        </nodeDefinition>
      </tree>
      <tree IterBinding="SCustomerView1Iterator" id="SCustomerView1">

      </dvt:thematicMap>
```

Once you have created a data bound thematic map you can add additional map layers representing available regions in the geographical hierarchy of the base map, and associate area or point data layers using the same data collection you used to create the thematic map. The Layer Browser represents the logical structure of the map layers, area and point data layers, and stylized areas and markers. Use the Layer Browser to:

- Add additional map layers in the base map geographical hierarchy to the thematic map.

- Define a custom map layer in the geographical hierarchy of the base map, using lower level regions to aggregate the regions in the custom layer. For more information, see How to Define a Custom Map Layer.
- Add, edit, or delete area or point (global or map layer specific) data layers. For more information, see How to Add Data Layers to Thematic Maps.
- Add, edit, or delete stylized areas or markers. For more information, see Styling Areas, Markers, and Images to Display Data.

After creating a thematic map using data controls, you can customize the default map labels, legend display, and add interactivity and animation effects. For more information, see in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Add Data Layers to Thematic Maps

You use data layers to associate map layers with a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image. When a map layer is displayed at runtime, the data appears as stylized areas, markers, or images.

How to Add an Area Data Layer to a Map Layer

Map layers can display data using an area data layer and/or one or more point data layers. Area data layers can be styled using areas, markers, or images. Point data layers can be styled using markers or images.

Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Creating Databound Thematic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
- Create a data bound thematic map to your JSF page, as described in How to Create a Thematic Map Using ADF Data Controls.

To add an area data layer to a map layer:

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, select the map layer to which you wish to bind a row in the data collection. If the Layer Browser is not open in the Visual Editor, right-click inside the map and choose **Open Layer Browser**.
3. From the **Add** icon dropdown list, choose **Add Data Layer**.
4. In the Create Data Layer dialog, enter the following:

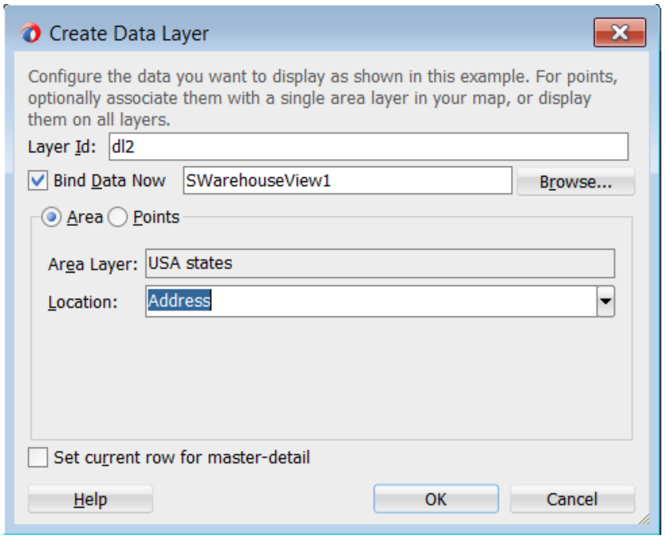
- **Layer Id**: Enter a unique name for the data layer you are defining. By default, a unique, consecutively numbered id is entered, `dl1`, `dl2`, and so on.
- **Bind Data Now**: Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your data layer.

> **Note:**
>
> Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your area data layer and areas. You can also use the Expression Builder dialog in each remaining field.

- **Area**: Select to add an area data layer to the map layer.
- **AreaLayer**: References the map layer to which you are adding a data layer.
- **Location**: Select attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. For more information, see What You May Need to Know About Base Map Location Ids.
- **Set current row for master-detail**: Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see What You May Need to Know About Configuring Master-Detail Relationships.

Figure 41-27 shows the completed Create Area Data Layer dialog.

Figure 41-27 Create Area Data Layer Dialog



Create Data Layer

Configure the data you want to display as shown in this example. For points, optionally associate them with a single area layer in your map, or display them on all layers.

Layer Id: dl2

☑ Bind Data Now SWarehouseView1 Browse...

● Area ○ Points

Area Layer: USA states

Location: Address

□ Set current row for master-detail

By default, an area data layer representing the `areaDataLayer` component, and an area, representing the `area` component is added in the Layer Browser hierarchy. The example below shows the code added to the JSF page when you add an area data layer to a map layer.

```
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="counties" id="al1">
    <dvt:areaDataLayer id="dl2"
                       value="#{bindings.TmapStatesView11.collectionModel}"
                       var="row">
      <dvt:areaLocation name="#{row.Name}" id="al2">
        <dvt:area id="a1"/>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
...
</dvt:thematicMap>
```

After adding the area data layer to the thematic map, you style the data using areas, markers, or images. For more information, see Styling Areas, Markers, and Images to Display Data.

How to Add a Point Data Layer to a Map Layer

Map layers can display data using an area data layer and/or one or more point data layers. Area data layers can be styled using areas, markers, or images. Point data layers can be styled using markers or images.

When a point data layer is associated with the base map as a direct child of `thematicMap` instead of as a child of a specific map layer, the data displays at all times and is called a global point layer.

Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Creating Databound Thematic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
- Create a data bound thematic map to your JSF page, as described in How to Create a Thematic Map Using ADF Data Controls.

To add a point data layer to a map layer:

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, select the map layer to which you wish to bind a data layer. If the Layer Browser is not open in the Visual Editor, right-click inside the map and choose **Open Layer Browser**.
3. From the **Add** icon dropdown list, choose **Add Data Layer**.

> **Note:**
>
> If you wish to create a global point layer that displays at all times on the thematic map, choose **Create Global Point Layer**.

4. In the Create Data Layer dialog, enter the following:
   - **Layer Id**: Enter a unique ID for the data layer you are defining. By default, a unique, consecutively numbered id is entered, `dl1`, `dl2`, and so on.
   - **Bind Data Now**: Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your data layer.

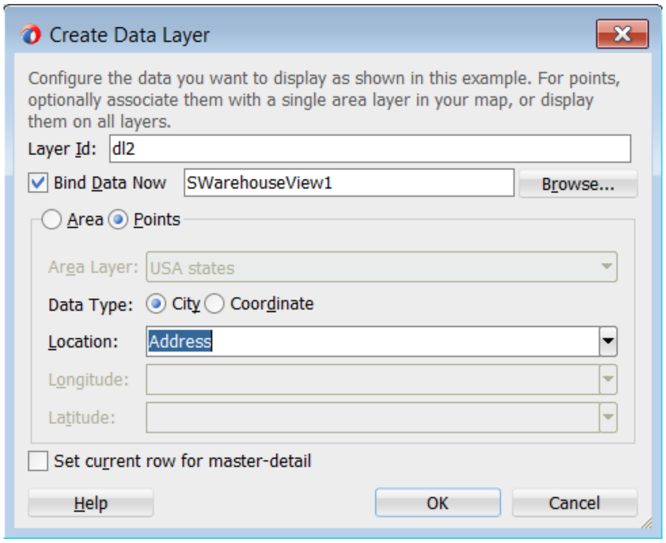
     > **Note:**
     >
     > Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your point data layer and markers. You can also use the Expression Builder dialog in each remaining field.

   - **Points**: Select to add a point data layer to the map layer.
   - **AreaLayer**: Use the dropdown list to select the map layer to which you are associating a data layer. If you select **All**, the point data layer will be configured as a global point layer and display at all times. If you select an available map layer, the point data layer will only display with that map layer is displayed.
   - **Data Type**: Choose one of the following:
     - **City**: Select to use a `pointName` data type representing the named points, such as cities, in the data collection that map to named points in the base map.
     - **Coordinates**: Select to use a `pointXY` data type representing the columns in the data collection that join `pointX` and `pointY` to define the point locations.
   - **Location**: Available if a City Data Type is specified. Use the dropdown list to select the attribute that represents the column in the data model that determines the location of the data for the points in the data layer. The locations are IDs of the points from the base map for which the data is being displayed. For more information, see What You May Need to Know About Base Map Location Ids.
   - **Longitude**: Available if a Coordinates Data Type is specified. Use the dropdown list to select the attribute in the data collection that represents the longitude, or `pointX` of the marker.
   - **Latitude**: Available if a Coordinates Data Type is specified. Use the dropdown list to select the attribute in the data collection that represents the latitude, or `pointY` of the markers.
   - **Set current row for master-detail**: Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is

a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see What You May Need to Know About Configuring Master-Detail Relationships.

Figure 41-28 shows the completed Create Point Data Layer dialog for a `pointName` data type.

Figure 41-28   Create Point Data Layer Dialog



Create Data Layer

Configure the data you want to display as shown in this example. For points, optionally associate them with a single area layer in your map, or display them on all layers.

Layer Id: dl2

☑ Bind Data Now: SWarehouseView1

○ Area ● Points

Area Layer: USA states

Data Type: ● City ○ Coordinate

Location: Address

Longitude:

Latitude:

☐ Set current row for master-detail

By default, a point data layer representing the `pointDataLayer` component, and a marker, representing the `marker` component is added in the Layer Browser hierarchy. The example below shows the code added to the JSF page when you add a point data layer to a map layer.

```
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="states" id="al1">
    <dvt:pointDataLayer id="dl1"
                        value="#{bindings.TmapCitiesView11.collectionModel}"
                        var="row">
      <dvt:pointLocation type="pointName" pointName="#{row.City}" id="pl1">
        <dvt:marker id="m2"/>
      </dvt:pointLocation>
    </dvt:pointDataLayer>
  </dvt:areaLayer>
...
</dvt:thematicMap>
```

The example below shows the code added to the JSF page when you add a global point data layer to a thematic map.

```
<dvt:thematicMap>
  <areaLayer layer="states" id="al1"/>
  <dvt:pointDataLayer id="dl2"
                      value="#{bindings.TmapCitiesView12.collectionModel}"
                      var="row">
    <dvt:pointLocation type="pointXY" pointX="#{row.Longitude}"
                       pointY="#{row.Latitude}" id="pl2">
      <dvt:marker id="m3"/>
    </dvt:pointLocation>
  </dvt:pointDataLayer>
...
</dvt:thematicMap>
```

After adding the point data layer to the thematic map, you style the data using markers or images. For more information, see Styling Areas, Markers, and Images to Display Data.

Styling Areas, Markers and Images to Display Data

An area data layer is used to associate map layers with a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image.

A point data layer is used to associate a set of points on a map with a data collection. The data point can be specified by a named point in a map layer, for example, cities in the US map, or by longitude and latitude. Using stamping, each row of data in the data model can be identified by a marker, for example a circle or square, or an image.

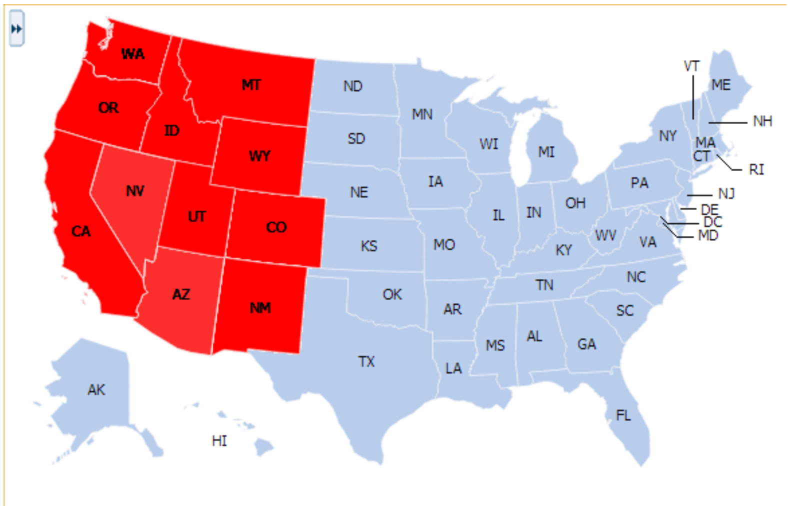
How to Style Areas to Display Data

You configure an area with a default stamp across all areas in the thematic map `areaLayer`, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the `area` tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence.

By default, when you add an area data layer, a configurable area is added to the Layer Browser. You can use the Layer Browser to add additional areas or markers to an area data layer, or markers to a point data layer. The Layer Browser reflects the logical structure of the map layers, area or point data layers, and areas or markers configured in the thematic map.

For example, you can style the states in the `states` layer of the `usa` base map with an attribute group to display states with warehouses using the color red as illustrated in Figure 41-29.

Figure 41-29 Thematic Map with Area Stamp Configured



Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Creating Databound Thematic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
- Create a data bound thematic map to your JSF page, as described in How to Create a Thematic Map Using ADF Data Controls.

To style areas using a default stamp:

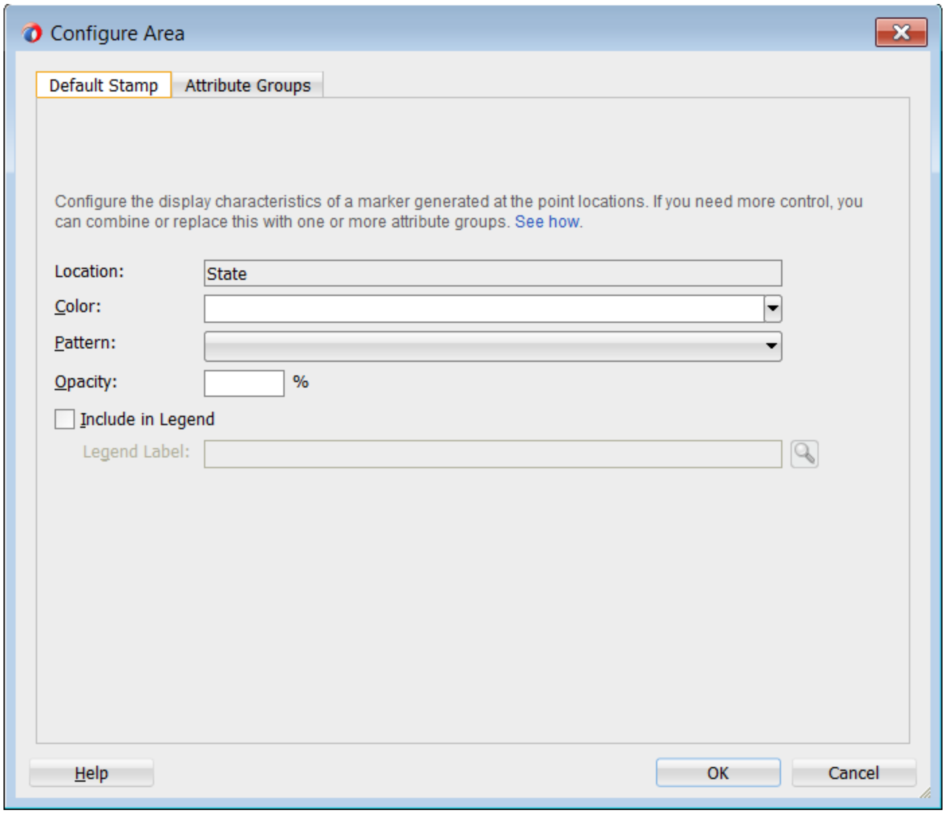
1. In the Layer Browser, select the area at the area location inside the map layer you are configuring.
2. Click the **Edit** icon.
3. In the Configure Area dialog, Default Stamp page, enter the following:
   - **Location**: By default, the attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. This read-only field displays the EL expression that maps the stamped area to a region in the base map. For more information, see What You May Need to Know About Base Map Location Ids.
   - **Color**: Optionally, from the dropdown list select the fill color for the area. Valid values are RGB hexidecimal. Choose **Custom Color** from the dropdown list to open a Color Picker dialog
   - **Pattern**: Optionally, from the dropdown list select one of twelve prebuilt patterns to style the area, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.
   - **Opacity**: Optionally, specify the opacity of the fill color of the area. Valid values range from **0.0** for transparent to **1.0** for opaque.
   - **Include in Legend**: Select and use the search icon to open a Select Text Resource dialog to select or create an application text resource to use for the legend text. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. If you need help, press F1 or click **Help**.

> **Note:**
>
> the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:
>
> `#{viewController.ResourceBundle[row.label]}`

- **Messages**: Review and clear as necessary any alerts related to the configuration of the area.

Figure 41-30 shows the Configure Area dialog for the Default Stamp page.

Figure 41-30 Configure Area Dialog Default Stamp Page



Configure the display characteristics of a marker generated at the point locations. If you need more control, you can combine or replace this with one or more attribute groups. See how.

Location: State

Color:

Pattern:

Opacity: %

□ Include in Legend

Legend Label:

The example below shows the code inserted in the JSF page for the configured area.

```
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="states" id="al1">
    <dvt:areaDataLayer id="dl1"
                       value="#{bindings.TmapStatesView1.collectionModel}"
                       var="row">
      <dvt:areaLocation name="#{row.Name}" id="al2">
        <dvt:area id="a1" fillColor="#ff0000">
          <f:attribute name="legendLabel"
                value="#{Bundle.US_STATES}"/>
        </dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>
```

If you wish to style areas using categorical groups of data in the data collection, use the Attribute Groups page of the Configure Area dialog. For details about using the Attribute Groups page including sample code, see the use case described in How to Create a Thematic Map Using ADF Data Controls.

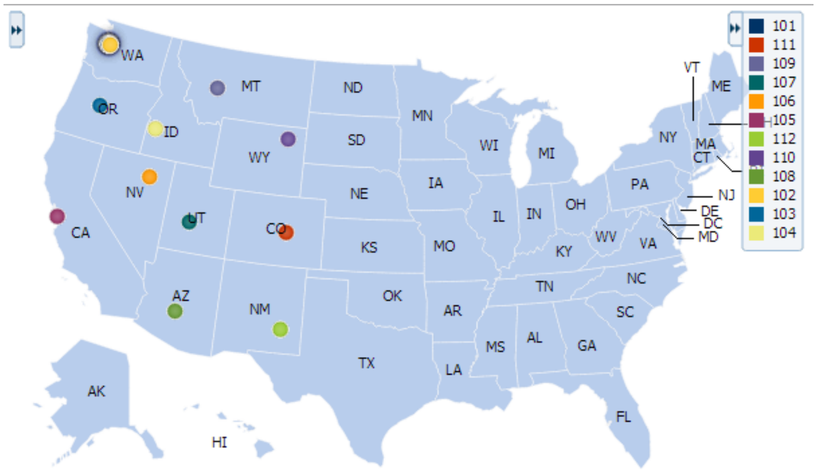
How to Style Markers to Display Data using a Default Stamp

You configure a marker with a default stamp across all markers in the thematic map layer, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the `marker` tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence.

By default, when you add a point data layer, a configurable marker element is added to the Layer Browser. You can use the Layer Browser to add additional areas or markers to an area data layer, or markers to a point data layer. The Layer Browser reflects the logical structure of the map layers, area or point data layers, and areas or markers configured in the thematic map.

For example, using the default stamp, you can identify all the predefined cities in the states layer of the USA base map with a red circle as illustrated in Figure 41-31. In the example, markers are styled on a point data layer. Styling markers on an area data layer is similar.

Figure 41-31   Thematic Map with Marker Default Stamp Configured



Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Creating Databound Thematic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
- Create a data bound thematic map to your JSF page, as described in How to Create a Thematic Map Using ADF Data Controls.

To style markers using a default stamp:

1. In the Layer Browser, select the marker at the point location inside the map layer you are configuring.
2. Click the **Edit** icon.
3. In the Configure Marker dialog, Default Stamp page, enter the following:
   - **Location**: By default, the attribute that represents the column in the data model that determines the location of the data for the markers in the data layer. The locations are Ids of the points from the base map for which the data is being displayed. This read-only field displays the EL expression that maps the stamped marker to a point in the base map. For more information, see What You May Need to Know About Base Map Location Ids.
   - **Color**: Optionally, from the dropdown list select the fill color for the marker. Valid values are RGB hexidecimal. Choose **Custom Color** from the dropdown list to open a Color Picker dialog.
   - **Pattern**: Optionally, from the dropdown list select one of twelve prebuilt patterns to style the marker, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.
   - **Opacity**: Optionally, specify the opacity of the fill color of the marker. Valid values range from **0.0** for transparent to **1.0** for opaque.
   - **Shape**: Optionally, select the shape of the marker. Valid values are **circle** (default), **square**, **plus**, **diamond**, **triangleUp**, **triangleDown**, and **human**.

     Optionally, use the **Custom Shape** field to specify the `shapePath` value to a Scalable Vector Graphics (SVG) file to use for the marker. Enter the path or use the **Search** icon to open the Select SVG File dialog and navigate to the file location. This option is only available if the default shape is selected in the **Shape** field.

     Shapes can also be specified using CSS style properties. Predefined marker shapes can be overwritten, and the paths to SVG files for custom markers can also be defined without using the `shapePath` attribute. For more information, see What You May Need to Know About Styling Markers.
   - **Size**: Optionally, enter a percentage by which to scale the marker from its default size for **ScaleX** (horizontal), and **ScaleY** (vertical). The percentages are then scaled to a float. For example, you can double the marker width by

setting **ScaleX** to `200`, written to the tag as `2.0`, and halve the height by setting **ScaleY** to `50`, written to the tag as `0.5`.

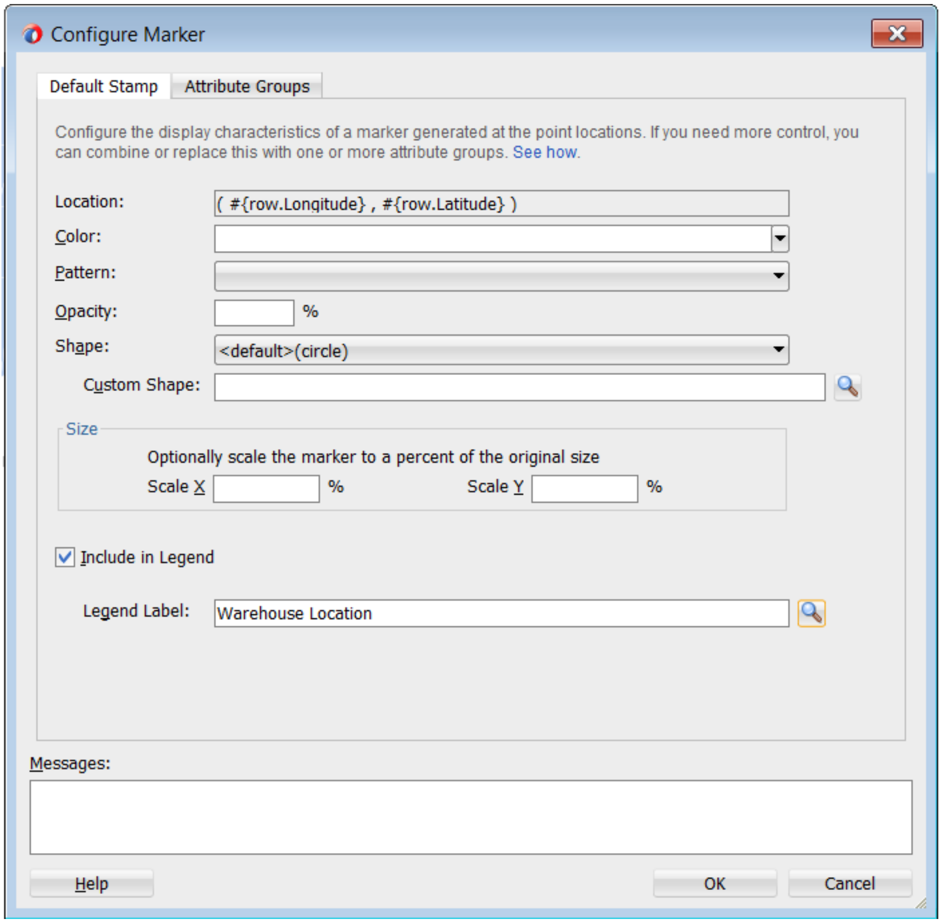
- **Include in Legend**: Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

> **Note:**
>
> the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:
>
> ```
> #{viewController.ResourceBundle[row.label]}
> ```

- **Messages**: Review and clear any messages related to the configuration of the marker.

Figure 41-32 shows the Configure Marker dialog, Default Stamp page.

Figure 41-32   Configure Marker Dialog Default Stamp Page



Configure the display characteristics of a marker generated at the point locations. If you need more control, you can combine or replace this with one or more attribute groups. See how.

Messages:

The example below shows the code inserted in the JSF page for the configured marker.

```
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="states" id="al1">
    <dvt:pointDataLayer id="dl2"
                        value="#{bindings.TmapCitiesView1.collectionModel}"
                        var="row">
      <<dvt:pointLocation type="pointName" pointName="#{row.City}" id="pl1">
        <dvt:marker id="m2" fillColor="#ff0000">
          <f:attribute name="legendLabel"
                value="#{Bundle.US_CITIES}"/>
        </dvt:marker>
      </dvt:pointLocation>
    </dvt:pointDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>
```

How to Style Markers to Display Data using Categorical Groups

You configure a marker with a default stamp across all markers in the thematic map layer, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the `marker` tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence.

If you wish to style markers using categorical groups of data in the data collection, use the Attribute Groups page of the Configure Marker dialog. You can configure markers for a point data layer or an area data layer.

Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Creating Databound Thematic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
- Create a data bound thematic map to your JSF page, as described in How to Create a Thematic Map Using ADF Data Controls.

To style markers using categorical groups of data:

1. In the Layer Browser, select the marker at the marker location inside the map layer you are configuring.
2. Click the **Edit** icon.
3. In the Configure Marker dialog, Attribute Groups page, enter the following:
   - **Grouping Rules**: Use this table to specify the styling of categorical groups of data in a data collection. Use the **Add** icon to add a row to the table

for configuring rules for a categorical group and use the **Delete** icon to remove any row selected in the table. Each grouping rule is represented as a `attributeGroups` component, and assigned a unique, consecutively numbered Id, `ag1`, `ag2`, and so on.

For each row added to the table, enter the following:

- **Group by Value**: Enter or use the dropdown list to select the attribute representing the column in the data set by which you wish to group the data values.

  > **Note:**
  >
  > The selected attribute should consist of discrete values that can be categorized. For example, a range of numeric values between 40 and 45, are not automatically grouped.

- **Marker Properties**: Use the dropdown list to select the property to use for styling that marker. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, **scaleY**, or any combination of these valid values. Choose **Select multiple attributes** from the dropdown list for a dialog to specify any combination of values.

  The default style values that are generated for each property are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the skin, and these can be customized by setting the index-based properties to the desired values. For more information, see What You May Need to Know About Default Style Values for Attribute Groups.

- **Legend Label**: Enter text or use the dropdown list to select the attribute representing the text to use for the categorical group in the thematic map legend. You can also select **Expression Builder** from the dropdown list to create an EL expression to specify the legend text. For more information, see Creating Databound Legends.

- **Value-Specific Rules**: Click to open the **Match Rules** and **Exception Rules** tables used to specify a finer detail for one or more data values for categorical groups in a data set.

  > **Note:**
  >
  > Any match or exception rule specified in these tables will override the settings defined in the **Grouping Rules** table.

- **Match Rules**: Use to specify the style rule matched to one or more data values in a group of data in a data collection. Use the **Add** icon to add a row to the table for configuring a match rule for a categorical group and use the **Delete** icon to remove any row selected in the table. Each match rule is represented as a `attributeMatchRule` component, and assigned a unique, consecutively numbered Id, `amr1`, `amr2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeMatchRule id="amrl" group="Mountain Dew">
  <f:attribute name="color" value="#ffff00"/>
</dvt:attributeMatchRule>
```

For each row added to the table, enter the following:

- **Group Value**: Enter the exact value for the **Group by Value** attribute that will trigger the Match Rule to execute.
- **Property**: Use the dropdown list to select the property to use for styling that data value. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, **scaleY**, or any combination of these valid values. The property selected here must match one of the property types listed in the **Marker Properties** for the attribute **Grouping Rules**.
- **Property Value**: Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

  Valid values for **color** are RGB hexidecimal colors.

  Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

  Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

  Valid values for **scaleX** and **scaleY** are percentages that are then scaled to a float.

- **Exception Rules**: Use to specify one or more exceptions to the style rules for categorical groups in the data set. Use the **Add** icon to add a row to the table for configuring an exception rule and use the **Delete** icon to remove any row selected in the table. Each exception rule is represented as an `attributeExceptionRule` component, and assigned a unique, consecutively numbered Id, `aer1`, `aer2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```
<dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}"
               label="Texas">
  <f:attribute name="color" value="#ff00ff"/>
</dvt:attributeExceptionRule>
```

For each row added to the table, enter the following:

- **Condition**: Enter an EL expression, or use the dropdown list to open an Expression Builder dialog to create an EL expression that replaces the style property value with another when certain conditions are met. For example:

  ```
  #{row.Sales gt 100000}
  ```

- **Property**: Use the dropdown list to select the property to use for styling that data value. Markers can be styled using **color**, **pattern**, **opacity**, **scaleX**, or **scaleY**. The property selected here must match one of the property types listed in the **Marker Properties** for the attribute **Grouping Rules**.
- **Property Value**: Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt

ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp

Valid values for **color** are RGB hexidecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from **0.0** for transparent to **1.0** for opaque.

Valid values for **scaleX** and **scaleY** are percentages that are then scaled to a float.

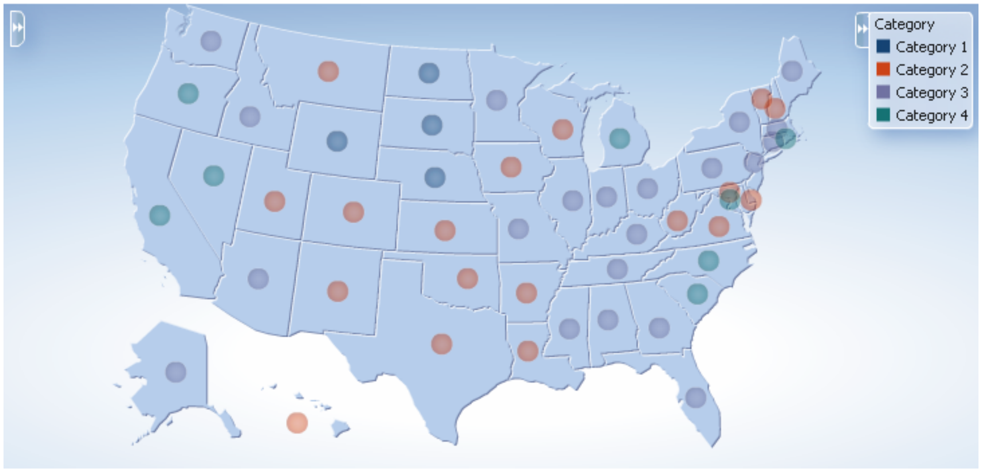
– **Legend Label**: Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

> **Note:**
>
> the text resource option is only available for a fixed area.
> For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:
>
> ```
> #{viewController.ResourceBundle[row.label]}
> ```

- **Messages**: Review and clear as necessary any alerts related to the configuration of the marker.

For example, you can use markers in an area data layer to display categorical groups of data using colors as illustrated in Figure 41-33.

Figure 41-33 Marker Attribute Groups by Color

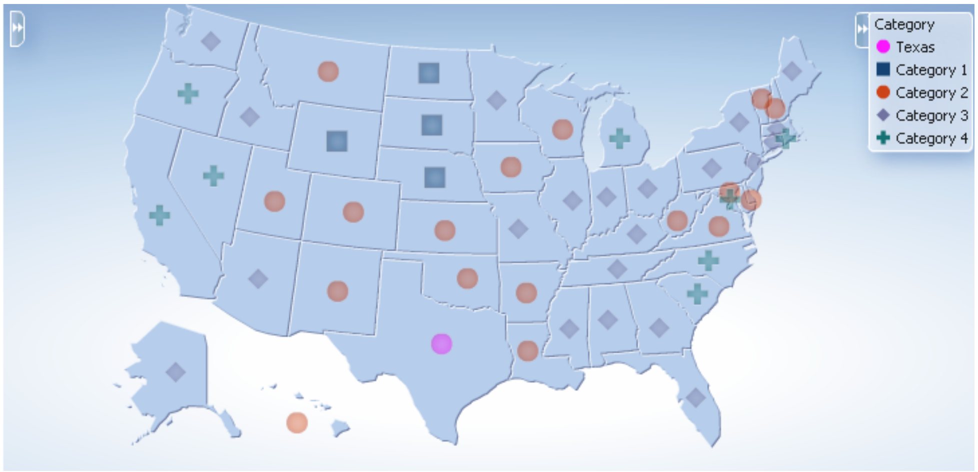


The example below shows the sample code for marker attribute groups by color.

```
<dvt:thematicMap basemap="usa" id="tm1"
  <dvt:areaLayer layer="states" id="al1" labelDisplay="off">
    <dvt:areaDataLayer id="dl1" var="row" value="#{stateData.colorModel}">
      <dvt:areaLocation id="al2" name="#{row.name}">
        <dvt:marker id="m1"
                    scaleX="3.0"
                    scaleY="3.0"
                    shape="circle">
          <dvt:attributeGroups id="ag1" type="color" value="#{row.category}"
                               label="#{row.category}"/>
        </dvt:marker>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:legend id="l1">
    <f:facet name="separator"/>
    <dvt:legendSection id="ls1" label="Category" source="ag1"/>
  </dvt:legend>
</dvt:thematicMap>
```

You can also use markers to display categorical groups of data using multiple attributes such as color and shape, and display an exception to the grouping rules when certain conditions are met. Figure 41-34 shows a thematic map with categorical groups using color and shape with an exception for the state of Texas.

Figure 41-34 Multiple Marker Attribute Groups with Exception Rule



The example below shows sample code for multiple marker attribute groups with exception rule.

```
<dvt:thematicMap basemap="usa" id="tm2"
  <dvt:areaLayer layer="states" id="al1" labelDisplay="off">
    <dvt:areaDataLayer id="dl1" var="row" value="#{stateData.colorModel}">
      <dvt:areaLocation id="al2" name="#{row.name}">
        <dvt:marker id="m1"
               scaleX="3.0"
               scaleY="3.0"
               shape="circle">
          <dvt:attributeGroups id="ag1" type="shape color"
value="#{row.category}"
               label="#{row.category}">
```

```
            <dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}"
               label="Texas">
              <f:attribute name="color" value="#ff00ff"/>
            </dvt:exceptionRule>
          </dvt:attributeGroups>
        </dvt:marker>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:legend id="l1">
    <f:facet name="separator"/>
    <dvt:legendSection id="ls1" label="Category" source="ag1"/>
  </dvt:legend>
</dvt:thematicMap>
```

What You May Need to Know About Styling Markers

Thematic maps support a predefined set of seven shapes (`circle`, `square`, and so on) that can be specified using the `shape` attribute in the `marker` component. For custom markers, the `shapePath` attribute can be used to specify the path of an SVG file that will get displayed in place of a predefined shape.

Scalable Vector Graphics (SVG) is the supported file format for creating custom shapes for thematic map markers.

SVG features that are not supported by custom shapes include:

- Image tags within the SVG file. Everything must be declared using SVG's vector shapes.
- Pattern fills
- Gradients on strokes

Marker shapes can be also specified through CSS style properties in an ADF skin. Using thematic map style properties, predefined marker shapes can be overwritten, and the paths to SVG files for custom markers can be defined without using the `shapePath` attribute. When using style properties, the `shape` attribute in the `marker` component is used for defining both predefined and custom shapes.

A predefined shape will be overwritten if a global or component-specific style property for that shape is specified in the ADF skin. For example, you can overwrite the predefined `circle` shape by specifying the `newCircle.svg` file in the thematic map component style property as follows:

```
af|dvt-thematicMap::shape-circle{
  -tr-path: url(/resources/path/newCircle.svg);
}
```

In the JSF page, the `marker` component `shape` attribute is set as follows:

```
<dvt:marker id="m1" shape="circle"/>
```

To specify a custom shape in the `marker` component `shape` attribute, you must use a prefix of `custom` in the shape style property name. For example, if the custom shape is named `customName`, then the ADF skin file should define either a global `.AFDVTShapeCustomName:alias` style property, or the thematic map specific `af|dvt-thematicMap::shape-customName` with the `-tr-path` property pointing to the SVG file as follows:

```
af|dvt-thematicMap::shape-customName{
  -tr-path: url(/resource/path/newCShape.svg);
}
```

In the JSF page, the marker component shape attribute is set as follows:

```
<dvt:marker id="m1" shape="customName"/>
```

For information about using ADF skins and style properties, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

What You May Need to Know About Default Style Values for Attribute Groups

The `attributeGroups` component is used to generate stylistic property values such as colors or shapes based on categorical grouping of the data in a data collection. Based on the attribute representing the column in the data model to group by, the `attributeGroups` component can generate style values for each unique value, or group, in the data.

The type of stylistic properties to generate values for is specified by the `type` attribute of the `attributeGroups` component. Supported types for `area` components are `color`, `pattern`, and `opacity`. Supported types for `marker` components are `color`, `shape`, `pattern`, `opacity`, `scaleX`, and `scaleY`. These types can be combined in a space-delimited list to generate multiple stylistic properties for each unique data value.

The default style values that are generated are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the ADF skin that can be customized by setting the index-based selectors to the desired values. The example below show sample code for using CSS style properties to specify attribute groups using CSS style properties.

```
af|dvt-attributeGroups::shape1{
  -tr-shape: square;
}
af|dvt-attributeGroups::shape2{
  -tr-shape: square;
}
...
af|dvt-attributeGroups::color1{
  -tr-fill-color: #003366;
}
```

The default ramps for each attribute groups type are displayed in Table 41-2.

Table 41-2 Default Ramps for Thematic Map Attribute Groups

Type	Default Ramps
`color`	j`#003366` (blue), `#CC3300` (red), `#666699` (lavender), `#0006666` (emerald), `#FF9900` (orange yellow), `#993366` (purple), `#99CC33` (lime green), `#624390` (violet,), `#669933` (green), `#FFCC33` (yellow), `#006699` (turquoise blue), and `#EBEA79` (pale yellow).
`shape`	`square`, `circle`, `diamond`, `plus`, `triangleDown`, `triangleUp`, and `human`

Table 41-2 (Cont.) Default Ramps for Thematic Map Attribute Groups

Type	Default Ramps
`pattern`	`smallDiagonalLeft`, `smallDiagonalRight`, `smallTriangle`, `smallChecker`, `smallChecker`, `smallCrosshatch`, `smallDiamond`, `largeDiagonalLeft`, `largeDiagonalRight`, `largeTriangle`, `largeChecker`, `largeCrosshatch`, `largeDiamond`
`opacity`	`0.25`, `0.50`, `0.75`, `1.0`
`scaleX` and `scaleY`	`1.0`, `2.0`, `3.0`, `4.0`, `5.0`

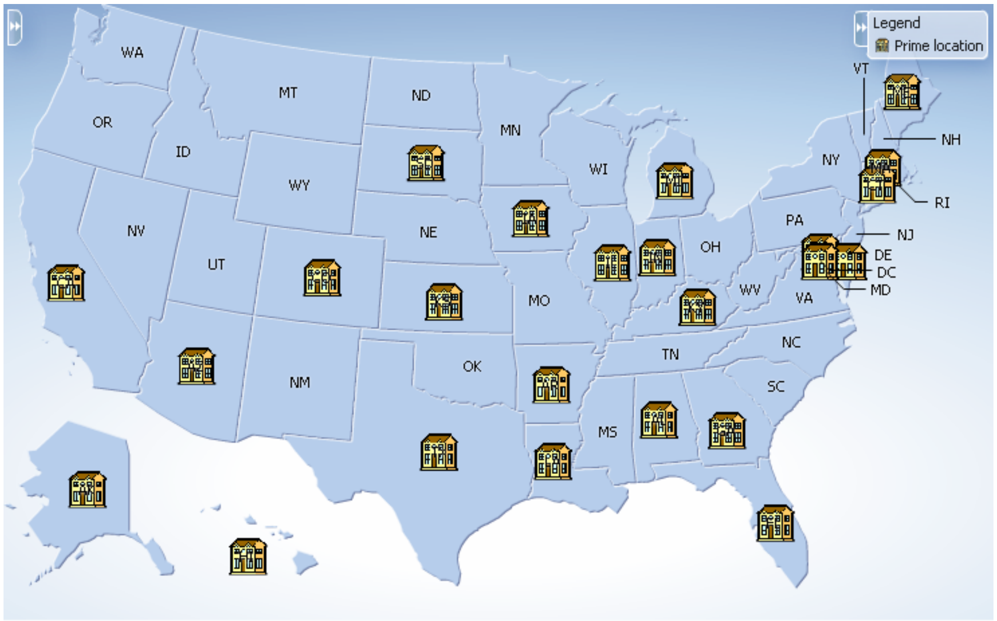
For information about using ADF skins and style properties, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Use Images to Display Data

As an alternative to using built-in or custom shapes to style data in a thematic map, you can use images to represent data. Images can be associated with either an area or point data layer.

For example, in an area data layer you can use a house image to identify prime real estate locations on the states map layer of a US base map as illustrated in Figure 41-35.

Figure 41-35 Thematic Map Styling Data with Images



Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Creating Databound Thematic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
- Create a data bound thematic map to your JSF page, as described in How to Create a Thematic Map Using ADF Data Controls.

To use an image to display data:

1. In the Layer Browser, select the area or point data layer where you are configuring an image to display data.
2. In the Structure window, right-click the area or point data layer child `areaLocation` or `pointLocation` component and select **insert inside dvt:areaLocation** or **insert inside dvt:pointLocation > Image**.
3. In the Insert Image dialog, enter the following:
   - **Source**: Enter the URI specifying the location of the image source. You can use the dropdown menu to choose **Edit** and open an Edit Property: Source dialog or the Expression Builder to specify the location of the image source.
   - **ShortDesc**: Enter the short description of the image used as the `alt` text for screen reader users.

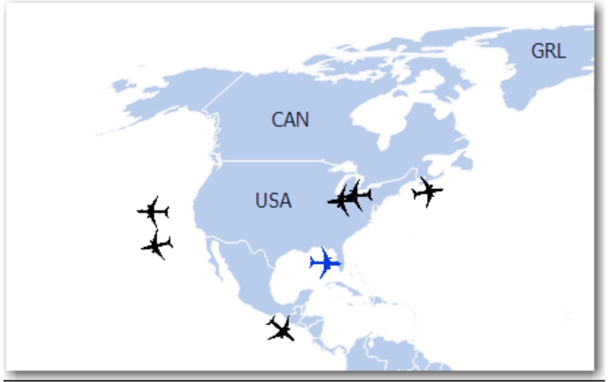
The example below shows a code sample for using images to display data for the thematic map illustrated in Figure 41-35.

```
<dvt:thematicMap id="thematicMap" imageFormat="flash" basemap="usa"
                 summary="Thematic map showing the important real estate
markets">
  <dvt:legend label="Legend">
    <dvt:legendSection source="areaLayer:dataLayer:img1"/>
  </dvt:legend>
  <dvt:areaLayer id="areaLayer" layer="states">
    <dvt:areaDataLayer id="dataLayer" contentDelivery="immediate"
                       value="#{tmapBean.colorModel}"
                       var="row"varStatus="rowStatus">
      <dvt:areaLocation id="dataLoc" name="#{row.name}">
        <af:image id="img1" source="/resources/images/geoMap/mansion.gif"
                            rendered="#{row.category == 'category1'}"
                            shortDesc="House image">
          <f:attribute name="legendLabel" value="Prime location"/>
        </af:image>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>
```

How to Use a Marker Image Source to Display Data

You can configure a marker to use an image file to display data. Separate images can be specified to display user selected and hover states on the thematic map. Support for the rotation of images is also supported when using the `dvt:marker` component. For example, the thematic map in Figure 41-36 represents the locations and tracks of airplane flights, rotating the image as it moves along the track.

Figure 41-36   Thematic Map Flight Tracker



Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Creating Databound Thematic Maps.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
- Create a data bound thematic map to your JSF page, as described in How to Create a Thematic Map Using ADF Data Controls.

To use an marker image source to display data:

1. In the Layer Browser, select the area or point data layer where you are configuring an image to display data.
2. In the Structure window, right-click the area or point data layer child `areaLocation` or `pointLocation` component and select **insert inside Area Location** or **insert inside Point Location > Marker**.
3. In the Structure window, right-click the **dvt:marker** component and choose **Go to Properties**.
4. In the Properties window, expand the **Appearance** section and set the following attributes:
   - **Source**: Enter the URI specifying the location of the image source. You can use the dropdown menu to choose **Edit** and open an Edit Property: Source dialog or the Expression Builder to specify the location of the image resource.

- **SourceHover:** Optionally enter the URI specifying the location of the image resource on hover.
- **SourceHoverSelected:** Optionally enter the URI specifying the location of the selected image resource on hover.
- **SourceSelected**: Optionally enter the URI specifying the location of the image resource on selection.
- **ShortDesc**: Enter the short description of the image used as the `alt` text for screen reader users.

5. Optionally, expand the **Other** section and use the **Rotation** attribute to specify the marker rotation in clockwise degrees around the center of the image.

The example below shows the code sample for the thematic map flight tracker in Figure 41-36.

```
<dvt:thematicMap id="thematicMap" basemap="world" animationOnDisplay="none"
                 tooltipDisplay="auto"
                 summary="flight tracker demo">
  <dvt:areaLayer id="al1" layer="countries">
    <dvt:pointDataLayer id="pdl1" contentDelivery="immediate"
                        value="#{flightTrackerBean.flights}"
                        selectionListener="#{flightTrackerBean.processSelection}"
                        var="row"
                        varStatus="rowStatus"
                        selectionMode="multiple" partialTriggers="::::sbcb1"
                        selectedRowKeys="#{flightTrackerBean.selectedKeys}">
    <dvt:pointLocation id="pl1" type="pointXY" pointX="#{row.currentLongLat.x}"
                       pointY="#{row.currentLongLat.y}">
      <dvt:marker id="m1" labelPosition="bottom" scaleX="3" scaleY="3"
                  rotation="#{row.rotation}"
                  shortDesc="OracleAir#{row.flightNumber}"#{row.flightNumber}"
                  sourceHover="/resources/images/thematicMap/planeHover.png"
                  source="/resources/images/thematicMap/plane.png"
                  sourceSelected="/resources/images/thematicMap/planeSel.png"
                  sourceHoverSelected="/resources/images/thematicMap/
                                      planeHoverSel.png"
                  labelDisplay="#{flightTrackerBean.showFlightNo ? 'on' :
'off'}"
                  value="Flight #{row.flightNumber}"/>
      </dvt:pointLocation>
    </dvt:pointDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>
```

What You May Need to Know About Base Map Location Ids

Each base map provided for the thematic map component has two or more prebuilt map layers that represent a set of regions. For example, the `world` base map includes a map layer for `continents` and another layer for `countries`. The regions in the lower level map layers are aggregated to make up the next level in the geographical hierarchy. The map layer is specified in the `layer` attribute of the `areaLayer` component.

When you are binding your data collection to a thematic map, you must provide a column in the data model that specifies the location of the area or point data using the map location Ids of the regions from the base map for which the data is being displayed. Area locations are specified in the `name` attribute of the `areaLocation` component, and point locations are specified in the pointName attribute for the pointLocation component when its type attribute is set to pointName.

For the United States base map, the locations Ids are determined by the following naming rules:

- country layer: USA
- states layer: Use the two-letter postal abbreviation. For example, the location Id for Massachusetts is MA, and the location Id for Texas is TX.
- counties layer: Use the states layer location Id, followed by an underscore, and then the name of the county, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for Middlesex county in Massachusetts is MA_MIDDLESEX, and the location Id for Red River county in Texas is TX_RED_RIVER.
- cities layer: Use the states layer location Id, followed by an underscore, and then the name of the city, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for the id for Boston, Massachusetts is MA_BOSTON, and the location Id for San Antonio, Texas is TX_SAN_ANTONIO.

For all other base maps, location Ids are determined by the following naming rules:

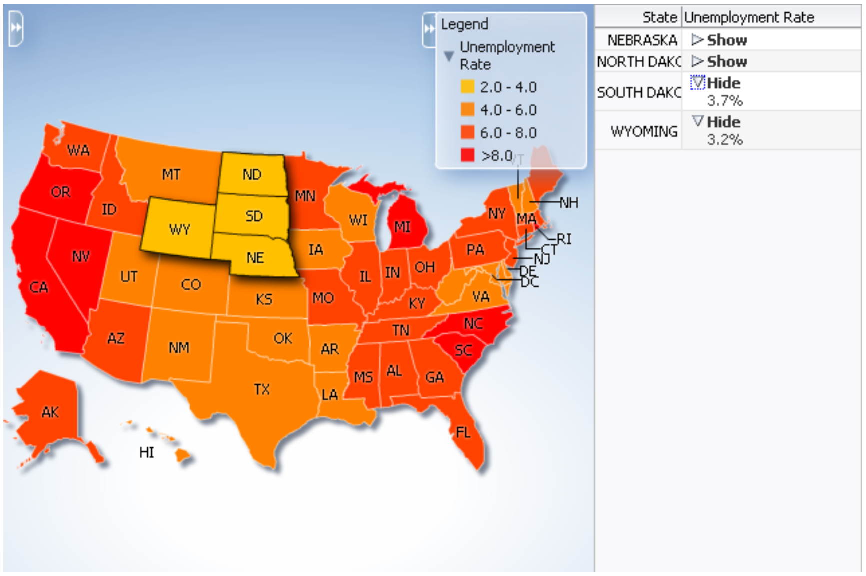
- continents layer: AF (Africa), AS (Asia), AU (Australia), EU (Europe), NA (North America), and SA (South America) for the world, africa, asia, australia, europe, northAmerica, and southAmerica base maps.
- worldRegions layers: APAC (Asia-Pacific), EMEA (Europe and the Middle East), LAT (Latin America), NA (United States and Canada) for the worldRegions, apac, emea, latinAmerica, and usaAndCanada base maps.
- countries layer: Use the ISO 3166-1 alpha-3 country codes. For example, the location Id for Canada is CAN, and the location Id for China is CHN.
- cities layer: Use the three-letter countries location ID, followed by an underscore, and then the name of the city, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for Toronto, Canada is CAN_TORONTO, and the location Id for Los Angeles, United States is USA_LOS_ANGELES.

You can download a comma-separated value (CSV) file for each of the prebuilt map layers with a complete listing of all the thematic map base map location Ids. Find these links in the tag documentation for the areaLocation component, name attribute. To access tag documentation for the data visualization components, select the component in the Structure window and click the help button in the Properties window.

What You May Need to Know About Configuring Master-Detail Relationships

You can configure a thematic map to display its associated data in another UI component on the page such as a table. In this configuration the data collection for the thematic map is a master in a master-detail relationship with a detail view in another UI component. Figure 41-37 shows a thematic map displaying unemployment rates by state. Users can select one or multiple states to display the data detail view in the table.

Figure 41-37 Thematic Map Master and Detail Table View



State	Unemployment Rate
NEBRASKA	▷ **Show**
NORTH DAKC	▷ **Show**
SOUTH DAKC	▽ **Hide** 3.7%
WYOMING	▽ **Hide** 3.2%

The following requirements must be met to achieve this master-detail processing declaratively:

- You must use the same data collection to provide data for both views as follows:
  - Bind the thematic map `areaDataLayer` or `pointDataLayer` to the data collection whose attributes represent the data to be styled by areas or markers in the thematic map layer.
  - Bind the other ADF component (such as a table) to same data collection.
- Select **Set the current row for master-detail** in the Create Data Layer dialog to automatically set a value for the `selectionListener` attribute of the thematic map `areaLayer` component and use the `processSelection` method that is already part of the thematic map binding.

  For example, if the `value` attribute of the thematic map area data layer component is `value="#{stateData.employmentData}"`, then the `selectionListener` attribute is set to:

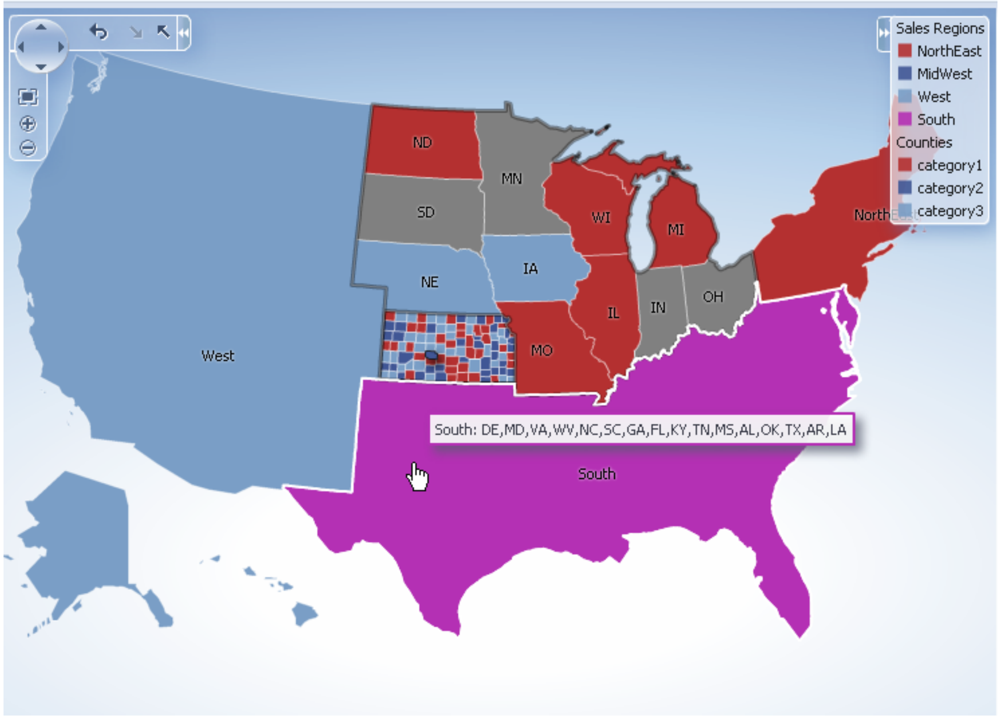
  ```
  selectionListener="#{stateData.employmentData.processSelection}".
  ```
- Ensure that the `selectionMode` attribute on the `areaDataLayer` or `pointDataLayer` component is set to `single` or `multiple`, depending on the requirements for the thematic map.

How to Define a Custom Map Layer

You can define a custom map layer from your own regional data and insert it into the natural geographical hierarchy of a thematic map. The custom layer is created by extending a predefined map layer and aggregating the lower level regions to form the new regions in the custom layer. After defining a custom map layer, it is used in the same way as any other map layer.

For example, you could define geographical regions for the NorthEast, Midwest, West and South in the United States in a US Regions custom map layer as illustrated in Figure 41-38. In the figure, the US Regions custom layer is extended from the states layer in the US base map. The new areas in the layer are aggregated from the states in the states layer. The label for the South US Region lists the states in that region. The MidWest US Region is drilled down to display the sales categories in the lower level counties region. For more information about drilling, see How to Configure Drilling in Thematic Maps.

Figure 41-38 US Regions Custom Map Layer



The `customAreaLayer` component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The `customAreaLayer` will automatically convert the instance into a `CollectionModel`.

Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the Configuring Thematic Maps section in *Developing Web User Interfaces with Oracle ADF Faces*.

You should already have an ADF data control or ADF managed bean that defines the aggregated areas in the predefined base map you are extending.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see How to Create a Thematic Map Using ADF Data Controls.

How to add and configure a custom map layer:

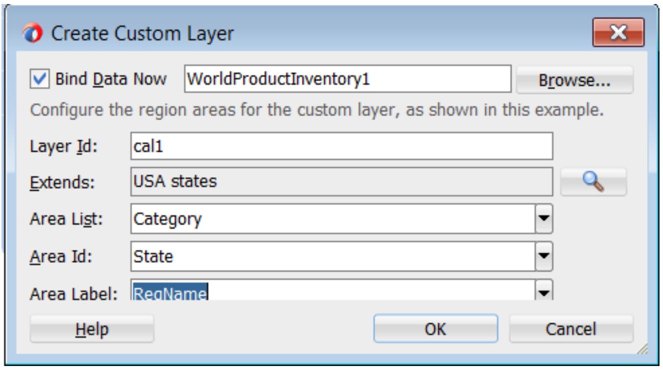
1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, from the **Add** icon dropdown list, choose **Add Custom Layer**. If the Layer Browser is not open in the Visual Editor, right-click in the map and choose **Open Layer Browser**.
3. In the Create Custom Layer dialog, enter the following:
   - **Bind Data Now**: Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your custom layer and areas.

     > **Note:**
     >
     > Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your custom layer and areas. You can also use the Expression Builder dialog in each remaining field.

   - **Layer Id**: Enter a unique identifier for the `customAreaLayer` component. For example, if you divide the US into aggregate regions (Northeast, Midwest, West, and South), then you might define them with corresponding Ids (NE, MW, W, and S).
   - **Extends**: Use the search icon to display the built-in map layers that can be used to aggregate areas for the custom layer. Select the map layer that the custom layer will extend.
   - **Area List**: Use the dropdown list to select the data collection attribute representing the list of lower level map regions that are used to aggregate the areas in the custom map layer. The comma separated list of values aggregate the regions in the may layer defined in the in the **Extends** attribute.
   - **Area Id**: Use the dropdown list to select the data collection attribute representing the unique identifier of lower level map regions that are used to aggregate the areas in the custom map layer. By default, a unique identifier, `ca1, ca2`, and so on, is used in the for the `customArea` component.
   - **Area Label**: Use the dropdown list to select the data collection attribute representing the names of lower level map regions that are used to aggregate the areas in the custom map layer. At runtime the label will display the comma separated list of the aggregated regions.

Figure 41-39 shows the completed Create Custom Layer dialog.

Figure 41-39   Create Custom Layer Dialog



☑ Bind Data Now: WorldProductInventory1

Configure the region areas for the custom layer, as shown in this example.

Layer Id: cal1

Extends: USA states

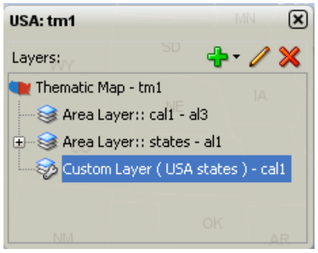
Area List: Category

Area Id: State

Area Label: RegName

[Figure 41-40](#) shows the Layer Browser after defining a custom layer. In the layer structure, the custom layer `cal1` is referenced in the map layer `al1`, where you add area or point data layers to display data. For more information, see [How to Add Data Layers to Thematic Maps](#).

Figure 41-40   Custom Map Layer in Layer Browser



USA: tm1

Layers:

- Thematic Map - tm1
  - Area Layer:: cal1 - al3
  - Area Layer:: states - al1
  - Custom Layer (USA states) - cal1

The example below shows the code inserted in the JSF page

```
<dvt:thematicMap>
...
  <dvt:areaLayer layer="states" id="al1"/>
  <dvt:areaLayer layer="cal1" id="al3"/>
  <dvt:customAreaLayer id="cal1"
                       value="#{bindings.TmapStatesView.collectionModel}"
                       var="row"
                       extendsLayer="states">
    <dvt:customArea areaId="#{row.RowID}" areaList="#{row.RowID}"
                    label="#{row.RowID}" id="ca1"/>
  </dvt:customAreaLayer>
...
 </dvt:thematicMap>
```

After configuring and adding a custom layer to the map layer hierarchy, you can then use the map layer in the same way as any other map layer. For example, to create the thematic map illustrated in [Figure 41-38](#), you will need to do the following:

- Configure the thematic map to support drilling. For more information, see [How to Configure Drilling in Thematic Maps](#).

> **Note:**
>
> If drilling is enabled for the thematic map, drilling between a custom layer and the map layer used to aggregate the custom layer is available without configuring data display for either layer.

- Add and configure an area data layer for the county data view. For more information, see How to Add Data Layers to Thematic Maps.
- Add and style area components to display the related data for each map layer. For more information, see Styling Areas, Markers, and Images to Display Data.
- Configure the thematic map legend. For more information, see Creating Databound Legends.

The example below shows sample code for using a custom layer in a thematic map.

```
<dvt:thematicMap id="thematicMap" imageFormat="flash" basemap="usa" drilling="on"
                 maintainDrill="true"
                 controlPanelBehavior="initExpanded" summary="US Custom Regions">
  <dvt:customAreaLayer id="crl1" value="#{tmapRegions.collectionModel}" var="row"
                       varStatus="rowStatus"
                       extendsLayer="states">
    <dvt:customArea areaId="#{row.name}" label="#{row.name}"
                    areaList="#{row.regions}" id="ca1"/>
  </dvt:customAreaLayer>
  <dvt:areaLayer id="custom" layer="crl1">
    <dvt:areaDataLayer contentDelivery="immediate"
                       value="#{tmapRegions.collectionModel}"
                       selectionMode="single"
                       var="row" varStatus="rowStatus" id="adl1">
      <dvt:areaLocation name="#{row.name}" id="al1">
        <dvt:area fillColor="#{row.color}" shortDesc="#{row.regions}"
                  id="a1" value="#{row.name}"/>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:areaLayer id="areaLayerS" layer="states"
    <dvt:areaDataLayer id="dataLayerS" selectionMode="multiple"
                       contentDelivery="immediate"
                       value="#{tmapStates.collectionModel}" var="row"
                       varStatus="rowStatus">
      <dvt:areaLocation id="areaLocS" name="#{row.name}">
        <dvt:area id="area1S" fillColor="#{row.color}"></dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:areaLayer id="areaLayer" layer="counties">
    <dvt:areaDataLayer id="dataLayer" selectionMode="single"
                       contentDelivery="immediate"
                       value="#{tmapCounty.collectionModel}" var="row"
                       varStatus="rowStatus">
      <dvt:areaLocation id="areaLoc" name="#{row.name}">
        <dvt:area id="area1" fillColor="#{row.color}"
                        value="#{row.category}"></dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:legend label="Sales Regions" id="l1">
```

```
    <dvt:legendSection source="custom:adl1:a1" id="ls1"/>
    <dvt:legendSection label="Counties" source="areaLayer:dataLayer:areaLoc"
                       id="ls3"/>
  </dvt:legend>
</dvt:thematicMap>
```

How to Configure Drilling in Thematic Maps

A thematic map with related data views in different map layers can be configured for drilling between the higher and lower level data views. For example, a thematic map can display data for sales category by USA state drilled down to USA county data as illustrated in Figure 41-38. When a state or county is selected, drilling up or down is initiated through a context menu choice or the Control Panel.

The following requirements must be met to achieve thematic map area drilling declaratively:

- For each map layer (`areaLayer`) in the drilling hierarchy, you must bind its child `areaDataLayer` with a data control that defines the related data for that map layer.
- Each `areaDataLayer` in the map layer drill hierarchy must have its `selectionMode` attribute set to `single` or `multiple`.
- You must configure the `area` in the lower level map layer drill hierarchy to display data using the same default stamp or categorical attribute style used in the higher level map layer `area` component.
- The `thematicMap` component `drilling` attribute must be set to `on`.

> **Note:**
>
> If drilling is enabled for the thematic map, drilling between a custom layer and the map layer used to aggregate the custom layer is available.

Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the Configuring Thematic Maps section in *Developing Web User Interfaces with Oracle ADF Faces*.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see How to Create a Thematic Map Using ADF Data Controls.

You should already have data controls that define the data model for each of the map layers in the drill hierarchy.

To configure a thematic map area for drilling:

1. In the Structure window, select the **dvt:thematicMap** component.
2. In the Properties window, expand the **Behavior** section. Use this section to set the following attributes:

- **Drilling**: Use to enable drilling the area data view between thematic map layers. From the dropdown list select **on** to enable drilling. The default value is **off**.
- **MaintainDrill**: Optionally, use to specify an optional **true** value for maintaining the drilled state of a previously drilled area when a new area is drilled. The default value is **false**.
- **DrillBehavior**: Optionally, use to specify an optional **zoomToFit** effect on the area being drilled. The default value is **none**.

3. In the Layer Browser, select each **Area Layer** component in the desired drilling hierarchy and do the following:
   - Click the **Add icon** and choose **Add Data Layer** to open the Create Data Layer dialog. Complete the dialog to add an area data layer and bind the data layer to the data control for that map layer. If you need help, press F1 or click **Help**.

     > **Note:**
     >
     > If the **Area Data Layer** is already present, click the **Edit icon** to confirm binding to the data control.

   - In the Properties window, expand the **Behavior** section and set the **SelectionMode** attribute to **single** or **multiple**.
4. In the Layer Browser, select each **Area Data Layer** component in the desired drilling hierarchy and do the following:
   - Click the **Add icon** and choose **Add Area** to open the Configure Area dialog. Complete the dialog to define a default stamp or use attribute groups to style the area for that map layer. If you need help, press F1 or click **Help**.

     > **Note:**
     >
     > If the **Area** is already present, click the **Edit icon** to confirm the styling of the area.

Figure 41-40 shows sample code for drilling enabled for USA states and counties map layers with an area styled to display data about sales categories.

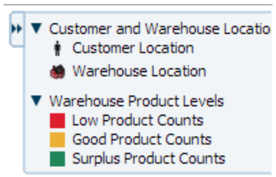
```
<dvt:thematicMap id="thematicMap"
                 basemap="usa"
                 drilling="on"
                 maintainDrill="true"
                 drillBehavior="zoomToFit"
                 animationOnDisplay="none"
  <dvt:areaLayer id="al1" layer="states">
    <dvt:areaDataLayer id="adl1"
                       selectionMode="single"
                       contentDeliver="immediate"
                       value="#{row.state}"
                       var="row"
                       var="rowStatus">
      <dvt:areaLocation id="areaLocS" name="#{row.stname}">
```

```
        <dvt:area id="a1" fillColor="#{row.state}"/>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:areaLayer id="al2" layer="counties">
    <dvt:areaDataLayer id="adl2"
                       selectionMode="single"
                       contentDelivery="immediate"
                       value="#{row.county}"
                       var="row"
                       varStatus="rowStatus">
      <dvt:areaLocation id="areaLocC" name="#{row.coname}">
        <dvt:area id="a2" fillColor="#{row.county}"/>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
...
</dvt:thematicMap>
```

Creating Databound Legends

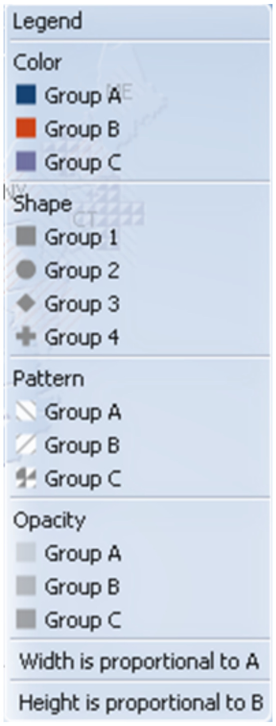
Legends provide an explanatory table of the thematic map's styled data in symbol and label pairs. Thematic map legend components (`legend`) support symbols for color, shape, custom shape, fill pattern, opacity, images and size. One or more child legend item components (`legendSection`) are sourced from thematic map `area`, `marker`, `attributeGroups`, or `af:image` components stamped to style the data displayed in the map. The legend section structure supports control over content ordering and appearance. You can wrap legend items into a disclosable section using a `showLegendSection` component. Figure 41-41 shows a legend with a disclosable section for map areas and a marker.

Figure 41-41   Legend with Disclosable Section and Marker



Legend items sourced from the `attributeGroups` component automatically split area or marker attribute types into different sections. You can specify a separator facet to draw separators between legend sections. Figure 41-42 shows a legend with attribute groups for color, shape, fill pattern, opacity, and size with separators between each section.

Figure 41-42   Legend with Attribute Groups



Legend

Color
- ■ Group A
- ■ Group B
- ■ Group C

Shape
- ■ Group 1
- ● Group 2
- ◆ Group 3
- ✚ Group 4

Pattern
- ▨ Group A
- ▨ Group B
- ▨ Group C

Opacity
- ■ Group A
- ■ Group B
- ■ Group C

Width is proportional to A

Height is proportional to B

Legends can be displayed in both Flash (default) and PNG image formats and both formats support locales with right-to-left display. When rendered in a PNG format, for example when printing the thematic map, disclosable sections in the legend are not supported, and legend items display as disclosed.

When you create a thematic map using the Data Controls panel and the thematic map binding dialogs, the legend data bindings are created for you. If you configure an area or marker as a default stamp across all areas in the thematic map, you can assign a static text resource to a fixed area or marker for the legend.

For default stamps displaying row-varying data, you can use an EL expression to assign the legend text and optionally, a managed bean to retrieve a row-varying key to look up the text resource in a resource bundle. The example below shows a code sample to generate legend entries for area and marker stamps. The code illustrates a disclosable section for a row-varying area and a fixed marker with an assigned text resource.

```
<dvt:thematicMap id="tm1" basemap="usa" ...>
  <dvt:legend label=“Legend“>
    <dvt:showLegendGroupLabel label="Voting Majority">
      <dvt:legendSection id="ls1" source="al1:adl1:areaStamp“/>
    </dvt:showLegendGroupLabel>
    <dvt:legendSection id="ls2" source="al1:adl1:fixedMarker">
  </dvt:legend>
  <dvt:areaLayer id="al1" layer="states">
    <dvt:areaDataLayer id="adl1"...>
      <dvt:areaLocation id="aloc1" ,,,>
        <dvt:area id="areaStamp">
                  fillColor="#{row.value > 50 ? tmapLegendBean,color1 :
                  tmapLegendBean.color2}"
          <f:attribute name="legendLabel" value="#{row.value > 50 ?
```

```
                          'Candidate 2' : 'Candidate 1'}" />
        <dvt:marker id=“fixedMarker“ shape=“human" fillColor=“"#FF9900"
                                     scaleX="3" scaleY="3">
          <f:attribute name="legendLabel“
                       value="#{Bundle.Office_Locations}"/>
        </dvt:marker>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:area>
</dvt:thematicMap>
```

If you configure an area or marker to use an attributes group to specify the styling of categorical groups of data in a data collection, you can use an EL expression to assign the legend text and optionally, a managed bean to retrieve a row-varying key to look up the text resource in a resource bundle.

If you specify a match rule for the attributes group, the legend text is specified in the `group` attribute. If you specify an exception rule, you can specify a text resource from the application resource bundle. The example below shows sample code for a legend with attribute groups, including both a match rule and an exception rule, and specifying a separator between legend sections.

```
<dvt:thematicMap id="tm1" basemap="usa" ...>
  <dvt:legend id="l1" label="Legend">
    <f:facet name="separator"
      <af:separator/>
    <dvt:legendSection id="ls1" source="al1:adl1:attributeGroupColor" />
    <dvt:legendSection id="ls2" source="al1:adl1:attributeGroupShape" />
    <dvt:legendSection id="ls3" source="al1:adl1:attributeGroupPattern" />
    <dvt:legendSection id="ls4" source="al1:adl1:attributeGroupOpacity" />>
  </dvt:legend>
  <dvt:areaLayer id="al1" layer="states">
    <dvt:areaDataLayer id="adl1" value=" " var=" " ...>
      <dvt:areaLocation id="dataLoc" name="#{row.name}">
        <dvt:marker id="m1"... >
          <dvt:attributeGroups id="attributeGroupColor" type="color"
                 label="#{row.category1}" value="#{row.category1}" />
            <dvt:attributeMatchRule id="amrl" group="Mountain Dew">
              <f:attribute name="color" value="#ffff00"/>
          </dvt:attributeMatchRule>
          <dvt:attributeGroups id="attributeGroupShape" type="shape"
                 label="#{row.category2}" value="#{row.category2}" />
            <dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}"
                 label="#{viewcontroller.Texas}">
              <f:attribute name="shape" value="human"/>
            </dvt:exceptionRule>
          <dvt:attributeGroups id="attributeGroupShape" type="pattern"
                 label="#{row.category3}" ... />
          <dvt:attributeGroups id="attributeGroupShape" type="opacity"
                 label="#{row.category4}" ... />
        </dvt:marker>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>
```

You configure thematic map legend areas or markers in a custom region in the same way as any other map layer. shows sample code for a custom map layer legend.

```
<dvt:thematicMap>
  <dvt:legend>
```

```
    <dvt:legendSection label=“Sales Regions" source="customAreaStamp"/>
      </dvt:legend>
      ...
  <dvt:customAreaLayer id="crl1“>
  ...
  </dvt:customAreaLayer>
  <dvt:areaLayer layer="crl1">
    <dvt:areaDataLayer var="row">
      <dvt:areaLocation name="#{row.name}" id="al1">
        <dvt:area id=“customAreaStamp" fillColor="#{row.color}“>
          <f:attribute name="legendLabel“ value=“#{row.name}"/>
        </dvt:area>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap
```

You can customize the appearance of thematic map legends using ADF skins. For more information, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*

42

Creating Databound Gantt Chart and Timeline Components

This chapter describes how to create Gantt charts and timelines from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization `projectGantt`, `resourceUtilizationGantt`, `schedulingGantt`, and `timeline` components to create Gantt charts and timelines that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.
If you are designing your page using simple UI-first development, then you can add the Gantt chart or timeline to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the Gantt chart and timeline components, see the Using Gantt Chart Components and Using Timeline Components chapters in *Developing Web User Interfaces with Oracle ADF Faces*.

This chapter includes the following sections:

About ADF Data Visualization Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the component is dictated by the data that is displayed.

There are three types of ADF Gantt chart components; a project Gantt chart used for project management, a scheduling Gantt chart used for resource scheduling, and a resource utilization Gantt chart used for displaying resource metrics. All Gantt charts display two regions combined with a splitter. The list region displays a list of tasks or resources, and the chart region displays task progress, resource utilization, or resource progress graphed over time.

The ADF timeline is an interactive data visualization tool that allows users to view events in chronological order and easily navigate forwards and backwards within a defined time range. Events are represented as timeline items using simple ADF components to display information such as text and images, or supply actions such a links. A dual timeline can be configured to display two series of events to allow a side-by-side comparison of related information.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

Data Visualization Components Use Cases and Examples

For detailed descriptions of each data visualization use cases and examples, see the following:

- Gantt chart components: Gantt Chart Component Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Timeline components: Timeline Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.

End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the following:

- Gantt chart components: End User and Presentation Features section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Timeline components: End User and Presentation Features section in *Developing Web User Interfaces with Oracle ADF Faces*.

Additional Functionality for Data Visualization Components

You may find it helpful to understand other **Oracle ADF** features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the Rerendering Partial Page Content chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the Allowing User Customization on JSF Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: By default, data visualization components are accessible. You can make your application pages available to screen readers. For more information, see the Developing Accessible ADF Faces Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages

before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls.

Creating Databound Gantt Charts

A Gantt chart is a type of bar chart displayed on the horizontal axis. It is used in planning and tracking projects to show tasks or resources in a time frame with a distinct beginning and end.

When you create a Gantt chart, you can choose from the following types:

- Project

  A project Gantt chart lists tasks vertically and shows the duration of each task as a bar on a horizontal time line.

- Resource Utilization

  A resource utilization Gantt chart shows graphically whether resources are over or under allocated. It shows resources vertically while showing their allocation and, optionally, capacity on the horizontal time axis.

- Scheduling

  A scheduling Gantt chart is based on manual scheduling boards and shows resources vertically with corresponding activities on the horizontal time axis. Examples of resources include people, machines, or rooms.

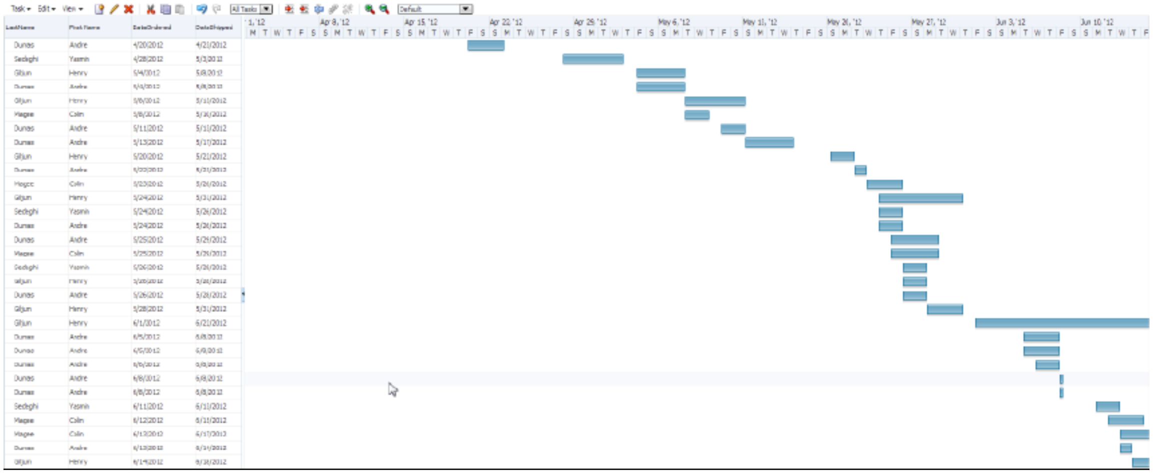
How to Create a Databound Project Gantt Chart

For a project Gantt chart, you must specify values for tasks. Optionally, you can specify values for split tasks, subtasks, recurring tasks, and dependencies between tasks, if your data collection has accessors for this additional information.

The project Gantt chart is displayed with default values for overall start time and end time and for the major and minor time axis values. In a project Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 42-1 shows a project Gantt chart in which each task is an order to be filled. The list region on the left side of the splitter shows columns with the name of the person responsible for the order and columns for the order date and ship date. In the chart region on the right side of the splitter, the Gantt chart displays a horizontal bar from the order date to the ship date for each order.

Figure 42-1 Project Gantt Chart for Orders Shipped



LastName	FirstName	DateOrdered	DateShipped
Dumas	Andre	4/20/2012	4/21/2012
Sedeghi	Yasmin	4/28/2012	5/3/2012

Giljun	Henry	6/14/2012	6/18/2012

To create a project Gantt chart using a data control, bind the project Gantt chart component to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

> **Tip:**
>
> You can also create a project Gantt chart by dragging a project Gantt chart component from the Components window and completing the Create Project Gantt dialog. This approach allows you to design the Gantt chart user interface before binding the component to data.

Before you begin:

It may be helpful to have an understanding of databound Gantt charts. For more information, see Creating Databound Gantt Charts.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an **application module** that contains instances of the **view objects** that you want in your data model, as described in Creating and Modifying an Application Module.

  For example, the data source for the project Gantt chart in Figure 42-1 comes from a view object representing shipping orders including their shipping and delivery dates, in the Summit sample application for ADF DVT components.

- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a project Gantt chart using the Data Controls panel:

1. From the Data Controls panel, select a data collection. Select a row set collection that produces a flat list of tasks, or a basic tree collection that produces a hierarchical list of tasks.

   Figure 42-2 shows an example where you could select the `OrderEmployee1` collection in the Data Controls panel to create a project Gantt chart that displays the progress of order shipping.

   Figure 42-2 Data Collection for Shipping Orders

   
   Data Controls
   - OrderEmployee1
     - DateOrdered
     - DateShipped
     - FirstName
     - Id
     - Id1
     - LastName
     - TitleId
     - Operations
     - Named Criteria

2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt** > **Project**.
3. In the Create Project Gantt dialog, in the **Tasks** page, select the columns in the data collection that correspond to the following attributes:
   - **Task Id**: The unique Id for the tasks represented in the Gantt chart.
   - **Start Time**: The starting time of the task.
   - **End Time**: The ending time of the task.
   - **Task Type**: The type used to specify the appearance of the task bar when it is rendered in the Gantt chart. If you do not bind the type to a column in your data collection, then all tasks default to `Normal`. Task types include:
     - `Normal`: The basic task type, a plain horizontal bar that shows the start time, end time, and duration of the task.
     - `Summary`: Shows start time and end time for a group of tasks, typically subtasks. A summary task cannot be moved or extended. However, your application should recalculate the summary task times when the dates of any subtask changes.
     - `Milestone`: Shows a specific date in the Gantt chart. There is only one date associated with a milestone task. A milestone task cannot be extended but it can be moved.
4. Click **Show More** to select additional columns in the data collection that correspond to the following attributes for the specified task type:
   - **Actual Start** and **Actual End**: When these attributes are specified, instead of drawing one bar, two bars are drawn. One bar indicates the base start and end date, the other bar indicates the actual start and end date. This is applicable to normal and milestone task types.
   - **% Complete**: When specified, an additional inner bar is drawn to indicate the percentage complete for the task.
   - **Completed Through**: Allows you to specify a date rather than a percentage. When specified, an additional inner bar is drawn to indicate the percentage complete based on the date that the attribute references.

- **Critical**: Changes the color of the bar to red to mark it as critical. This is applicable to normal, summary, and milestone task types.
- **Edits Allowed**: Boolean value to specify if the task start date, end date, or duration is supported in the chart region.
- **Is Container**: Boolean value to specify if the node definition is a container.

5. If the data collection has an accessor for subtasks, use the **Subtasks** page to select the **Subtasks Accessor** from the dropdown list, and then the columns in the data collection that correspond to the following attributes:

   - **Subtask ID**: The unique Id for the list of subtasks in the data collection.
   - **Start Time**: The starting time of the subtask.
   - **End Time**: The ending time of the subtask.
   - **Subtask Type**: The type used to specify the appearance of the subtask bar when it is rendered in the Gantt chart. If you do not bind the type to a column in your data collection, then all tasks default to `Normal`. Task types include:
     - `Normal`: The basic task type, a plain horizontal bar that shows the start time, end time, and duration of the task.
     - `Summary`: Shows start time and end time for a group of tasks, typically subtasks. A summary task cannot be moved or extended. However, your application should recalculate the summary task times when the dates of any subtask changes.
     - `Milestone`: Shows a specific date in the Gantt chart. There is only one date associated with a milestone task. A milestone task cannot be extended but it can be moved.

   If you do not bind subtasks, then the Gantt chart cannot render a hierarchy view of tasks. If you bind subtasks, you can drill from tasks to subtasks in the hierarchy view of the Gantt chart.

6. If the data collection has an accessor for dependent tasks, use the Dependent Tasks page to select the **Dependent Task** accessor from the dropdown list, and then the columns in the data collection that correspond to the following attributes:

   - **Dependency Type**: Specifies the type of the dependency. Valid values are `start-start`, `start-finish`, `finish-finish`, `finish-start`, `start-before`, `start-together`, `finish-after`, and `finish-together`.
   - **From Task Id**: Specifies the first task in the dependent relationship.
   - **To Task Id**: Specifies the last task in the dependent relationship.

7. If the data collection has an accessor for split tasks, use the **Split Tasks** page to select the **Split Task** accessor from the dropdown list, and then the columns in the data collection that correspond to the following attributes:

   - **Split Task Id**: The unique Id for a task split into two horizontal bars, usually linked by a line. The time between the bars represents idle time due to traveling or down time.
   - **Start Time**: The starting time of the split task.
   - **End Time**: The ending time of the split task.

8. If the data collection has an accessor for recurring tasks, use the **Recurring Tasks** page to select the **Recurring Tasks** accessor from the dropdown list, and then the columns in the data collection that correspond to the following attributes:

- **Recurring Task Id**: A unique Id for a task repeated in a Gantt chart, each instance with its own start and end date. Individual recurring tasks can optionally contain a subtype. All other properties of the individual recurring tasks come from the task which they are part of. However, if an individual recurring task has a subtype, this subtype overrides the task type.
- **Type**: Specifies the type of the recurring task.
- **Start Time**: The starting time of the recurring task.
- **End Time**: The ending time of the recurring task.

9. In the **Appearance** page, specify the attributes that correspond to the **Label** of the task bar, and up to three icons to associate with the task bar.
10. In the **Table Columns** section, specify the columns to display for each row in the list region of the Gantt chart. Use the **New** icon to add new rows, the **Delete** icon to remove rows, and the arrow icons to arrange the rows in the sequence that you want the columns to appear in the Gantt chart list.

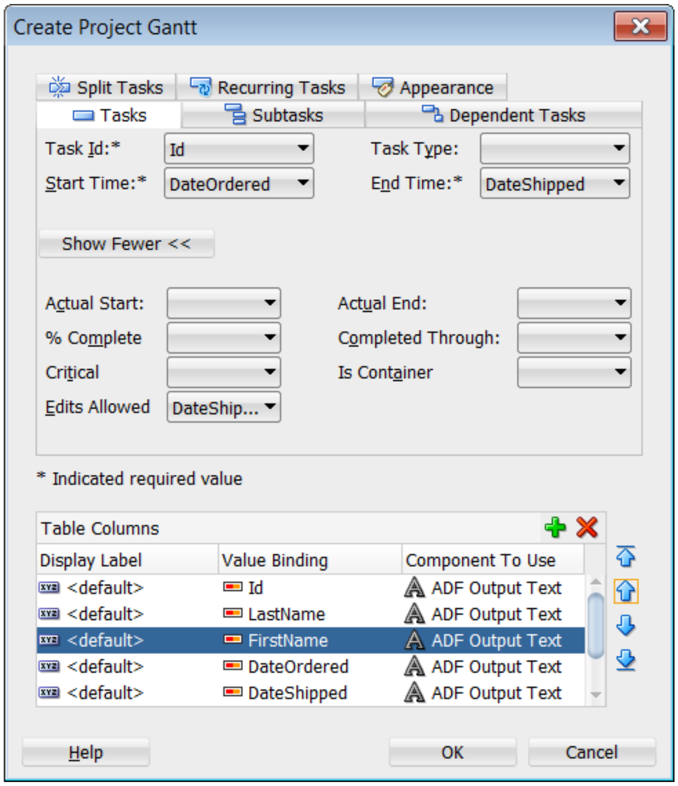
   > **Note:**
   >
   > The first row that you specify in the **Table Columns** section designates the `nodestamp` column for the list region. If you specify a subtask accessor, this row is used as the parent in a hierarchical relationship that can be expanded or collapsed.

   For each row, specify the following:

   - **Display Label**: Select the values for the headers of the columns in the Gantt chart list. If you select **<default>**, the text for the header is automatically retrieved from the data binding.
   - **Value Binding**: Select the columns in the data collection to use for the columns in the Gantt chart list. The available values are the same as those for the tasks group.
   - **Component to Use**: Select the type of component to display in the cell of the Gantt chart list. You can specify that a cell is editable by using an ADF input component. The default is the ADF Output Text component.
11. Click **OK**.

   Figure 42-3 shows the dialog used to create the project Gantt chart in Figure 42-1 from the data collection for shipping orders.

Figure 42-3 Create Project Gantt Dialog for Orders Shipped



Task Id:* Id

Task Type:

Start Time:* DateOrdered

End Time:* DateShipped

Actual Start:

Actual End:

% Complete

Completed Through:

Critical

Is Container

Edits Allowed DateShip...

* Indicated required value

Table Columns

Display Label	Value Binding	Component To Use
<default>	Id	ADF Output Text
<default>	LastName	ADF Output Text
<default>	FirstName	ADF Output Text
<default>	DateOrdered	ADF Output Text
<default>	DateShipped	ADF Output Text

12. In the Structure window, right-click the `dvt:projectGantt` component and select **Go to Properties**.

13. In the Properties window, expand the **Common** section, and specify the dates (`yyyy-mm-dd`) for the **StartTime** and **EndTime** attributes representing the start and end dates respectively for the time period of the Gantt chart data.

    The dates that you specify determine the initial view that appears in the project Gantt chart at runtime.

14. If you want to include a legend in the Gantt chart, right-click the project Gantt chart node in the Structure window and choose **Insert Inside Project Gantt** > **Legend**.

    The legend shows information about each symbol and color coded bar used to represent different task types. It also shows detailed information about the task selected in the Gantt chart.

After creating the project Gantt chart, use the Properties window to specify values for additional attributes. For detailed information about Gantt chart use cases, end user and presentation features, tag structure, and adding special features to Gantt charts, see the Using Gantt Chart Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Create a Project Gantt Chart from a Data Control

Dragging and dropping a view object from the Data Controls panel to create a project Gantt chart has the following effect:

- Creates the bindings for the Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

The example below displays the row set bindings generated for the project Gantt chart in Figure 42-1 to display shipped orders. This code example shows the node defined for tasks with attributes for task Id, start date, and end dates. There are also nodes defined for subtasks, dependent tasks, split tasks, and recurring tasks with no defined attributes.

```
<bindings>
  <gantt IterBinding="OrderEmployee1Iterator" id="OrderEmployee1"
         xmlns="http://xmlns.oracle.com/adfm/dvt">    <ganttDataMap>
<nodeDefinition DefName="model.OrderEmployee" type="Tasks">        <AttrNames>
          <Item Value="TaskId" type="taskId"/>
          <Item Value="StartDate" type="startTime"/>
          <Item Value="EndDate" type="endTime"/>
          <Item Value="TaskType" type="taskType"/>
        </AttrNames>
      </nodeDefinition>
      <nodeDefinition type="subTasks">
        <AttrNames/>
      </nodeDefinition>
      <nodeDefinition type="Dependents">
        <AttrNames/>
      </nodeDefinition>
      <nodeDefinition type="SplitTasks">
        <AttrNames/>
      </nodeDefinition>
      <nodeDefinition type="RecurringTasks">
        <AttrNames/>
      </nodeDefinition>
  </ganttDataMap>
 </gantt>
</bindings>
```

The example below shows the code generated on the JSF page for the project Gantt chart. This tag code contains settings for the overall start and end time for the project Gantt chart. It also shows the default time axis settings for the major axis in weeks and the minor axis in days. Finally, it lists the specifications for each column that appears in the list region of the Gantt chart.

```
<dvt:projectGantt id="gantt1"
value="#{bindings.OrderEmployee1.projectGanttModel}"
                  dataChangeListener="#{bindings.OrderEmployee1.projectGanttModel
                      .processDataChanged}"
                  var="row"
                  startTime="2012-03-31" endTime="2012-06-30">
  <f:facet name="major">
    <dvt:timeAxis scale="weeks" id="ta1"/>
  </f:facet>
  <f:facet name="minor">
    <dvt:timeAxis scale="days" id="ta2"/>
  </f:facet>
  <f:facet name="nodeStamp">
    <af:column
        sortProperty="#{bindings.OrderEmployee1.hints.FirstName.name}"
        sortable="false"
        headerText="#{bindings.OrderEmployee1.hints.FirstName.label}"
        id="c1">
        <af:outputText value="#{row.FirstName}" id="ot1"/>
      </af:column>
    </f:facet>
      <af:column sortProperty="LastName" sortable="false"
                 headerText="#{bindings.OrderEmployee1.hints.LastName.label}">
        <af:outputText value="#{row.LastName}"/>
      </af:column>
      <af:column sortProperty="OrderDate" sortable="false"
                 headerText="#{bindings.OrderEmployee1.hints.OrderDate.label}">
         <af:outputText value="#{row.OrderDate}">
           <af:convertDateTime
               pattern="#{bindings.OrderEmployee1.hints.OrderDate.format}"/>
         </af:outputText>
       </af:column>
       <af:column sortProperty="ShippedDate" sortable="false"
           headerText="#{bindings.OrderEmployee1.hints.ShippedDate.label}">
         <af:outputText value="#{row.ShippedDate}">
         <af:convertDateTime
           pattern="#{bindings.OrderEmployee1.hints.ShippedDate.format}"/>
         </af:outputText>
       </af:column>
       <af:column sortProperty="TaskType" sortable="false"
           headerText="#{bindings.OrderEmployee1.hints.TaskType.label}">
         <af:outputText value="#{row.TaskType}"/>
       </af:column>
   </projectGantt>
```

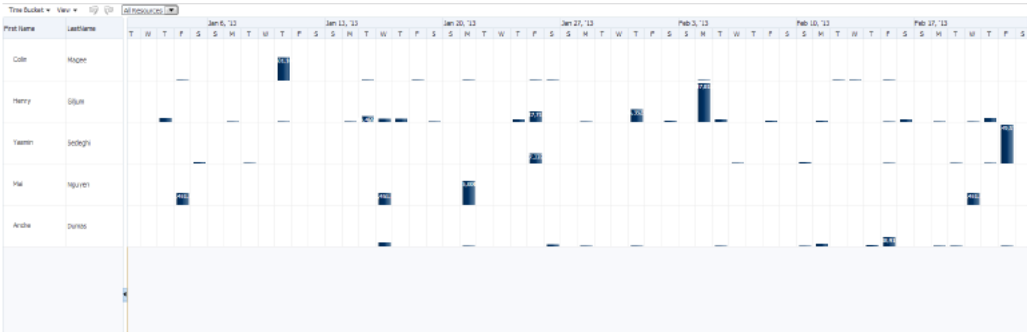
How to Create a Databound Resource Utilization Gantt Chart

For a resource utilization Gantt chart, you must supply identification for resources, identification for time, and start and end times for resource usage. Optionally, you can provide data values for subresources.

The resource utilization Gantt chart is displayed with default values for the major and minor time axis values. In a resource utilization Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 42-4 shows a resource utilization Gantt chart that lists each resource and an associated calendar that can display when the resource is in use.

Figure 42-4   Resource Utilization Gantt Chart



To create a resource utilization Gantt chart using a data control, you bind the resource utilization component to a data collection. JDeveloper allows you to do this declaratively by dragging a collection from the Data Controls panel and dropping it on a JSF page.

> **Tip:**
>
> You can also create a resource utilization Gantt chart by dragging a resource utilization Gantt chart component from the Components window and completing the Create Resource Utilization Gantt dialog. This approach gives you the option of designing the Gantt chart user interface before binding the component to data.

Before you begin:

It may be helpful to have an understanding of databound Gantt charts. For more information, see Creating Databound Gantt Charts.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.

  For example, the data source for the Gantt chart in Figure 42-4 comes from view objects in the Summit ADF DVT sample application. Use the `SalesRepViewObj1` view object representing the sales personnel with a view link to the `SOrdView2` view object that includes the time bucket accessor and attributes for order and ship dates.

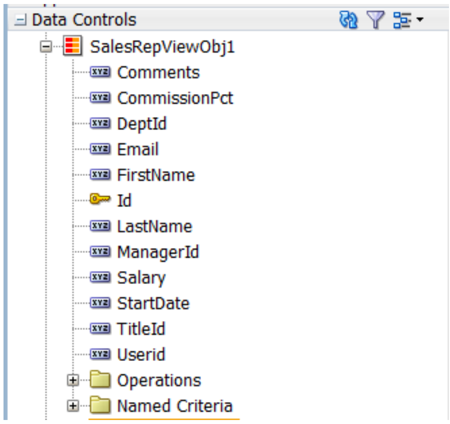
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a resource utilization Gantt chart using the Data Controls panel:

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection or a basic tree collection.

   Figure 42-5 shows an example where you could select the `SalesRepViewObj1` collection in the Data Controls panel to create a resource utilization Gantt chart to display the usage of a resource.

Figure 42-5 Data Collection for Resource Utilization Gantt Chart



Data Controls
SalesRepViewObj1
Comments
CommissionPct
DeptId
Email
FirstName
Id
LastName
ManagerId
Salary
StartDate
TitleId
Userid
Operations
Named Criteria

2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt** > **Resource Utilization**.

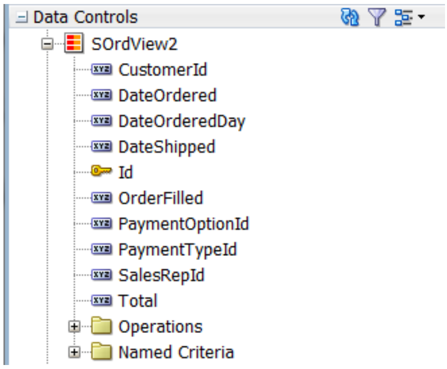
3. In the Create Resource Utilization Gantt dialog, select the columns in the data collection that correspond to the following attributes:

   - **Resource Id**: The unique identifier of the resource, for example `Id` representing the sales representatives in the view object.
   - **Is Container**: Boolean. Specify whether or not the node definition is a container.

4. In the **Time Buckets** page, select a value from the **Bucket Accessor** dropdown list that contains the time buckets assigned to the resource, and select a value from the **Bucket Date** dropdown list that corresponds to a unit of time.

   For example, the `SOrdView2` view object includes attributes representing the date ordered and date shipped for each order assigned to a sales representative. Figure 42-6 shows the view object used for the bucket accessor.

Figure 42-6 Resource Utilization Gantt Chart Bucket Accessor



Data Controls
SOrdView2
CustomerId
DateOrdered
DateOrderedDay
DateShipped
Id
OrderFilled
PaymentOptionId
PaymentTypeId
SalesRepId
Total
Operations
Named Criteria

5. In the **Bucket Metrics** list, specify attributes that appear as bars within the time bucket. Use the **New** icon to add new rows, the **Delete** icon to remove rows, and the arrow icons to arrange the rows in the sequence that you want the metrics to appear in the Gantt chart region.

   Each attribute that you specify in the **Bucket Metrics** list must be of type Number as the value of the attribute is used to calculate the height of the bar.

6. In the **Table Columns** section, specify the columns to display for each row in the list region of the Gantt chart. Use the **New** icon to add new rows, the **Delete** icon to remove rows, and the arrow icons to arrange the rows in the sequence that you want the columns to appear in the Gantt chart list.

   > **Note:**
   >
   > The first row that you specify in the **Table Columns** section designates the `nodestamp` column for the list region. If you specify a subresource accessor, this row displays the parent in a hierarchical relationship that can be expanded or collapsed.

   For each row, specify the following:

   - **Display Label**: Select the values for the headers of the columns in the Gantt chart list. If you select **<default>**, the text for the header is automatically retrieved from the data binding.
   - **Value Binding**: Select the columns in the data collection to use for the columns in the Gantt chart list. The available values are the same as those for the tasks group.
   - **Component to Use**: Select the type of component to display in the cell of the Gantt chart list. You can specify that a cell is editable by using an ADF input component. The default is the ADF Output Text component.

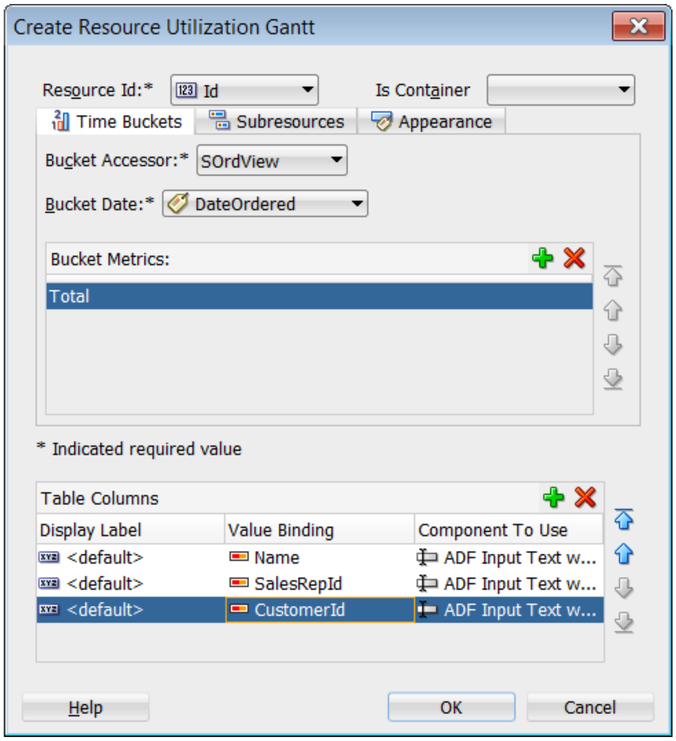
7. If the data collection has an accessor for subresources, use the **Subresources** page to select a **Subresources accessor** from the dropdown list, and then select a unique identifier for the subresource from the **Resource Id** dropdown list.

8. In the **Appearance** page, specify the attributes that correspond to the **Label** of the task bar.

9. Click **OK**.

   Figure 42-7 shows the dialog used to create a resource utilization Gantt chart from the data collection for resources available for a project.

Figure 42-7 Create Resource Utilization Gantt Chart Dialog



Create Resource Utilization Gantt

Resource Id:* Id

Is Container

Bucket Accessor:* SOrdView

Bucket Date:* DateOrdered

Bucket Metrics:

Total

* Indicated required value

Table Columns

Display Label	Value Binding	Component To Use
<default>	Name	ADF Input Text w...
<default>	SalesRepId	ADF Input Text w...
<default>	CustomerId	ADF Input Text w...

10. In the Structure window, right-click the `dvt:resourceUtilizationGantt` component and select **Go to Properties**.
11. In the Properties window, expand the **Common** section, and specify the dates (`yyyy-mm-dd`) for the **StartTime** and **EndTime** attributes representing the start and end dates respectively for the time period of the Gantt chart data.

    The dates that you specify determine the initial view that appears in the resource utilization Gantt chart at runtime.
12. If you want to include a legend in the Gantt chart, right-click the resource utilization Gantt chart node in the Structure window and choose **Insert Inside Resource Utilization Gantt** > **Legend**.

    The legend shows information about each symbol and color coded bar used to represent different tasks. It also shows detailed information about the task selected in the Gantt chart.

After creating the resource utilization Gantt chart, use the Properties window to specify values for additional attributes. For detailed information about Gantt chart use cases, end user and presentation features, tag structure, and adding special features to Gantt charts, see the Using Gantt Chart Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Create a Resource Utilization Gantt Chart

Dragging and dropping a view object from the Data Controls panel onto a JSF page to create a resource utilization Gantt chart has the following effects:

- Creates bindings for the resource utilization Gantt chart and adds the bindings to the page definition file

- Adds the necessary code for the UI components to the JSF page

The example below shows the row set bindings that were generated for the resource utilization Gantt chart illustrated in Figure 42-7.

```
<bindings>
  <gantt IterBinding="SalesRepViewObj1Iterator" id="SalesRepViewObj1"
         xmlns="http://xmlns.oracle.com/adfm/dvt">
    <ganttDataMap>
      <nodeDefinition DefName="model.SalesRepViewObj" type="Resources">
        <AttrNames>
          <Item Value="Id" type="resourceId"/>
        </AttrNames>
        <Accessors>
          <Item Value="SOrdView" type="timeBuckets"/>
        </Accessors>
      </nodeDefinition>
      <nodeDefinition type="TimeBuckets" DefName="model.SOrdView">
        <AttrNames>
          <Item Value="DateOrderedDay" type="time"/>
          <Item type="metric" Value="Total"/>
        </AttrNames>
      </nodeDefinition>
      <nodeDefinition type="Subresources">
        <AttrNames/>
      </nodeDefinition>
    </ganttDataMap>
  </gantt>
</bindings>
```

The example below shows the code generated on the JSF page for the resource utilization Gantt chart. This tag code contains settings for the overall start and end time for the resource utilization Gantt chart. These settings have to be edited manually. The code also shows the time axis settings for the major time axis (in weeks) and the minor time axis (in days). Finally, it lists the specifications for each column to appear in the list region of the resource utilization Gantt chart.

```
<dvt:resourceUtilizationGantt id="gantt1"
            value="#{bindings.SalesRepViewObj1.resourceUtilizationGanttModel}"
            var="row" metrics="#{bindings.SalesRepViewObj1.metrics}"
            taskbarFormatManager="#{bindings.SalesRepViewObj1.
                resourceUtilizationGanttTaskbarFormatManager}"
            startTime="2012-05-09" endTime="2013-05-15"
            summary="#{viewcontrollerBundle.RESOURCE_UTILIZATION_GANTT_CHART}">
  <f:facet name="major">
    <dvt:timeAxis scale="weeks" id="ta1"/>
  </f:facet>
  <f:facet name="minor">
    <dvt:timeAxis scale="days" id="ta2"/>
  </f:facet>
  <f:facet name="nodeStamp">
    <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.FirstName.name}"
               sortable="false"
               headerText="#{bindings.SalesRepViewObj1.hints.FirstName.label}"
               id="c1">
      <af:outputText value="#{row.FirstName}"

shortDesc="#{bindings.SalesRepViewObj1.hints.FirstName.tooltip}"
                  id="ot1"/>
    </af:column>
  </f:facet>
```

```
    <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.LastName.name}"
               sortable="false"
               headerText="#{bindings.SalesRepViewObj1.hints.LastName.label}"
               id="c2">
      <af:outputText value="#{row.LastName}"

shortDesc="#{bindings.SalesRepViewObj1.hints.LastName.tooltip}"
                   id="ot2"/>
    </af:column>
    <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.Email.name}"
               sortable="false"
               headerText="#{bindings.SalesRepViewObj1.hints.Email.label}"
               id="c3">
      <af:outputText value="#{row.Email}"
                     shortDesc="#{bindings.SalesRepViewObj1.hints.Email.tooltip}"
                     id="ot3"/>
    </af:column>
</dvt:resourceUtilizationGantt>
```

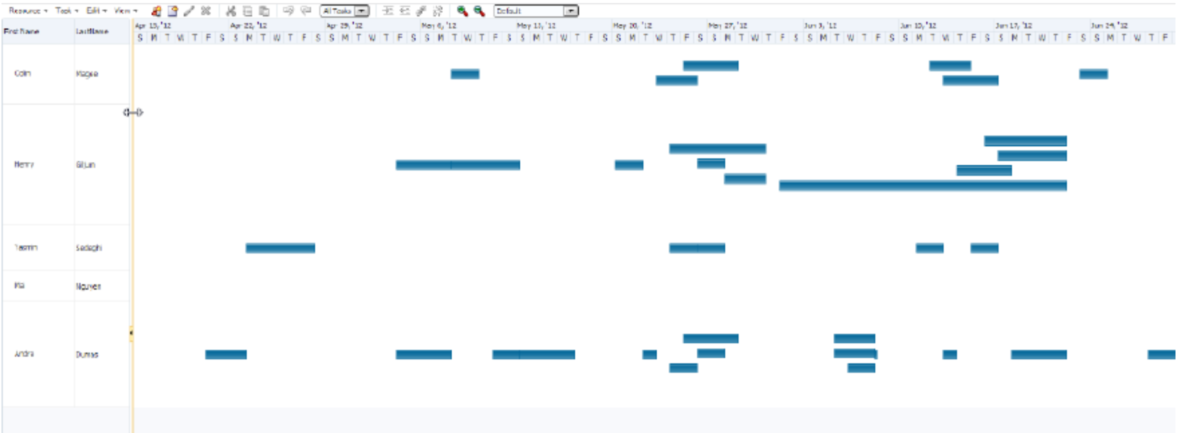
How to Create a Databound Scheduling Gantt Chart

For a scheduling Gantt chart, you must supply identification for resources, identification for tasks, and start and end times for tasks. Optionally, you can provide data values for subresources, recurring tasks, split tasks, and dependencies between tasks.

The scheduling Gantt chart is displayed with default values for overall start and end time and for the major and minor time axis values. In a scheduling Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 42-8 shows a scheduling Gantt chart that lists each resource and all the orders for which that resource is responsible. In contrast to a project Gantt chart, the scheduling Gantt chart shows all the tasks for a given resource on the same line, while the project Gantt chart lists each task on a separate line.

Figure 42-8   Scheduling Gantt Chart for Order Shipping



First Name	LastName
Colin	Magee
Henry	Gilun
Yasmin	Sadeghi
Mai	Nguyen
Andra	Dumas

To create a scheduling Gantt chart using a data control, you bind the `schedulingGantt` tag to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

Before you begin:

It may be helpful to have an understanding of databound Gantt charts. For more information, see Creating Databound Gantt Charts.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.

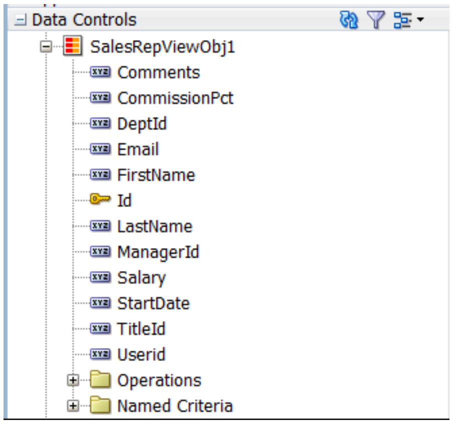
  For example, the data source for the Gantt chart in Figure 42-8 comes from view objects in the Summit ADF DVT sample application. Use the `SalesRepViewObj1` view object representing the sales personnel with a view link to the `SOrdView2` view object that includes the tasks accessor and attributes for order and ship dates.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a scheduling Gantt chart using the Data Controls panel:

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection or a basic tree collection.

   Figure 42-9 shows an example where you could select the `SalesRepViewObj1` data collection to create a scheduling Gantt chart that displays the orders each sales representative is responsible for managing.

Figure 42-9 Data Collection for Scheduling Gantt Chart



2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt** > **Scheduling**.
3. In the Create Scheduling Gantt dialog, select the columns in the data collection that correspond to the following attributes:
   - **Resource Id**: The unique Id for the resource represented in the scheduling Gantt chart.
   - **Working Start Time**: The work start date of the scheduling Gantt chart.

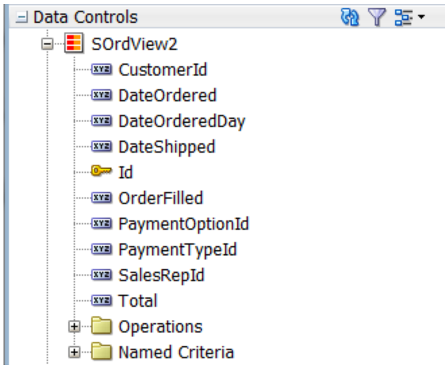
- **Working End Time**: The work end date of the scheduling Gantt chart.
- **Working Days of Week**: Specifies a list of the working days of the week.
- **Is Container**: Boolean. Specify whether or not the node definition is a container.

4. In the **Tasks** page, select the **Task Accessor** from the dropdown list, and then select the columns in the data collection that correspond to the following attributes:

   - **Task Id**: The unique Id for the task associated with a resource in the Gantt chart.
   - **Task Type**: The type used to specify the appearance of the task bar when it is rendered in the Gantt chart. If you do not bind the type to a column in your data collection, then all tasks default to `Scheduled`.
   - **Start Time**: The starting time of the task.
   - **End Time**: The ending time of the task.
   - **Startup Time**: The time to start up the task before beginning.
   - **Shutdown Time**: The time to shut down the task after completion.

   For example, the `SOrdView2` view object includes attributes representing the date ordered and date shipped for each order assigned to a sales representative. Figure 42-10 shows the view object used for the task accessor.

   Figure 42-10 Scheduling Gantt Chart Task Accessor

5. If the data collection has an accessor for dependent tasks, use the **Dependent Tasks** page to select the **Dependent Task** accessor, and then select the columns in the data collection that correspond to the following attributes:

   - **Dependency Type**: Specifies the type of the dependency. Valid values are `start-start`, `start-finish`, `finish-finish`, `finish-start`, `start-before`, `start-together`, `finish-after`, and `finish-together`.
   - **From Task Id**: Specifies the first task in the dependent relationship.
   - **To Task Id**: Specifies the last task in the dependent relationship.

   Dependent tasks are linked by their associations with the finish and start times between them.

6. If the data collection has an accessor for split tasks, use the **Split Tasks** page to select the **Split Tasks** accessor, and then select the columns in the data collection that correspond to the following attributes:

- **Split Task Id**: The unique Id for a task split into two horizontal bars, usually linked by a line. The time between the bars represents idle time due to traveling or down time.
- **Start Time**: The starting time of the split task.
- **End Time**: The ending time of the split task.

7. If the data collection has an accessor for recurring tasks, use the **Recurring Tasks** page to select the **Recurring Tasks** accessor from the dropdown list, and then select the columns in the data collection that correspond to the following attributes:

   - **Recurring Task Id**: A unique Id for a task repeated in a Gantt chart, each instance with its own start and end date. Individual recurring tasks can optionally contain a subtype. All other properties of the individual recurring tasks come from the task which they are part of. However, if an individual recurring task has a subtype, this subtype overrides the task type.
   - **Type**: Specifies the type of the recurring task.
   - **Start Time**: The starting time of the recurring task.
   - **End Time**: The ending time of the recurring task.

8. If the data collection has an accessor for subresources, use the **Subresources** page to select the **Subresources Accessor** from the dropdown list, and then select the column in the data collection that corresponds to the **Subresource Id**, the unique Id for the list of subresources in the data collection.

   If you do not bind subresources, then the Gantt chart cannot render a hierarchy view of resources. If you bind subresources, then you can drill from resources to subresources in the hierarchy view of the Gantt chart.

9. In the **Appearance** page, specify the attributes that correspond to the **Label** of the task bar, and up to three icons to associate with the task bar.

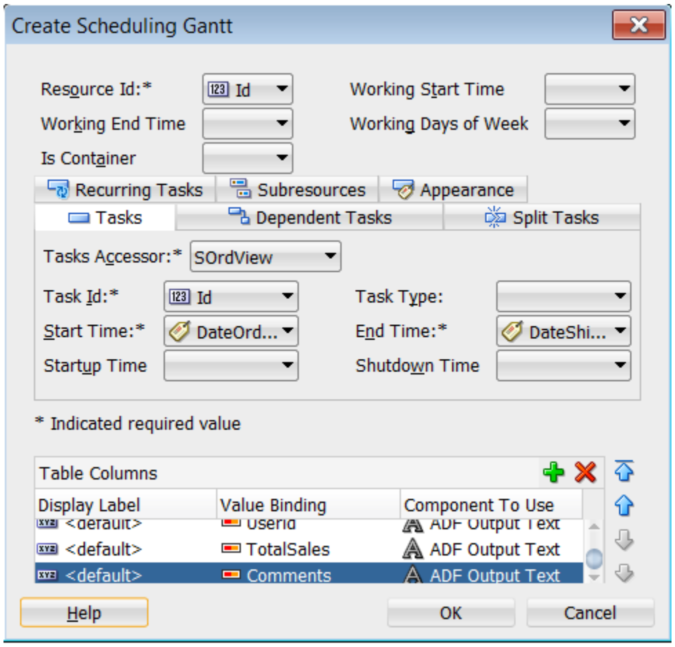
10. In the **Table Columns** section, specify the columns that will appear in the list region of the Gantt chart on the left side of the splitter. Specify one row of information for each column that is to appear. Use the **New** icon to add new rows. Use the arrow icon to arrange the rows in the exact sequence that you want the columns to appear in the Gantt chart list. For each row, you provide the following specifications:

    - **Display Label:** Select the values for the headers of the columns in the Gantt chart list. If you select `<default>`, then the text for the header is automatically retrieved from the data binding.
    - **Value Binding:** Select the columns in the data collection to use for the column in the Gantt chart list. The available values are the same as those for the tasks group.
    - **Component to Use:** Select the type of component to display in the cell of the Gantt chart list. The default is the **ADF Output Text** component.

11. Click **OK**.

    Figure 42-11 shows the dialog used to create the scheduling Gantt chart from the data collection for sales representatives responsible for shipping orders.

Figure 42-11 Create Scheduling Gantt Dialog



Resource Id:* Id
Working Start Time
Working End Time
Working Days of Week
Is Container

Tasks Accessor:* SOrdView
Task Id:* Id
Task Type:
Start Time:* DateOrd...
End Time:* DateShi...
Startup Time
Shutdown Time

* Indicated required value

Table Columns

Display Label	Value Binding	Component To Use
<default>	UserId	ADF Output Text
<default>	TotalSales	ADF Output Text
<default>	Comments	ADF Output Text

12. In the Structure window, right-click the `dvt:schedulingGantt` component and select **Go to Properties**.
13. In the Properties window, expand the **Common** section, and specify the dates (`yyyy-mm-dd`) for the **StartTime** and **EndTime** attributes representing the start and end dates respectively for the time period of the Gantt chart data.

    The dates that you specify determine the initial view that appears in the scheduling Gantt chart at runtime.
14. If you want to include a legend in the Gantt chart, right-click the scheduling Gantt chart node in the Structure window and choose **Insert Inside Scheduling Gantt** > **Legend**.

    The legend shows information about each symbol and color coded bar used to represent different tasks. It also shows detailed information about the task selected in the Gantt chart.

What Happens When You Create a Scheduling Gantt Chart

Dropping a scheduling Gantt chart from the Data Controls panel has the following effect:

- Creates the bindings for the Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

The example below shows the row set bindings that were generated for the scheduling Gantt chart that displays resources and orders shipped.

```
<bindings>
  <gantt IterBinding="SalesRepViewObj1Iterator" id="SalesRepViewObj1"
         xmlns="http://xmlns.oracle.com/adfm/dvt">
    <ganttDataMap>
      <nodeDefinition DefName="model.SalesRepViewObj" type="Resources">
```

```
          <AttrNames>
            <Item Value="Id" type="resourceId"/>
          </AttrNames>
          <Accessors>
            <Item Value="SOrdView" type="tasks"/>
          </Accessors>
        </nodeDefinition>
        <nodeDefinition type="Tasks" DefName="model.SOrdView">
          <AttrNames>
            <Item Value="Id" type="taskId"/>
            <Item Value="DateOrdered" type="startTime"/>
            <Item Value="DateShipped" type="endTime"/>
          </AttrNames>
        </nodeDefinition>
        <nodeDefinition type="Dependents">
          <AttrNames/>
        </nodeDefinition>
        <nodeDefinition type="SplitTasks">
          <AttrNames/>
        </nodeDefinition>
        <nodeDefinition type="RecurringTasks">
          <AttrNames/>
        </nodeDefinition>
        <nodeDefinition type="Subresources">
          <AttrNames/>
        </nodeDefinition>
      </ganttDataMap>
    </gantt>
  </bindings>
```

The example below shows the code generated on the JSF page for the scheduling Gantt chart. This tag code contains settings for the overall start and end time for the scheduling Gantt chart. It also shows the time axis settings for the major time axis in weeks and the minor time axis in days. Finally, it lists the specifications for each column that appears in the list region of the Gantt chart.

```
<dvt:schedulingGantt id="gantt1"
                     value="#{bindings.SalesRepViewObj1.schedulingGanttModel}"
                     dataChangeListener="#{bindings.SalesRepViewObj1.
                         schedulingGanttModel.processDataChanged}"
                     var="row" startTime="2012-04-15" endTime="2013-05-15"
                     summary="#{viewcontrollerBundle.SCHEDULING_GANTT_CHART}">
  <f:facet name="major">
    <dvt:timeAxis scale="weeks" id="ta1"/>
  </f:facet>
  <f:facet name="minor">
    <dvt:timeAxis scale="days" id="ta2"/>
  </f:facet>
<f:facet name="nodeStamp">
  <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.FirstName.name}"
             sortable="false"
             headerText="#{bindings.SalesRepViewObj1.hints.FirstName.label}"
             id="c1">
    <af:outputText value="#{row.FirstName}"
                   shortDesc="#{bindings.SalesRepViewObj1.hints.
                       FirstName.tooltip}"
                   id="ot1"/>
  </af:column>
</f:facet>
  <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.LastName.name}"
             sortable="false"
```

```
           headerText="#{bindings.SalesRepViewObj1.hints.LastName.label}"
           id="c2">
      <af:outputText value="#{row.LastName}"

shortDesc="#{bindings.SalesRepViewObj1.hints.LastName.tooltip}"
                  id="ot2"/>
    </af:column>
    <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.Email.name}"
               sortable="false"
               headerText="#{bindings.SalesRepViewObj1.hints.Email.label}" id="c3">
      <af:outputText value="#{row.Email}"
                     shortDesc="#{bindings.SalesRepViewObj1.hints.Email.tooltip}"
                     id="ot3"/>
    </af:column>
</dvt:schedulingGantt>
```

What You May Need to Know About Data Change Event Handling

When you use ADF data controls to data bind project and scheduling Gantt charts, a data change listener is automatically provided for data change events that require an update to row attributes, for example:

- DURATION_CHANGE: End time of a task; resize task bar
- PROGRESS_CHANGE: Progress of task; resize progress bar
- TIME_CHANGE: Start and end time of a task; move the task bar

At design time, the data change listener provides a built-in processDataChange method for project and scheduling Gantt bindings as illustrated in the example below.

```
<dvt:projectGantt id="gantt1"
                  dataChangeListener="#{bindings.GanttProjectView1.
                      projectGanttModel.processDataChanged}"
                  value="#{bindings.GanttProjectView1.projectGanttModel}"
                  ...
</dvt:projectGantt>
```

Data change events requiring row insertion or deletion are not supported, for example:

- TASK_SPLITTED: Split a task
- TASK_MERGED: Merge task with another task
- LINK: Link two tasks together
- UNLINK: Unlink two tasks linked together
- COPY: Copy one or more tasks or resources
- CREATE: Create a new task
- CREATE_RESOURCE: Create a new resource
- CUT: Cut one or more tasks or resources
- PASTE: Paste tasks or resources
- UPDATE: Update a task
- UPDATE_RESOURCE: Update a resource
- TASKS_PROPERTIES_UPDATE: Task properties dialog event
- INDENT: Indent a task or resource

- OUTDENT: Outdent a task or resource
- DELETE: Delete one or more tasks or resources

If you wish to configure your application to handle events that do not have a default implementation, specify a method in a backing bean and delegate to the built-in processDataChange method. For example, the first block of code below shows a dataChangeListener configured to use a handleDataChange method to handle a TASK_PROPERTIES_UPDATE event using the backing bean shown in the class code below.

```
<dvt:projectGantt id="gantt1"
                  dataChangeListener="#{backingBeanScope.backing_
                      projectGantt.handleDataChange}"
                  value="#{bindings.GanttProjectView1.projectGanttModel}"
                  ...
</dvt:projectGantt>
```

```
public void handleDataChange(DataChangeEvent evt)
{
    // handle events not supported by built-in "processDataChange" method
    int _type = evt.getActionType();
    if (_type == DataChangeEvent.TASK_PROPERTIES_UPDATE)
    {
        // handle event.
    }
    else  // delegate to built-in "processDataChange" method.
    {
                Application app = facesContext.getApplication();
        String expression =
            "#{bindings.GanttProjectView1.projectGanttModel.processDataChanged}";
        ExpressionFactory elFactory = app.getExpressionFactory();
        ELContext elContext = facesContext.getELContext();
        MethodExpression methodExp = elFactory.createMethodExpression(elContext,
            expression, null, new Class[] {DataChangeEvent.class});
        methodExp.invoke(elContext, new Object[] {evt});
    }
}
```

Note:

The project and scheduling Gantt chart's default implementation of a dataChangeListener for ADF data controls will not perform commit or rollback changes to the database. You must configure your application to handle those operations.

Creating Databound Timelines

A timeline is an interactive data visualization tool that allows users to view date-based events in chronological order and easily navigate forwards and backwards within a defined time range.

A timeline is composed of the display of events as timeline items along a time axis, a movable overview window that corresponds to the period of viewable time in the timeline, and an overview time axis that displays the total time increment for the timeline. A horizontal zoom control is available to change the viewable time range. Timeline items corresponding to events display associated information or actions and are connected to the date of the event in the time axis. Timelines items are represented by a marker in the overview panel. No more that two series of events are supported by the timeline component.

A dual timeline can be used for a side-by-side comparison of events. For example, you can use a timeline to display the hire dates of employees, or use a dual timeline to compare multiple human resource events between two employees.

Figure 42-12 shows a timeline in the Summit ADF DVT sample application. In this example, two lines of text are displayed along with images. When selection is configured, the timeline item, line feeler, and the event marker in the overview panel are highlighted.

Figure 42-12 Sample Timeline

The content of timeline items, marker display, and time axis are configurable. For detailed information about timeline use cases, end user and presentation features, tag structure, and adding special features to timelines, see the Using Timeline Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Timeline Using ADF Data Controls

The data displayed in a timeline is based on data collections. The `timeline` component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The data layer will automatically convert the instance into a `CollectionModel`.

Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a data collection from the Data Controls panel that generates one (up to two) series of events onto the JSF page.

Before you begin:

It may be helpful to have an understanding of databound timelines. See Creating Databound Timelines.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. See Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.

  For example, the data source for the timeline in Figure 42-12 comes from a single table in the Summit ADF DVT sample application. Use the `SEmp` table to create a view object representing the employees including their hire dates.

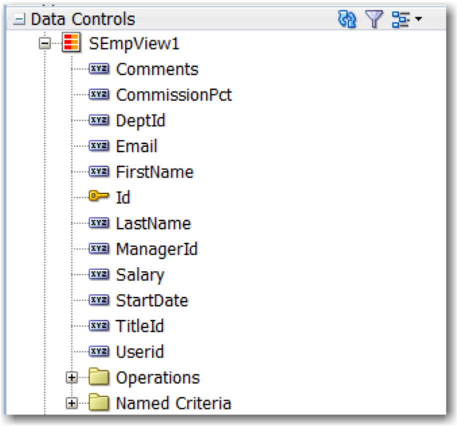
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a timeline using the Data Controls panel:

1. From the Data Controls panel, select a collection.

   Figure 42-14 shows an example where you could select the `SEmpView1` collection in the Data Controls panel to create a timeline that displays the hire dates of employees.

   Figure 42-14   Data Collection for Timeline of Employee Hire Dates

2. Drag the collection onto the JSF page, and from the context menu choose **Timeline**.

3. In the Create Timeline dialog, configure the time axis and overview axis by setting the following values:

   a. **Start Time**: Enter the starting date to use for the time range of the timeline using the format `yyyy-mm-dd`. Select a start date that will include events in the data collection you wish to display on the timeline. From the dropdown list you can select `Current Date`. You can also click the Calendar icon to display a date picker dialog. The default value is set for three months before the current date.

   b. **End Time**: Enter the ending date to use for the timeline time range using the format `yyyy-mm-dd`. Select an end date that will include events in the data collection you wish to display on the timeline. From the dropdown list you can select `Current Date`. You can also click the Calendar icon to display a date picker dialog. The default value is `Current Date`.

   c. **Axis Scale**: Use the dropdown list to select the time scale to use for the timeline time axis. The time axis shows the user the current time increment for the timeline.

      You must use a smaller time scale than the **Overview Scale**. For example, you cannot set the axis scale to `years` if the overview scale is set to `months`. You can also specify a custom axis scale.

      Valid values are `twoyears`, `years`, `halfyears`, `quarters` (default), `twomonths`, `months`, `twoweeks`, `weeks`, `days`, `sixhours`, `threehours`, `hours`, `halfhours`, `quarterhours`. You can also specify a custom axis scale. See How to Add a Custom Time Scale to a Timeline in *Developing Web User Interfaces with Oracle ADF Faces*.

d. **Overview Scale**: Use the dropdown list to select the time scale to use for the timeline overview axis. The overview axis shows the user the total time increment covered by the timeline.

   Valid values are `twoyears`, `years` (default), `halfyears`, `quarters`, `twomonths`, `months`, `twoweeks`, `weeks`, `days`, `sixhours`,`threehours`, `hours`, `halfhours`, `quarterhours`. You can also specify a custom axis scale. See How to Add a Custom Time Scale to a Timeline in *Developing Web User Interfaces with Oracle ADF Faces*.

4. In the Create Timeline dialog, configure the timeline data model for at least one (at most two for a dual timeline), by setting the following values:

   a. **Series Value**: Use the dropdown list to select the data collection to use in the timeline. By default, the data collection you inserted from the Data Controls panel is displayed. JDeveloper automatically lists any collection from the application module that includes at least one qualifying date-based attribute from which to choose.

   b. **Item Date Value**: Use the dropdown list to select the date-based attribute to use for the timeline items stamped in the timeline. JDeveloper automatically lists all qualifying attributes in the collection referenced in the **Series Value** from which to choose.

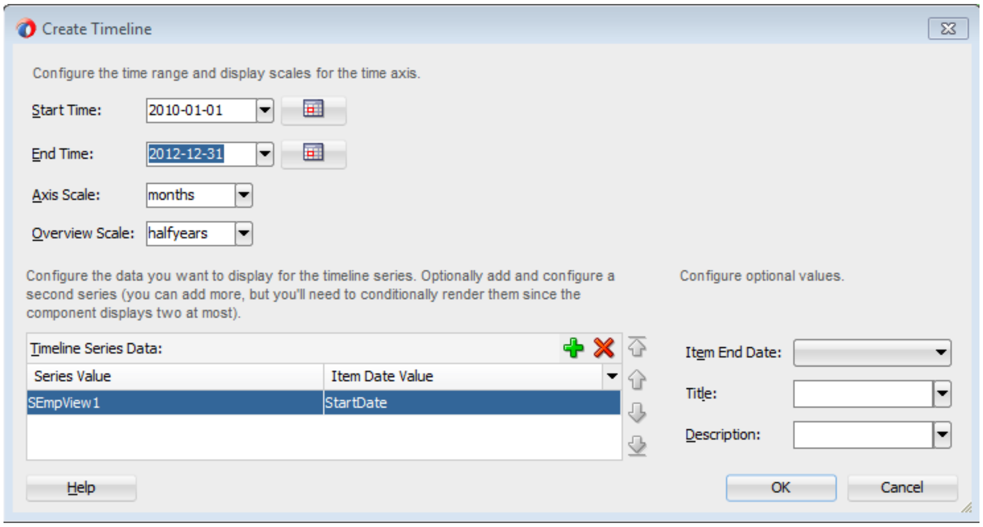
> **Note:**
>
> You can add and configure more series, but you will need to conditionally render them since the component displays two at most.

5. You can also configure the following values that are optional:

   - **Item End Date**: Specify the time-related attribute in the data collection that represents the end date for the timeline item. Use the dropdown list to display a list of available choices.
   - **Title**: Enter text or use the dropdown to specify the attribute in the data collection that represents the title for the timeline item.
   - **Description**: Enter text or use the dropdown to specify the attribute in the data collection that represents the description for the timeline item.

   For example, in Figure 42-15 you can specify all the values.

Figure 42-15 Create Timeline Dialog



Create Timeline

Configure the time range and display scales for the time axis.

Start Time: 2010-01-01

End Time: 2012-12-31

Axis Scale: months

Overview Scale: halfyears

Configure the data you want to display for the timeline series. Optionally add and configure a second series (you can add more, but you'll need to conditionally render them since the component displays two at most).

Timeline Series Data:

Series Value	Item Date Value
SEmpView1	StartDate

Configure optional values.

Item End Date:

Title:

Description:

6. Click **OK** to complete the definition of the data binding, or **Cancel** to end the creation of the timeline.

What Happens When You Use Data Controls to Create a Timeline

When you use ADF data controls to create a timeline, JDeveloper:

- Defines the bindings for the timeline in the page definition file of the JSF page, and
- Inserts code in the JSF page for the DVT timeline components.

The example below shows the bindings defined in the page definition file of the JSF page for the Summit ADF DVT sample timeline in Figure 42-12.

```
<bindings>
  <tree IterBinding="SEmpView1Iterator" id="SEmpView1" ChangeEventPolicy="ppr">
    <nodeDefinition DefName="model.SEmpView" Name="SEmpView1">
      <AttrNames>
        <Item Value="DeptId"/>
        <Item Value="FirstName"/>
        <Item Value="Id"/>
        <Item Value="LastName"/>
        <Item Value="StartDate"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

The example below shows the code inserted in the JSF page for the example timeline in Figure 42-12.

```
<dvt:timeline id="tl1" startTime="2010-01-01" endTime="2011-12-31"
itemSelection="multiple"
              binding="#{extEditor.component}" summary="Timeline Component Demo">
    <dvt:timeSeries id="ts1" var="evt" value="#{timeline.model}">
        <dvt:timeItem id="ti1" value="#{evt.date}" title="#{evt.description}"
description="#{evt.date}"
                      thumbnail="/resources/images/timeline/employment.png"/>
    </dvt:timeSeries>
    <dvt:timeAxis id="ta1" scale="weeks" zoomOrder="quarters months weeks days"/>
    <dvt:timelineOverview id="ov1">
        <dvt:timeAxis id="ta2" scale="years"/>
    </dvt:timelineOverview>
</dvt:timeline>
```

What You May Need to Know About Using Data Controls to Create a Dual Timeline

When you use the Data Controls panel to create a dual timeline, you can configure the same or different data collections to configure the two timeline series and specify the timeline item display attributes and overview marker for each one. JDeveloper automatically lists any data collection from the application module that includes at least one qualifying date-based attribute from which to choose in the Create Timeline wizard.

The example below shows the sample code for the dual timeline displayed in Figure 42-13.

```
<dvt:timeline id="tl1" startTime="2000-01-01" endTime="2011-12-31"
                       inlineStyle="width:1024px;height:500px"
itemSelection="single" currentTime="2010-04-01">
    <dvt:timeSeries id="ts1" var="evt" value="#{timeline.firstModel}">
        <dvt:timeItem id="ti1" value="#{evt.date}" group="#{evt.group}"
title="#{evt.description}"
                      description="#{evt.date}" thumbnail="/resources/images/
timeline/#{evt.type}.png">
            <f:facet name="overviewItem">
                <dvt:marker id="m1" shape="circle" fillColor="#ff0000"/>
            </f:facet>
        </dvt:timeItem>
    </dvt:timeSeries>
    <dvt:timeSeries id="ts2" var="evt" value="#{timeline.secondModel}">
        <dvt:timeItem id="ti2" value="#{evt.date}" title="#{evt.description}"
                      description="#{evt.date}" thumbnail="/resources/images/
timeline/#{evt.type}.png">
            <f:facet name="overviewItem">
                <dvt:marker id="m2" shape="circle" fillColor="#0000ff"/>
            </f:facet>
        </dvt:timeItem>
   </dvt:timeSeries>
   <dvt:timeAxis id="ta1" scale="quarters" zoomOrder="quarters months weeks
days"/>
   <dvt:timelineOverview id="ov1">
       <dvt:timeAxis id="ta2" scale="years"/>
   </dvt:timelineOverview>
</dvt:timeline>
```

For information about the data requirements, tag structure, and options for customizing the look and behavior of the component, see the Using Timeline Components chapter in the *Developing Web User Interfaces with Oracle ADF Faces*.

43

Creating Databound Hierarchy Viewer, Treemap, and Sunburst Components

This chapter describes how to create a hierarchy viewer, treemap, or sunburst from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization `hierarchyViewer`, `treemap`, and `sunburst` components to create hierarchy viewers, treemaps, and sunbursts that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.

If you are designing your page using simple UI-first development, then you can add the hierarchy viewer, treemap, or sunburst to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the hierarchy viewer, treemap, and sunburst components, see the Using Hierarchy Viewer Components and Using Treemap and Sunburst Components chapters in *Developing Web User Interfaces with Oracle ADF Faces*.

This chapter includes the following sections:

About ADF Data Visualization Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

The ADF hierarchy viewer component produces an interactive graphic that displays hierarchical data as a set of linked shapes. The shapes and links correspond to the elements and relationships in the data. For example, a hierarchy viewer component might be used to generate an organizational chart based on employee data. At runtime, end users can pan and zoom the graphic and expand, select, and navigate the management hierarchy that the graphic displays.

Use treemaps and sunbursts to display quantitative hierarchical data across two dimensions, represented visually by size and color. Treemaps and sunbursts use a shape called a node to reference the data in the hierarchy. For example, you can use a treemap or sunburst to display quarterly regional sales and to identify sales trends, using the size of the node to indicate each region's sales volume and the node's color to indicate whether that region's sales increased or decreased over the quarter. The appearance and content of the nodes are configurable at each level of the hierarchy.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the following:

- Hierarchy Viewer components: End User and Presentation Features section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Treemap and Sunburst components: End User and Presentation Features of Treemaps and Sunbursts section in *Developing Web User Interfaces with Oracle ADF Faces*.

Data Visualization Components Use Cases and Examples

For detailed descriptions of each data visualization use case and example, see the following:

- Hierarchy Viewer components: Hierarchy Viewer Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Treemap and Sunburst components: Treemap and Sunburst Use Cases and Examples section in *Developing Web User Interfaces with Oracle ADF Faces*.

Additional Functionality for Data Visualization Components

You may find it helpful to understand other Oracle ADF features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the Rerendering Partial Page Content chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the Allowing User Customization on JSF Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: You can make your data visualization components accessible. For more information, see the Developing Accessible ADF Faces Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see the Customizing the Appearance Using

Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls.

Creating Databound Hierarchy Viewers

A hierarchy viewer is an ADF Data Visualization component that visually displays data where parent-child relationships exist within the data. This component is useful where you want to display organization charts, network diagrams, social networks, or similar visual displays.

Hierarchy viewers use a shape called a node to reference the data in a hierarchy. The shape and content of the nodes are configurable, as well as the visual layout of the nodes. Nodes can display multiple views in a panel card.

Figure 43-1 shows a runtime view of a hierarchy viewer component that renders an organization chart.

Each hierarchy viewer component (`dvt:hierarchyViewer`) that you create can include:

- One or more node elements (`dvt:node`)
- One or more link elements (`dvt:link`)

The optional panel card element (`dvt:panelCard`) can be used in conjunction with the hierarchy viewer component. The panel card provides a method to switch dynamically between multiple sets of content referenced by a node element using animation by, for example, horizontally sliding the content or flipping a node over.

For detailed information about hierarchy viewer end user and presentation features, use cases, tag structure, and adding special features to hierarchy viewers, see the Using Hierarchy Viewer Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Hierarchy Viewer Using ADF Data Controls

Hierarchy viewers are based on data collections where a master-detail relationship exists between one or more detail collections and a master data collection. Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a data collection from the Data Controls panel that generates one or more root nodes onto a JSF page.

Before you begin:

It may be helpful to have an understanding of databound hierarchy viewers. For more information, see Creating Databound Hierarchy Viewers.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

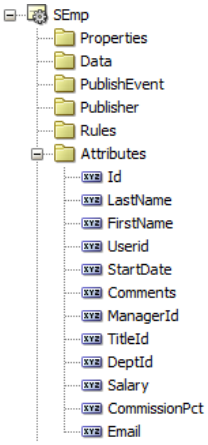
- Create an application module that contains instances of the view objects that you want in your data model for the hierarchy viewer, as described in Creating and Modifying an Application Module.

  For example, the data source for the hierarchy viewer in Figure 43-1 comes from a single table representing the employees in the Summit sample application for ADF DVT components. To set up a hierarchical relationship in the Summit ADF DVT sample application between the managers and employees using the `SEmp` table and to establish the highest level employee as the root of the hierarchy, do the following:

  1. Create an entity object based on the `SEmp` table.

     Figure 43-2 shows the `SEmp` entity object based on the `SEmp` table. Each row in the table includes both the employee's ID and the employee's manager ID. For help with creating entity objects, see Creating Entity Objects and Associations.

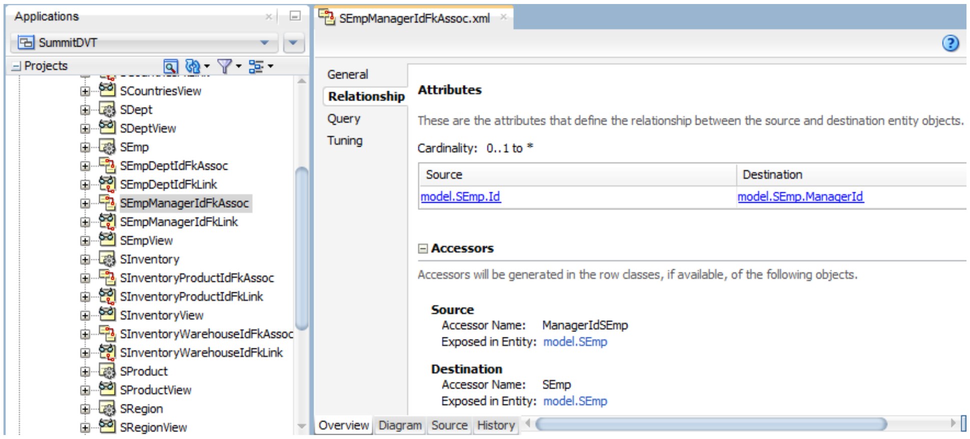
Figure 43-2 SEmp Entity Object in the Summit ADF DVT Sample Application



2. Create an association between `SEmp.Id` and `SEmp.ManagerID` to establish the relationship between the employee and manager.

   Figure 43-3 shows the `SEmpManagerIdFkAssoc` association in the Summit ADF DVT sample application. In this example, the association is automatically created when you create the `SEmp` entity object. For additional information about associations, see Creating Entity Objects and Associations.

Figure 43-3 Association Between Manager and Employees in the Summit ADF DVT Sample Application



Attributes

These are the attributes that define the relationship between the source and destination entity objects.

Cardinality: 0..1 to *

Source	Destination
model.SEmp.Id	model.SEmp.ManagerId

Accessors

Accessors will be generated in the row classes, if available, of the following objects.

Source
Accessor Name: ManagerIdSEmp
Exposed in Entity: model.SEmp

Destination
Accessor Name: SEmp
Exposed in Entity: model.SEmp

3. To establish the hierarchy between the managers and employees, create a view link between the managers and employees based on the `SEmpManagerIdFkAssoc` association.

   Figure 43-4 shows the `SEmpManagerIDFKLink` view link in the Summit ADF DVT sample application. For additional information about establishing the master-detail relationship using view links, see How to Create a Master-Detail Hierarchy Based on Entity Associations.

Figure 43-4 View Link Between Managers and Employees in the Summit ADF DVT Sample Application

Query

Attributes

These are the attributes or associations that define the relationship between the source and destination

Cardinality: 1 to *

Source	Destination
model.SEmpManagerIdFkAssoc	model.SEmpManagerIdFkAssoc

Accessors

Accessors will be generated in the row classes, if available, of the following entity and view objects:

Source

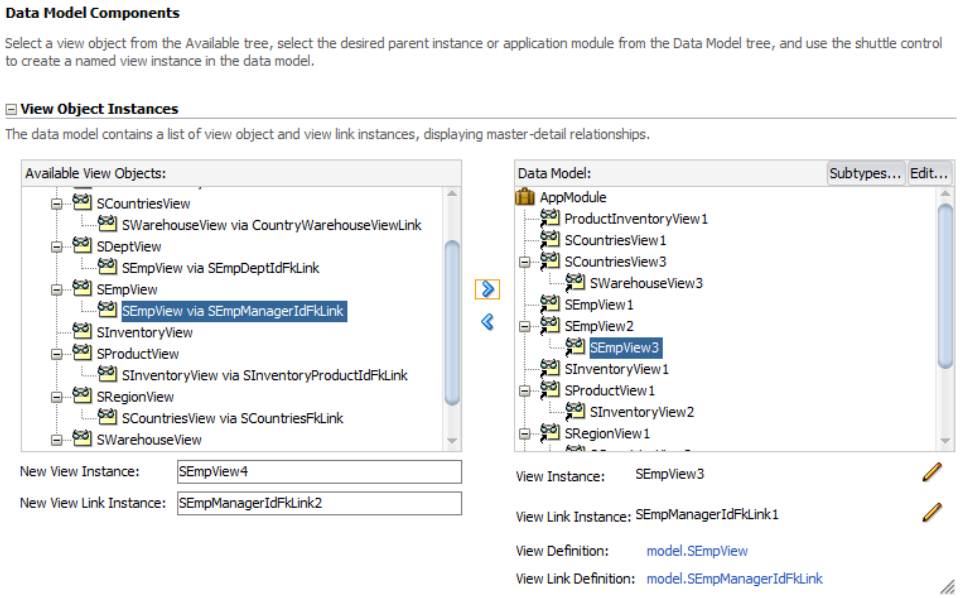
Accessor Name:	ManagerIdSEmpView
Exposed in View Object:	Not selected.
Exposed in Entity:	Not selected.

Destination

Accessor Name:	SEmpView

4. To use the SEmpManagerIDFKLink, create a new view object that ties the managers with the employees as shown in Figure 43-5.

Figure 43-5 Managers-Employees View Object in the Summit ADF DVT Sample Application



Data Model Components

Select a view object from the Available tree, select the desired parent instance or application module from the Data Model tree, and use the shuttle control to create a named view instance in the data model.

View Object Instances

The data model contains a list of view object and view link instances, displaying master-detail relationships.

Available View Objects:

- SCountriesView
  - SWarehouseView via CountryWarehouseViewLink
- SDeptView
  - SEmpView via SEmpDeptIdFkLink
- SEmpView
  - SEmpView via SEmpManagerIdFkLink
- SInventoryView
- SProductView
  - SInventoryView via SInventoryProductIdFkLink
- SRegionView
  - SCountriesView via SCountriesFkLink
- SWarehouseView

Data Model:

- AppModule
  - ProductInventoryView1
  - SCountriesView1
  - SCountriesView3
    - SWarehouseView3
  - SEmpView1
  - SEmpView2
    - SEmpView3
  - SInventoryView1
  - SProductView1
    - SInventoryView2
  - SRegionView1

New View Instance:	SEmpView4
New View Link Instance:	SEmpManagerIdFkLink2

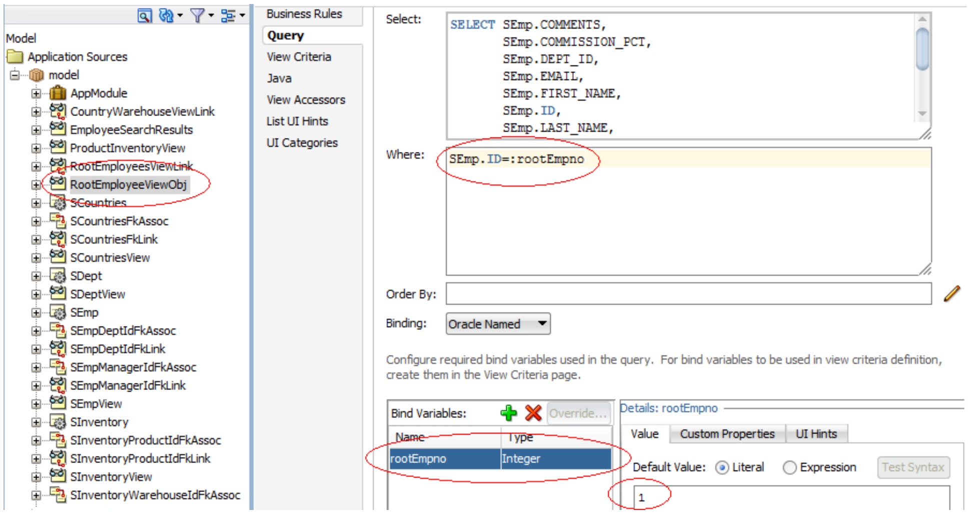
View Instance:	SEmpView3
View Link Instance:	SEmpManagerIdFkLink1
View Definition:	model.SEmpView
View Link Definition:	model.SEmpManagerIdFkLink

5. Create a view object that retrieves the root value from the data collection.

   For example, in the Summit ADF DVT sample application, Carmen Velasquez is the highest level manager and has a employee ID of 1. To create a view object based on the Summit ADF DVT sample application, create a view object that retrieves the employee whose ID is 1.

   Figure 43-6 shows the RootEmployeeViewObject for the Summit ADF DVT sample application. The query retrieves the employee whose ID is 1 and stores it in the rootEmpno bind variable. For more information about working with view objects and bind variables, see Working with Bind Variables.

Figure 43-6   RootEmployeeViewObject Sample for Hierarchy Viewer



Select:

```
SELECT SEmp.COMMENTS,
       SEmp.COMMISSION_PCT,
       SEmp.DEPT_ID,
       SEmp.EMAIL,
       SEmp.FIRST_NAME,
       SEmp.ID,
       SEmp.LAST_NAME,
```

Where:

```
SEmp.ID=:rootEmpno
```

Order By:

Binding: Oracle Named

Configure required bind variables used in the query. For bind variables to be used in view criteria definition, create them in the View Criteria page.

Bind Variables: Override...

Name	Type
rootEmpno	Integer

Details: rootEmpno

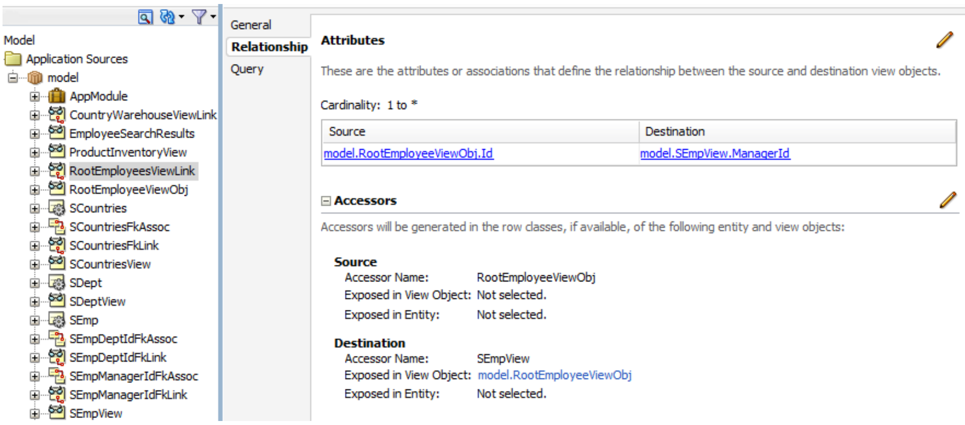
Value | Custom Properties | UI Hints

Default Value: ● Literal ○ Expression Test Syntax

1

6. To establish the hierarchy between the root employee and the lower-level managers and employees, add a view link between the `RootEmployeeViewObj` and the managers-employees view object created in Step 4.

Figure 43-7   RootEmployeesViewLink in the Summit ADF DVT Sample Application



Attributes

These are the attributes or associations that define the relationship between the source and destination view objects.

Cardinality: 1 to *

Source	Destination
model.RootEmployeeViewObj.Id	model.SEmpView.ManagerId

Accessors

Accessors will be generated in the row classes, if available, of the following entity and view objects:

Source

Accessor Name:	RootEmployeeViewObj
Exposed in View Object:	Not selected.
Exposed in Entity:	Not selected.

Destination

Accessor Name:	SEmpView
Exposed in View Object:	model.RootEmployeeViewObj
Exposed in Entity:	Not selected.

7. In the Data Controls panel, click **Refresh** to update the data controls.

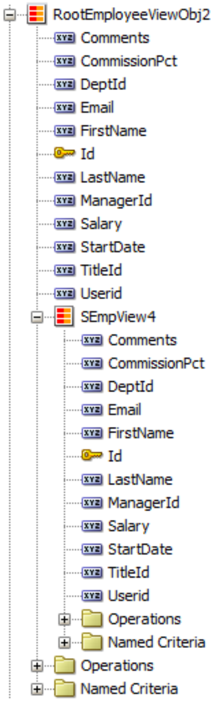
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a hierarchy viewer using the Data Controls panel:

1. From the Data Controls panel, select a collection.

   Figure 43-8 shows an example where you could select the `RootEmployeeViewObj2` collection in the Data Controls panel to create a hierarchy viewer representing the personnel data in an organizational chart.

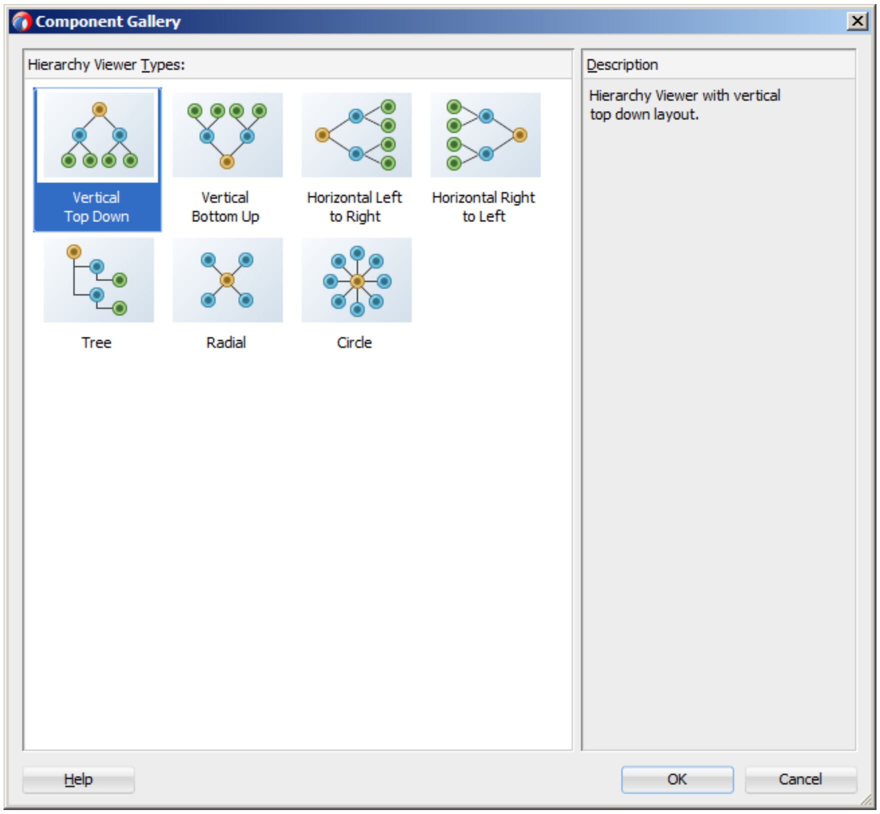
Figure 43-8 Data Collection for Personnel Organizational Chart



2. Drag the collection onto a JSF page and, from the context menu, choose **Hierarchy Viewer.**

3. From the Component Gallery, select the layout of the hierarchy viewer you want to create. Figure 43-9 shows the Component Gallery with the vertical top down layout selected.

Figure 43-9 Hierarchy Viewer Component Gallery



Hierarchy Viewer with vertical top down layout.

4. In the Create Hierarchy Viewer dialog, enter the following:
   - **Hierarchy**: Select the collections you want to include as nodes in the runtime diagram. By default, the root collection is selected. You can also choose to configure ancestors or descendants in the hierarchy.
   - **Node**: For each collection that you select in the Hierarchy list, configure the attributes in the Title Area, and the title and attributes in each panel card, using one or more of the zoom levels available to you. By default, the node for the 100% zoom level follows an algorithm that:
     - Assigns the first three attributes in the data collection to the **Title Area**.
     - Assigns the next two attributes to the first panel card.
     - Assigns the following two attributes to the second panel card.

     Select the panel card title or node attributes to configure one or more of the following for that element:
     - **Text**: Available for panel card titles. Not available for the **Title Area** element. Enter text for the panel card title in the hierarchy, or choose **Select Text Resource** from the dropdown list to open a dialog to select or add a text resource to use for the title. The text resource is a translatable string from an application resource bundle. If you need help, press F1 or click **Help**.
     - **Panel Card Data Source**: Available for panel cards. The data source indicates which data collection will be used for the panel card attributes. By default, the collection associated with the current hierarchy level will be used for attribute selection.

Figure 43-10 shows a Create Hierarchy Viewer dialog for a hierarchy viewer using data collections based on the Summit ADF schema. In this example, the **Panel Card Data Source** is the default `SEmpView` collection.

Figure 43-10 Hierarchy Viewer Configured With Default Panel Card Data Source

Panel Card Data Source:

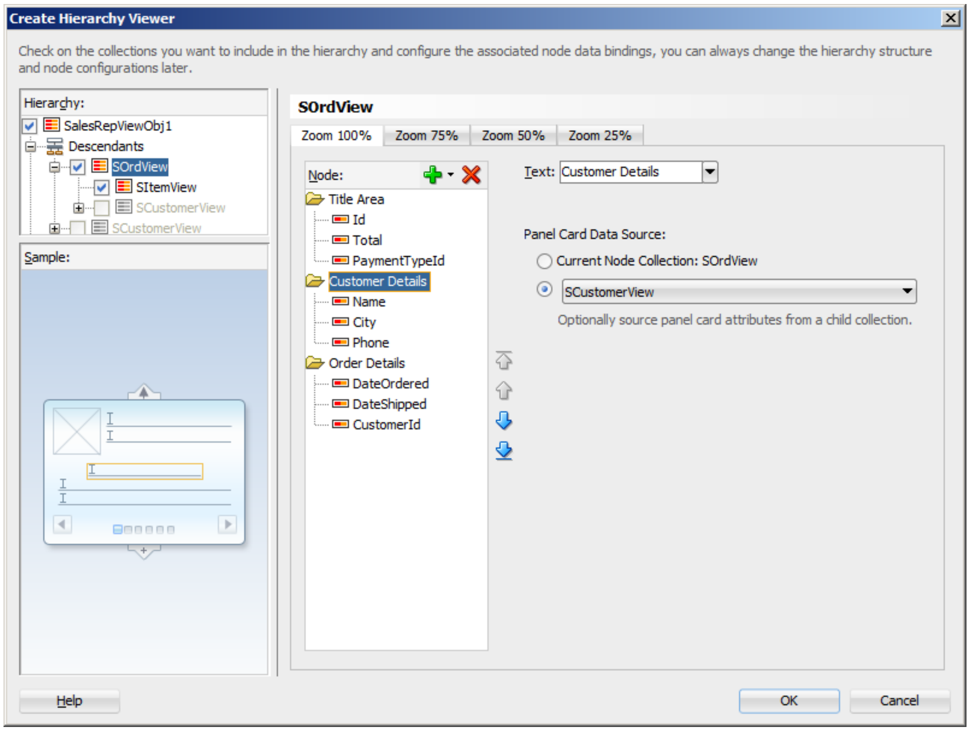
● Current Node Collection: SEmpView

○

Optionally source panel card attributes from a child collection.

To use an alternative child accessor for the panel card attributes, select an alternative child accessor from the dropdown list as shown in Figure 43-11. For additional information, see How to Configure an Alternate View Object for a Databound Panel Card.

Figure 43-11 Create Hierarchy Viewer Dialog Showing Alternate Panel Card Data Source



Create Hierarchy Viewer

Check on the collections you want to include in the hierarchy and configure the associated node data bindings, you can always change the hierarchy structure and node configurations later.

Text: Customer Details

Panel Card Data Source:

○ Current Node Collection: SOrdView

● SCustomerView

Optionally source panel card attributes from a child collection.

- **Component**: Available for attributes. Select the type of component to use to display the data in the node. Valid values are: **ADF Output Text w/Label**, **ADF Output Text**, **ADF Output Formatted Text w/Label**, and **ADF Output Formatted Text**. For more information about using these components, see the Using Output Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- **Attribute**: Available for attribute and image elements. From the dropdown list, select the attribute in the data collection that represents the value you wish to display in the hierarchy viewer node.
- **Label**: Available for attributes when you select the **Output Text w/ Label** or **ADF Output Formatted Text w/Label** component from the **Component** field's dropdown list. You can use the default **Use Attribute Name** to render the value as a string using the label from the `UIHints` for that attribute in the underlying `ViewObject`. You can also select **No Label** from the attribute's dropdown menu to render no label for the attribute, or choose **Select Text Resource** to open a Select Text Resource dialog to select or add a text resource to use for the label. The text resource is a translatable string from an application resource bundle.

Click the **New** icon to add a new panel card, attribute, or image to the node, relative to your selection in the node. After selecting an existing element, use the arrow icons (**Up**, **Down**, **Top**, **Bottom**) to reorder the element, or use the **Delete** icon to delete the selected element.

Use the 75%, 50%, and 25% pages to specify the expanded display of the hierarchy at each page level. Select **Add Zoom Level** to enable the zoom level for a page level. By default, the algorithms to assign node attributes and panel cards in the node are similar to the 100% zoom level.

> **Note:**
>
> The hierarchy viewer component defines four zoom levels. You cannot modify these zoom levels or create new zoom levels. The default zoom level is 100%.

- **Sample**: A nonconfigurable display of the sample outline of the hierarchy viewer node. Areas such as Title Area and attributes are highlighted in the sample when selected in the node area.

5. Click **OK**.

Figure 43-12 shows a completed Create Hierarchy Viewer dialog for the root level of the hierarchy viewer using data from a data collection named `RootEmployeeViewObj2`.

Attribute: /images/#{node.Id}.png

After completing the Create Hierarchy Viewer dialog, you can use the Properties window to specify settings for the hierarchy viewer attributes, and you can also use the child tags associated with the hierarchy viewer tag to customize the hierarchy viewer further. For detailed information about hierarchy viewer end user and presentation features, use cases, tag structure, and adding special features to hierarchy viewers, see the Using Hierarchy Viewer Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

When editing the hierarchy viewer in the visual editor, the display approximates the runtime display and functionality. You can rearrange attributes in the Structure window, or bind new attributes by dragging and dropping attributes from the Data Controls panel onto the Structure window.

What Happens When You Create a Databound Hierarchy Viewer

Creating a hierarchy viewer from Data Controls panel has the following effect:

- Creates the bindings for the hierarchy viewer in the page definition file of the JSF page
- Adds the necessary tags to the JSF page for the hierarchy viewer component

The example below displays bindings that JDeveloper generated for a hierarchy viewer component. The rules for populating the nodes of the master-detail tree are defined as a node definition. The example shows that two node definitions were generated. Each of these node definitions references a view object and associated attributes. The code example also references an accessor `SEmpView`.

```
<parameters/>
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="RootEmployeeViewObj2" RangeSize="25"
            DataControl="AppModuleDataControl"
            id="RootEmployeeViewObj2Iterator"/>
</executables>
<bindings>
  <tree IterBinding="RootEmployeeViewObj2Iterator" id="RootEmployeeViewObj2">
    <nodeDefinition DefName="model.RootEmployeeViewObj"
                    Name="RootEmployeeViewObj20">
      <AttrNames>
        <Item Value="ManagerId"/>
        <Item Value="TitleId"/>
        <Item Value="Userid"/>
        <Item Value="Comments"/>
        <Item Value="DeptId"/>
        <Item Value="StartDate"/>
        <Item Value="Email"/>
        <Item Value="Salary"/>
        <Item Value="FirstName"/>
        <Item Value="Id"/>
        <Item Value="CommissionPct"/>
        <Item Value="LastName"/>
      </AttrNames>
      <Accessors>
        <Item Value="SEmpView">
          <Properties>
            <CustomProperties>
              <Property Name="hierarchyType" Value="children"/>
            </CustomProperties>
          </Properties>
        </Item>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SEmpView" Name="RootEmployeeViewObj21">
      <AttrNames>
        <Item Value="ManagerId"/>
        <Item Value="TitleId"/>
        <Item Value="Userid"/>
        <Item Value="Comments"/>
        <Item Value="DeptId"/>
        <Item Value="StartDate"/>
        <Item Value="Email"/>
        <Item Value="Salary"/>
```

```
          <Item Value="FirstName"/>
          <Item Value="Id"/>
          <Item Value="CommissionPct"/>
          <Item Value="LastName"/>
        </AttrNames>
        <Accessors>
          <Item Value="SEmpView">
            <Properties>
              <CustomProperties>
                <Property Name="hierarchyType" Value="children"/>
              </CustomProperties>
            </Properties>
          </Item>
        </Accessors>
      </nodeDefinition>
    </tree>
</bindings>
```

The example below shows the code generated on the JSF page that is associated with the page definition file in the above example. For brevity, the details in the facet elements named `zoom75`, `zoom50`, and `zoom25` and panel card `showDetailItem` components have been omitted. In addition, the details for the second node in the hierarchy viewer have also been omitted.

The example shows a hierarchy viewer component that references the `RootEmployeeViewObj2` tree binding. It includes a node `(dvt:node)` component that in turn includes a panel card component `(dvt:panelCard)`. The panel card component defines `slide_horz` as the effect to use when changing the display of content referenced by the node.

Once you create your hierarchy viewer, you can modify the layout of the component or add additional components, such as a panel card, using the Create Hierarchy dialog illustrated in Figure 43-12. To open the dialog, use the **Edit** icon in the Properties window for the `hierarchyViewer` component. You can also customize the layout of a hierarchy viewer component directly in the code, in the visual editor, or by setting values in the Properties window. You can add additional components, such as panel cards, using the Components window.

```
<dvt:hierarchyViewer id="hv1" var="node"
                     value="#{bindings.RootEmployeeViewObj2.treeModel}"

selectionListener="#{bindings.RootEmployeeViewObj2.treeModel.makeCurrent}"
                     detailWindow="none" layout="hier_vert_top"
                     levelFetchSize="#{bindings.RootEmployeeViewObj2.rangeSize}"
                     styleClass="AFStretchWidth" summary="Hierarchy Viewer Demo">
  <dvt:link linkType="orthogonalRounded" id="l1"/>
  <dvt:node type="model.RootEmployeeViewObj" width="233" height="233" id="n1">
    <f:facet name="zoom100">
      <af:panelGroupLayout styleClass="AFStretchWidth AFHVNodeStretchHeight
                                       AFHVNodePadding"
                           layout="vertical" id="pgl1">
        <af:panelGroupLayout layout="horizontal" id="pgl2">
          <af:panelGroupLayout id="pgl7">
            <af:image source="/images/#{node.Id}.png" shortDesc="Employee Image"
                      id="i1" styleClass="AFHVNodeImageSize"/>
          </af:panelGroupLayout>
          <af:panelGroupLayout layout="vertical" id="pgl3">
            <af:outputText value="#{node.LastName}"
              shortDesc="#{bindings.RootEmployeeViewObj2.hints.LastName.tooltip}"
                           styleClass="AFHVNodeTitleTextStyle" id="ot1"/>
            <af:outputText value="#{node.FirstName}"

shortDesc="#{bindings.RootEmployeeViewObj2.hints.FirstName.tooltip}"
                           styleClass="AFHVNodeSubtitleTextStyle" id="ot2"/>
            <af:panelLabelAndMessage

label="#{bindings.RootEmployeeViewObj2.hints.Id.label}"
                           styleClass="AFHVNodeLabelStyle" id="plam1">
              <af:outputText value="#{node.Id}"

shortDesc="#{bindings.RootEmployeeViewObj2.hints.Id.tooltip}"
                             styleClass="AFHVNodeTextStyle" id="ot3">
                <af:convertNumber groupingUsed="false"

pattern="#{bindings.RootEmployeeViewObj2.hints.Id.format}"/>
              </af:outputText>
            </af:panelLabelAndMessage>
          </af:panelGroupLayout>
        </af:panelGroupLayout>
        <af:spacer height="5" id="s1"/>
        <dvt:panelCard effect="slide_horz" styleClass="AFHVNodePadding" id="pc1">
          <af:showDetailItem text="Contact Details" id="sdi1">
            <af:spacer height="2" id="s2"/>
            <af:panelFormLayout styleClass="AFStretchWidth AFHVNodeStretchHeight
                                            AFHVNodePadding"
                                id="pfl1">
              <af:panelLabelAndMessage
                       label="#{bindings.RootEmployeeViewObj2.hints.Email.label}"
                       styleClass="AFHVPanelCardLabelStyle" id="plam2">
                <af:outputText value="#{node.Email}"
                 shortDesc="#{bindings.RootEmployeeViewObj2.hints.Email.tooltip}"
                             styleClass="AFHVPanelCardTextStyle" id="ot4"/>
              </af:panelLabelAndMessage>
              <af:panelLabelAndMessage

label="#{bindings.RootEmployeeViewObj2.hints.Userid.label}"
                       styleClass="AFHVPanelCardLabelStyle" id="plam3">
                <af:outputText value="#{node.Userid}"

shortDesc="#{bindings.RootEmployeeViewObj2.hints.Userid.tooltip}"
                             styleClass="AFHVPanelCardTextStyle" id="ot5"/>
              </af:panelLabelAndMessage>
            </af:panelFormLayout>
          </af:showDetailItem>
            ... remaining showDetailItem panel card details omitted
        </dvt:panelCard>
      </af:panelGroupLayout>
    </f:facet>
      ... remaining zoom levels omitted
  </dvt:node>
  <dvt:node type="model.SEmpView" width="233" height="233" id="n2">
    ... second node details are similar to first node and are omitted
  </dvt:node>
</dvt:hierarchyViewer>
```

How to Configure an Alternate View Object for a Databound Panel Card

You can specify an alternate view object as the data source for a panel card when you create or edit a databound hierarchy viewer. For example, you may have a data collection that has a master-detail relationship between sales representatives and orders, but you want your panel card to display details about the customer who placed the order.

Figure 43-13 shows a portion of the runtime view of a hierarchy viewer configured to display the orders and order details for sales representatives using the Summit ADF schema. In this example, the hierarchy viewer is configured to use an alternate view object for the Customer Details panel card.

Figure 43-13   Hierarchy Viewer Panel Card Configured With Alternate View Object

The alternate view object must be a child of the parent collection. You can establish this parent-child relationship by creating a view link between the parent and child collection.

Before you begin:

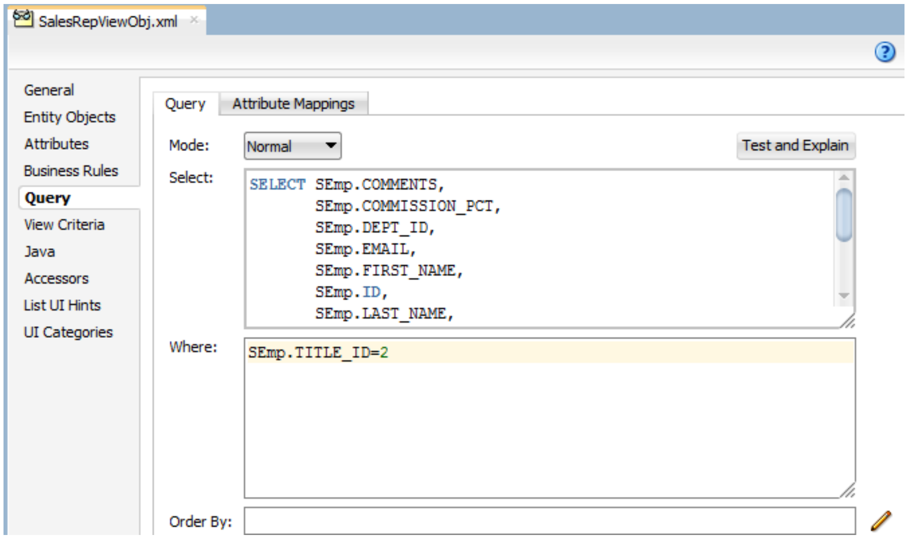
It may be helpful to have an understanding of databound hierarchy viewers. For more information, see Creating Databound Hierarchy Viewers.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

Create an application module that contains instances of the entity and view objects that you want in your application, as described in Creating and Modifying an Application Module.

Create the data model for the hierarchy viewer. For example, the hierarchy viewer in Figure 43-13 uses a top level view object based on the `SEmp` entity in the Summit ADF DVT sample application. In this example, the view object retrieves all sales representatives in the Summit ADF employee database by retrieving all employee records with a `TITLE_ID` of `2`. Figure 43-14 shows the `SalesRepViewObj` view object.

Figure 43-14 Sales Representatives View Object Using the Summit ADF Schema



Mode: Normal

Select:

```
SELECT  SEmp.COMMENTS,
        SEmp.COMMISSION_PCT,
        SEmp.DEPT_ID,
        SEmp.EMAIL,
        SEmp.FIRST_NAME,
        SEmp.ID,
        SEmp.LAST_NAME,
```

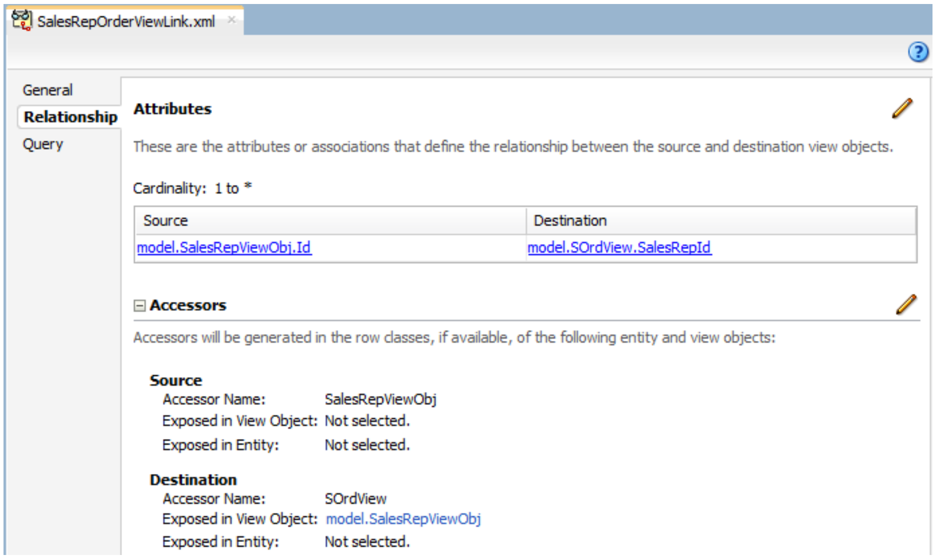
Where:

```
SEmp.TITLE_ID=2
```

For information about creating a view object, see How to Create an Entity-Based View Object.

The master-detail relationship between the Summit sales representatives and orders is established with a view link between `SalesRepViewObj` and `OrdersViewObj`. Figure 43-15 shows the relationship between the view objects.

Figure 43-15   View Link Between Summit Sales Representatives and Orders



SalesRepOrderViewLink.xml

Attributes

These are the attributes or associations that define the relationship between the source and destination view objects.

Cardinality: 1 to *

Source	Destination
model.SalesRepViewObj.Id	model.SOrdView.SalesRepId

Accessors

Accessors will be generated in the row classes, if available, of the following entity and view objects:

Source

Accessor Name:	SalesRepViewObj
Exposed in View Object:	Not selected.
Exposed in Entity:	Not selected.

Destination

Accessor Name:	SOrdView
Exposed in View Object:	model.SalesRepViewObj
Exposed in Entity:	Not selected.

For additional information about establishing the master-detail relationship using view links, see How to Create a Master-Detail Hierarchy Based on Entity Associations.

To configure an alternate view object for a databound panel card:

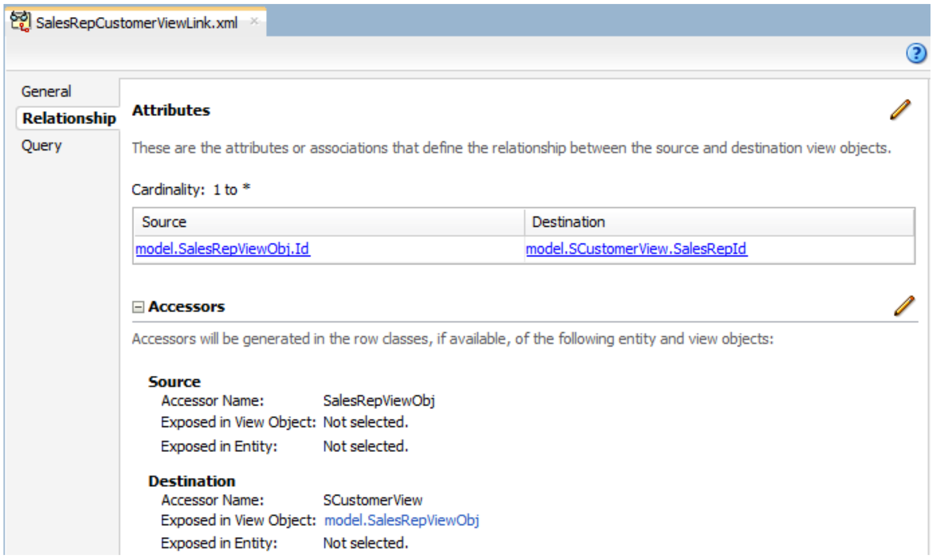
1. If you have not already done so, create the view object that will be the alternate data source for the panel card.

   For example, the hierarchy viewer in Figure 43-13 uses a view object based on the `SCustomer` entity object in the Summit ADF DVT sample application.

2. Create a view link between the parent collection and the alternate view object.

   Figure 43-16 shows the view link between the sales representatives and customers in the Summit ADF DVT sample application. For help with creating view links, see How to Create a Master-Detail Hierarchy Based on Entity Associations.

Figure 43-16 View Link Between Sales Representatives and Customers in the Summit ADF DVT Sample Application



Attributes

These are the attributes or associations that define the relationship between the source and destination view objects.

Cardinality: 1 to *

Source	Destination
model.SalesRepViewObj.Id	model.SCustomerView.SalesRepId

⊟ **Accessors**

Accessors will be generated in the row classes, if available, of the following entity and view objects:

Source

Accessor Name:	SalesRepViewObj
Exposed in View Object:	Not selected.
Exposed in Entity:	Not selected.

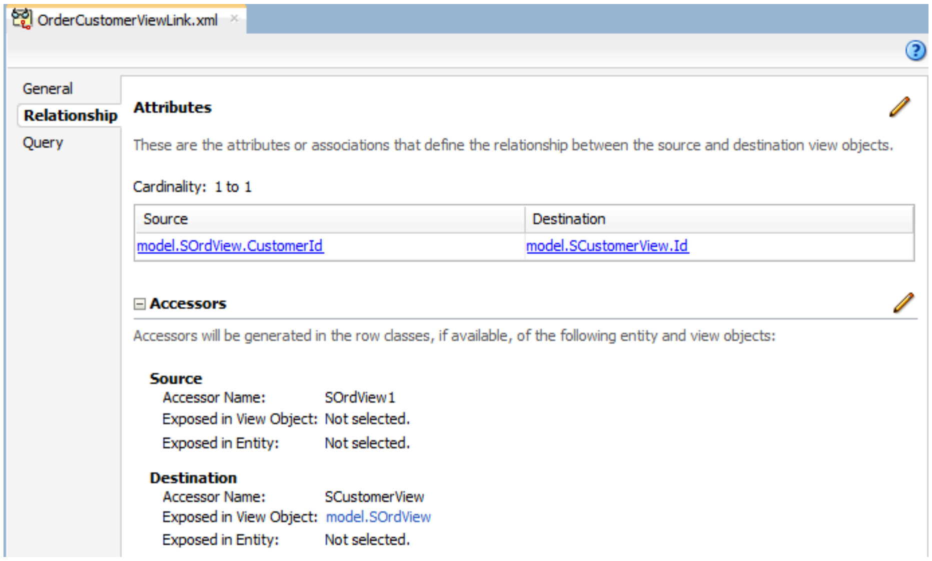
Destination

Accessor Name:	SCustomerView
Exposed in View Object:	model.SalesRepViewObj
Exposed in Entity:	Not selected.

3. If needed, create a view link to establish the hierarchy between the parent collection and the alternate child collection.

   For example, to establish the hierarchy between orders and customers in the Summit ADF DVT sample application, create a view link between the `SOrdView` and `SCustomerView` collections. Figure 43-17 shows the sample view link.

Figure 43-17 View Link Between Orders and Customers in the Summit ADF DVT Sample Application



Attributes

These are the attributes or associations that define the relationship between the source and destination view objects.

Cardinality: 1 to 1

Source	Destination
model.SOrdView.CustomerId	model.SCustomerView.Id

⊟ **Accessors**

Accessors will be generated in the row classes, if available, of the following entity and view objects:

Source

Accessor Name:	SOrdView1
Exposed in View Object:	Not selected.
Exposed in Entity:	Not selected.

Destination

Accessor Name:	SCustomerView
Exposed in View Object:	model.SOrdView
Exposed in Entity:	Not selected.

What Happens When You Use an Alternate View Object for a Hierarchy Viewer Panel Card

When you configure your hierarchy viewer to use an alternate view object for the panel card data source, JDeveloper adds the bindings for the hierarchy viewer and alternate source in the page definition file of the JSF page.

The example below shows the sample bindings for the hierarchy viewer displayed in Figure 43-13. The entries for the alternate source are highlighted. Note that the alternate data source is defined as one of the hierarchy viewer's node definitions.

```
<bindings>
  <tree IterBinding="SalesRepViewObj2Iterator" id="SalesRepViewObj2">
    <nodeDefinition DefName="model.SalesRepViewObj" Name="SalesRepViewObj20">
      <AttrNames>
        <Item Value="ManagerId"/>
        <Item Value="TitleId"/>
        <Item Value="Userid"/>
        <Item Value="Comments"/>
        <Item Value="DeptId"/>
        <Item Value="StartDate"/>
        <Item Value="Email"/>
        <Item Value="Salary"/>
        <Item Value="FirstName"/>
        <Item Value="Id"/>
        <Item Value="CommissionPct"/>
        <Item Value="LastName"/>
      </AttrNames>
      <Accessors>
        <Item Value="SOrdView">
          <Properties>
            <CustomProperties>
              <Property Name="hierarchyType" Value="children"/>
            </CustomProperties>
          </Properties>
        </Item>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SOrdView" Name="SalesRepViewObj21">
      <AttrNames>
        <Item Value="DateShipped"/>
        <Item Value="DateOrdered"/>
        <Item Value="Id"/>
        <Item Value="Total"/>
      </AttrNames>
      <Accessors>
        <Item Value="SItemView">
          <Properties>
            <CustomProperties>
              <Property Name="hierarchyType" Value="children"/>
            </CustomProperties>
          </Properties>
        </Item>
        <Item Value="SCustomerView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SCustomerView" Name="SalesRepViewObj22">
      <AttrNames>
        <Item Value="Name"/>
        <Item Value="Phone"/>
        <Item Value="City"/>
      </AttrNames>
    </nodeDefinition>
    <nodeDefinition DefName="model.SItemView" Name="SalesRepViewObj23">
      <AttrNames>
        <Item Value="QuantityShipped"/>
        <Item Value="ItemId"/>
        <Item Value="Quantity"/>
        <Item Value="Price"/>
        <Item Value="OrdId"/>
        <Item Value="ProductId"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

How to Create a Databound Search in a Hierarchy Viewer

The search function in a hierarchy viewer is based on the searchable attributes or columns of the data collection that is the basis of the hierarchy viewer data model. Using a query results collection defined in data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop an **ExecuteWithParams** operation into an existing hierarchy viewer component on the page.

Figure 43-18 shows the Summit ADF DVT employee hierarchy viewer configured to search for employees by last name. In this example, the user can enter an employee's last name in the Search panel or specify a pattern match using `%` or `_`.

Before you begin:

It may be helpful to have an understanding of databound hierarchy viewers. For more information, see Creating Databound Hierarchy Viewers.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

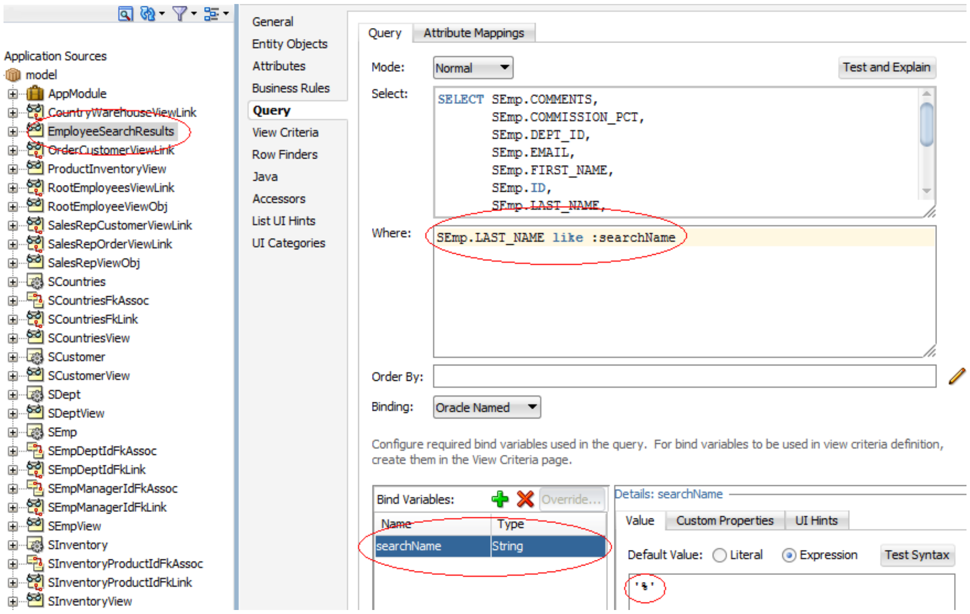
You will need to complete these tasks:

1. Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.
2. Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.
3. Create a databound hierarchy viewer component as described in How to Create a Hierarchy Viewer Using ADF Data Controls.
4. Verify the query that retrieves the root node in the hierarchy viewer.

   For example, Figure 43-6 shows retrieving the root node by the `Id` column and storing it in the `rootEmpno` bind variable.
5. Create a view object that performs the search.

   For example, Figure 43-19 shows the `EmployeesSearchResults` view object that performs the search based on the `LastName` column in the data collection with a default value of `%` for matching any value, and a comparison value of `like` to enable pattern matching.

Figure 43-19 EmployeeSearchResults View Object



Mode: Normal

Select:

```
SELECT SEmp.COMMENTS,
       SEmp.COMMISSION_PCT,
       SEmp.DEPT_ID,
       SEmp.EMAIL,
       SEmp.FIRST_NAME,
       SEmp.ID,
       SEmp.LAST_NAME,
```

Where:

```
SEmp.LAST_NAME like :searchName
```

Order By:

Binding: Oracle Named

Configure required bind variables used in the query. For bind variables to be used in view criteria definition, create them in the View Criteria page.

Bind Variables:

Name	Type
searchName	String

Details: searchName

Default Value: ○ Literal ● Expression

```
'%'
```

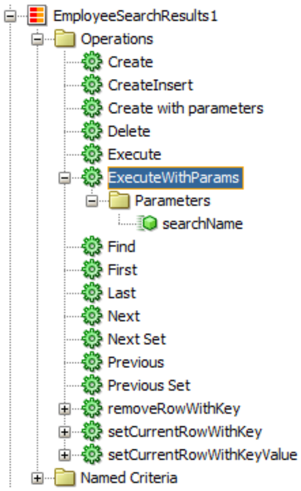
For information about creating a view object, see How to Create an Entity-Based View Object.

To create a databound search with a hierarchy viewer:

1. From the Data Controls panel, select the collection that corresponds to the query results and expand the **Operations** node to display the **ExecuteWithParams** operation.

Figure 43-20 shows the expanded `EmployeeSearchResults1` operations node in the Summit ADF DVT sample application.

Figure 43-20 ExecuteWithParams Operation for Hierarchy Viewer Search Example



2. Drag the **ExecuteWithParams** operation and drop it onto the hierarchy viewer in the visual editor or onto the component in the Structure window.

3. In the Create Hierarchy Viewer Search dialog, use the **Add** icon to specify the list of results to display in the Search Results panel, and specify the following for each result:

   a. **Display Label**: Select the values for the headers of the nodes in the hierarchy. If you select `<default>`, then the text for the header is automatically retrieved from the data binding.

   b. **Value Binding:** Select the columns in the data collection to use for nodes in the tree for the hierarchy viewer.

   c. **Component to Use**: Select the type of component to display in the node. The default is the ADF Output Text component.

   After selecting an existing field, use the arrow icons (**Up**, **Down**, **Top**, **Bottom**) to reorder the results or use the **Delete** icon to delete that result.

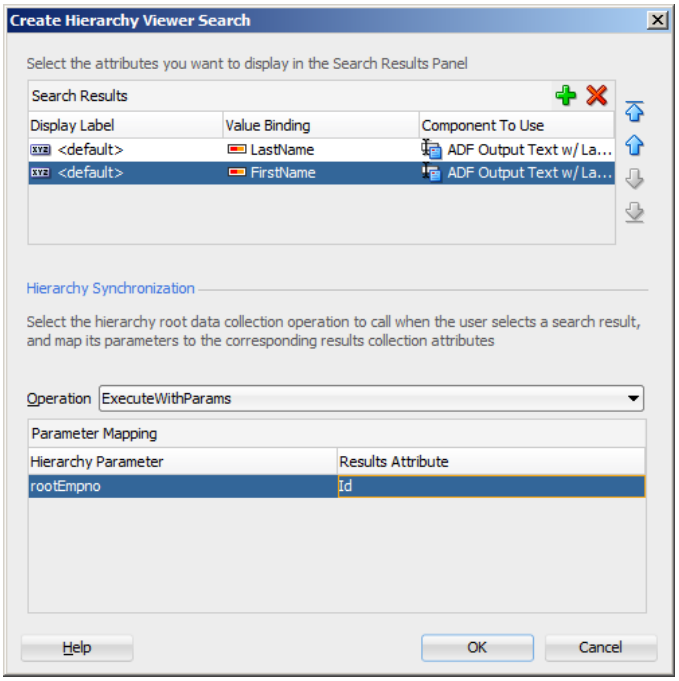
4. In the **Operation** dropdown list, select the hierarchy root data collection to use when a search result is selected. Valid values include:

   - **removeRowWithKey**: Uses the row key as a `String` converted from the value specified by the input field to remove the data object in the bound data collection.
   - **setCurrentRowWithKey**: Sets the row key as a `String` converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection.
   - **setCurrentRowWithKeyValue**: Sets the current object on the iterator, given a key's value.
   - **ExecuteWithParams**: Sets the values to the named bind variables passed as parameters.

5. In the **Parameter Mapping** table, use the dropdown list in the **Results Attribute** column to select the results collection attribute to map to the parameter displayed in the **Hierarchy Parameter** column.

Figure 43-21 shows the Create Hierarchy Viewer Search dialog that appears if you create a hierarchy viewer using data from a data collection named `EmployeesSearchResults1`.

Figure 43-21 Create Hierarchy Viewer Search Dialog



Create Hierarchy Viewer Search

Select the attributes you want to display in the Search Results Panel

Search Results

Display Label	Value Binding	Component To Use
<default>	LastName	ADF Output Text w/ La...
<default>	FirstName	ADF Output Text w/ La...

Hierarchy Synchronization

Select the hierarchy root data collection operation to call when the user selects a search result, and map its parameters to the corresponding results collection attributes

Operation: ExecuteWithParams

Parameter Mapping

Hierarchy Parameter	Results Attribute
rootEmpno	Id

The example below shows the code on the JSF page after you click OK and the `dvt:search` is added to the page as a child of the hierarchy viewer component.

```
<dvt:search value="#{bindings.searchName.inputValue}"
            actionListener="#{bindings.ExecuteWithParams.execute}" id="s19">
  <f:facet name="end">
    <af:link text="Advanced" styleClass="AFHVAdvancedSearchLinkStyle" id="l1"/>
  </f:facet>
  <dvt:searchResults id="sr1"
                     value="#{bindings.EmployeeSearchResults.collectionModel}"
                     emptyText="#{bindings.EmployeeSearchResults.viewable ?
                               'No data to display.' : 'Access Denied.'}"
                     fetchSize="#{bindings.EmployeeSearchResults.rangeSize}"
                     resultListener="#{bindings.ExecuteWithParams1.execute}"
                     var="resultRow">
    <af:setPropertyListener type="action" from="#{resultRow.Id}"
                            to="#{bindings.rootEmpno.inputValue}"/>
    <f:facet name="content">
      <af:panelGroupLayout layout="horizontal" id="pgl27">
        <af:panelLabelAndMessage

label="#{bindings.ExecuteWithParams.hints.LastName.label}"
                        id="plam29">
          <af:outputText value="#{resultRow.LastName}"
```

```
shortDesc="#{bindings.ExecuteWithParams.hints.LastName.tooltip}"
                  id="ot45"/>
        </af:panelLabelAndMessage>
        <af:panelLabelAndMessage

label="#{bindings.ExecuteWithParams.hints.FirstName.label}"
                       id="plam30">
          <af:outputText value="#{resultRow.FirstName}"

shortDesc="#{bindings.ExecuteWithParams.hints.FirstName.tooltip}"
                 id="ot46">
            <af:convertNumber groupingUsed="false"

pattern="#{bindings.ExecuteWithParams.hints.FirstName.format}"/>
          </af:outputText>
        </af:panelLabelAndMessage>
      </af:panelGroupLayout>
    </f:facet>
  </dvt:searchResults>
</dvt:search>
```

At runtime, the search results are displayed in a table by `LastName` and `FirstName`. Figure 43-22 shows the search results panel if a user enters `C%` to search for all employees whose last names begin with `C`.

Creating Databound Treemaps and Sunbursts

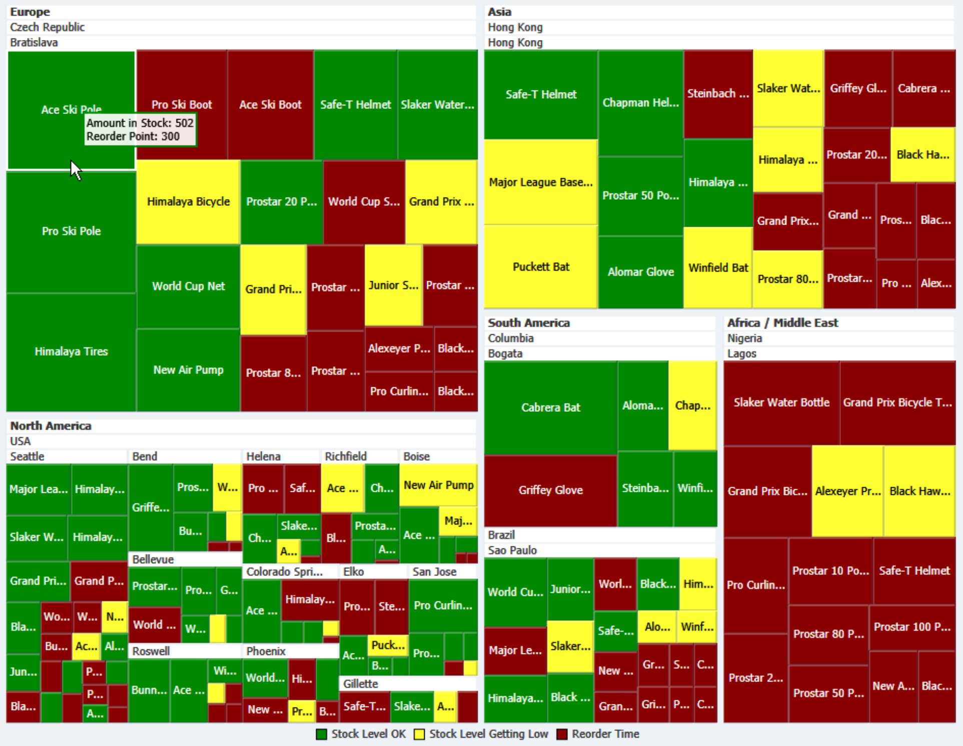
Treemaps and sunbursts are ADF Data Visualization components that display quantitative hierarchical data across two dimensions, represented visually by size and color. This is used to identify data trends easily and quickly.

For example, you can use a treemap or sunburst to display quarterly regional sales and to identify sales trends, using the size of the node to indicate each region's sales volume and the node's color to indicate whether that region's sales increased or decreased over the quarter.

Treemaps and sunbursts use a shape called a `node` to reference the data in the hierarchy. Treemaps display nodes as a set of nested rectangles. Each branch of the tree is given a rectangle, which is then tiled with smaller rectangles representing sub-branches.

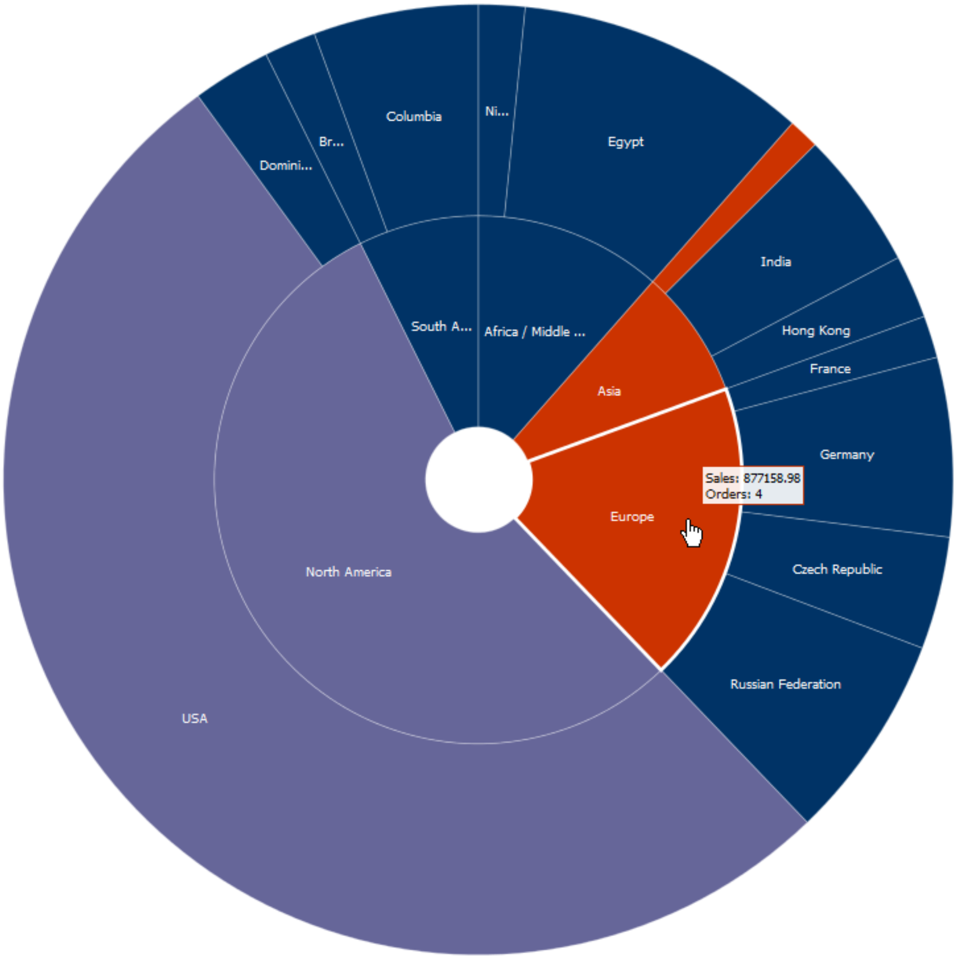
Figure 43-24 shows a treemap displaying the products available at warehouses in the Summit ADF DVT sample application. In this example, the node size represents the amount in stock for each product, and node color represents inventory status.

Figure 43-24 Treemap Showing Product Availability and Inventory Levels



Sunbursts display the nodes in a radial rather than a rectangular layout, with the top of the hierarchy at the center and deeper levels farther away from the center. Figure 43-25 shows a sunburst configured to show sales by region and country, with color used to indicate the number of orders per region and country.

Figure 43-25 Sunburst Showing Product Availability and Inventory Levels



The shape and content of the nodes are configurable, as well as the visual layout of the nodes. For detailed information about treemap and sunburst end user and presentation features, use cases, tag structure, and adding special features, see the Using Treemap and Sunburst Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create Treemaps and Sunbursts Using ADF Data Controls

Treemaps and sunbursts are based on data collections where a master-detail relationship exists between one or more detail collections and a master data collection. Treemaps and sunbursts also require that the following attributes be set in JDeveloper:

- `value`: the size of the node
- `fillColor`: the color of the node
- `label`: a text identifier for the node

The values for the `value` and `label` attributes must be stored in the treemap's or sunburst's data model or in classes and managed beans if you are using UI-first development. You can specify the `fillColor` values in the data model, classes, and managed beans, or declaratively in the Properties window.

In order to configure a treemap or sunburst successfully, ensure that the data adheres to the following rules:

- Each child node can have only one parent node.
- There can be no skipped levels.

Using data controls in Oracle ADF, JDeveloper makes treemap and sunburst creation a declarative task. You drag and drop a data collection from the Data Controls panel that generates one or more nodes onto a JSF page.

Before you begin:

It may be helpful to have an understanding of databound treemaps and sunbursts. For more information, see Creating Databound Treemaps and Sunbursts.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Creating and Modifying an Application Module.

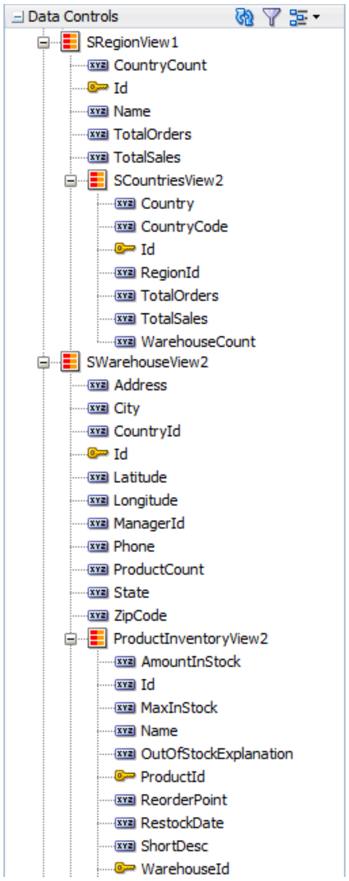
  If you need help working with master-detail relationships, see Displaying Master-Detail Data.
- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a treemap or sunburst using the Data Controls panel:

1. From the Data Controls panel, select a collection.

   Figure 43-26 shows the data collection for the treemap in Figure 43-24 and the sunburst in Figure 43-25.

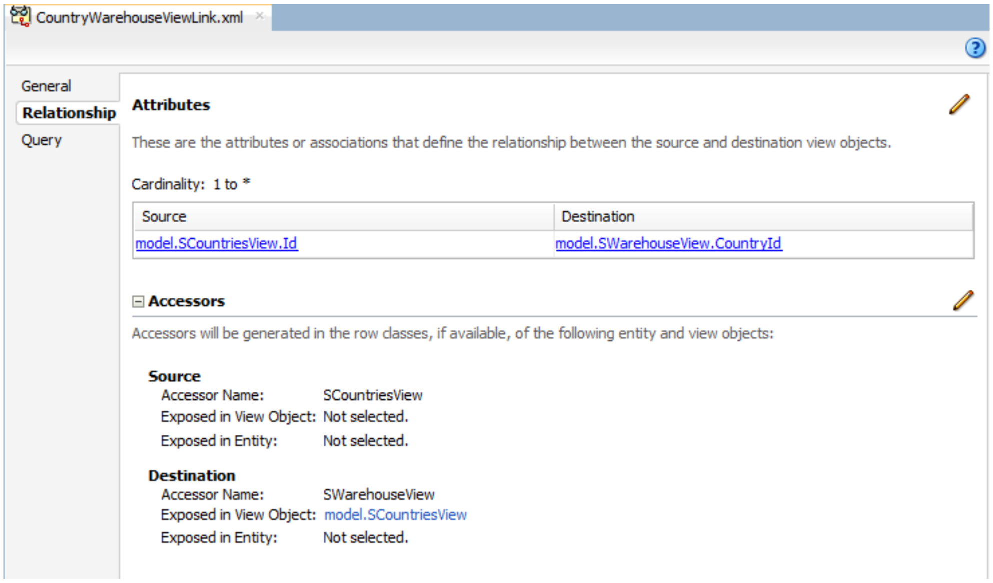
Figure 43-26   Sample Data Collection for Treemap and Sunburst



```
Data Controls
  SRegionView1
    CountryCount
    Id
    Name
    TotalOrders
    TotalSales
    SCountriesView2
      Country
      CountryCode
      Id
      RegionId
      TotalOrders
      TotalSales
      WarehouseCount
  SWarehouseView2
    Address
    City
    CountryId
    Id
    Latitude
    Longitude
    ManagerId
    Phone
    ProductCount
    State
    ZipCode
    ProductInventoryView2
      AmountInStock
      Id
      MaxInStock
      Name
      OutOfStockExplanation
      ProductId
      ReorderPoint
      RestockDate
      ShortDesc
      WarehouseId
```

In the Summit ADF DVT sample, the application uses a view link between the `SCountriesView2` collection and the `SWarehouseView2` collection to establish a hierarchy between the `SRegionView1` and `SWarehouseView2` data collections. Figure 43-27 shows the sample view link.

Figure 43-27 Sample View Link Between Country and Warehouse



Attributes

These are the attributes or associations that define the relationship between the source and destination view objects.

Cardinality: 1 to *

Source	Destination
model.SCountriesView.Id	model.SWarehouseView.CountryId

Accessors

Accessors will be generated in the row classes, if available, of the following entity and view objects:

Source
Accessor Name: SCountriesView
Exposed in View Object: Not selected.
Exposed in Entity: Not selected.

Destination
Accessor Name: SWarehouseView
Exposed in View Object: model.SCountriesView
Exposed in Entity: Not selected.

Table 43-1 shows the data collection and size, label, and color values used to create the treemap in Figure 43-24.

Table 43-1 Sample Values for Treemap Inventory Example

Collection	Size Value	Label Value	Color Value
`SRegionView1`	`CountryCount`	`Name`	`CountryCount`
`SCountriesView2`	`WarehouseCount`	`Country`	`WarehouseCount`
`SWarehouseView2`	`ProductCount`	`City`	`ProductCount`
`ProductInventoryView2`	`AmountInStock`	`Name`	Varies by stock level

The `CountryCount`, `WarehouseCount`, and `ProductCount` attributes are transient attributes that count the number of countries, warehouses, and products in the data collection. For example, the number of countries in a region is calculated by counting the number of unique `Id` values in the `SCountriesView` child collection that match the `RegionId` of the region:

```
SCountriesView.count('Id')
```

Table 43-2 shows the data collection and size, label, and color values used to create the sunburst in Figure 43-25.

Table 43-2 Sample Values for Sunburst Sales Example

Collection	Size Value	Label Value	Color Value
`SRegionView1`	`TotalSales`	`Name`	`TotalOrders`
`SCountriesView2`	`TotalSales`	`Country`	`TotalOrders`

The TotalSales and TotalOrders attributes are transient attributes that calculate the total sales volume and number of orders for each region and country in the data collection. For example, the total sales in a region is calculated by summing the TotalSales in the SCountriesView collection:

```
SCountriesView.sum ('TotalSales')
```

For information about adding transient attributes to view objects, see Adding Calculated and Transient Attributes to a View Object.

2. Drag the collection onto a JSF page and, from the context menu, choose **Treemap** or **Sunburst**.
3. In the Create Treemap dialog or Create Sunburst dialog, in the **Hierarchy** section, select the collections you want to include as nodes in the runtime treemap or sunburst. By default, the root collection is selected.
4. For each collection that you select in the Hierarchy list, enter a value for the following.
   - **Value**: From the dropdown list, select the attribute in the data collection that represents the size value for the sunburst. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression. For help with the Expression Builder dialog, press **F1** or click **Help**.

     For example, to create a treemap or sunburst using the data collection in Figure 43-26, select CountryCount for the **SRegionView1** value to represent the size value for the first node.
   - **Label**: From the dropdown list, select the attribute in the data collection that represents the label you wish to display for the sunburst node label. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

     For example, select Name for the **SRegionView1** node label.
   - Optionally, in the **View Area** section, click **New** to configure an attribute group for the node. Use attribute groups if you want the node's display to vary based on color or pattern. You can also specify the node's fill color or pattern in the node's fillColor and fillPattern properties after you create the treemap or sunburst.

     If you do not configure an attribute group to vary by color or specify a fillColor attribute on the node, the node will display in black. By default, no pattern will be displayed on the node.

     In the treemap and sunburst example, attribute groups are configured for each level in the hierarchy.

     To configure an attribute group, enter values for the following:
     - **Group by value**: From the dropdown list, select the attribute in the data collection to group by in the attribute group. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

       In the treemap example, the colors used are based on the count metric for each level in the hierarchy. For example, select **CountryCount** as the **Group by value** for the SRegionView1 collection, and the colors displayed on the **Regions** node will vary depending upon the number of countries in a given region.

In the sunburst example, the colors used are based on the number of orders for each level in the hierarchy. For example, select **TotalOrders** as the **Group by value** for the `SRegionView1` collection, and the colors displayed on the **Regions** node will vary depending upon the number of orders in a given region.

- **Area**: From the dropdown list, select **Color** if you want the attribute group to vary by color or select **Pattern** if you want the attribute group to vary by pattern. To vary the attribute group by both color and pattern, select **Select Multiple Attributes** and select both **Color** and **Pattern**. Click **OK**.

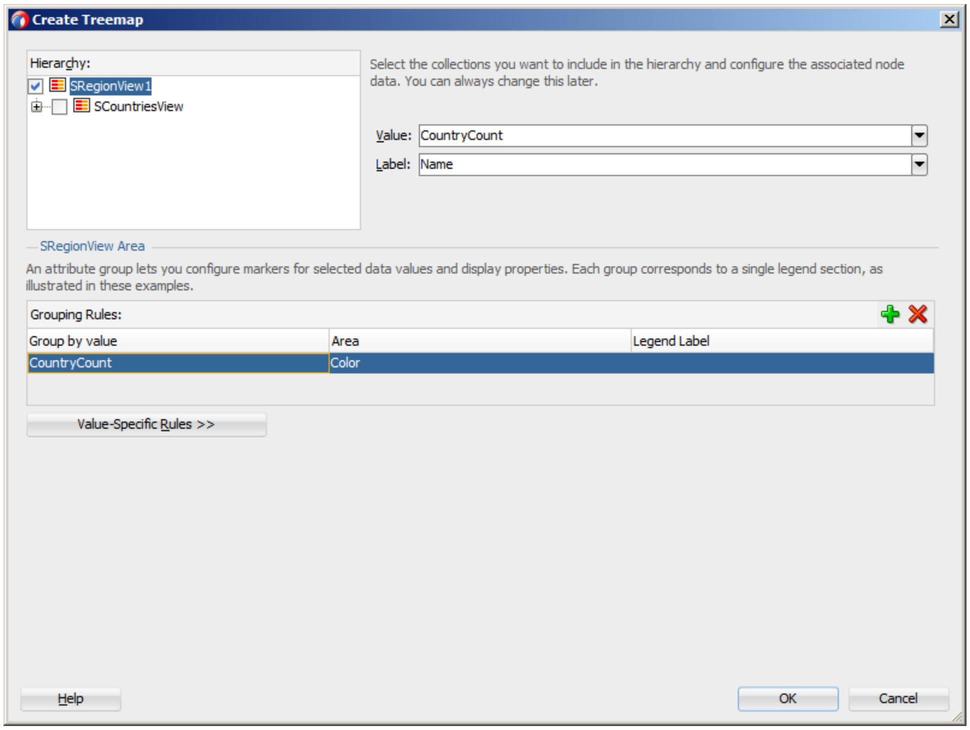
  In the treemap and sunburst examples, color is used for each level of the hierarchy.

- **Legend Label**: From the dropdown list, select the attribute in the data collection to display in the treemap's legend. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

  In the treemap and sunburst examples, this value is left blank.

Figure 43-28 shows the Create Treemap dialog completed for the first node in the Summit ADF DVT sample application.

Figure 43-28 Create Treemap Dialog for a Region Node



Hierarchy:
☑ SRegionView1
□ SCountriesView

Select the collections you want to include in the hierarchy and configure the associated node data. You can always change this later.

Value: CountryCount
Label: Name

SRegionView Area

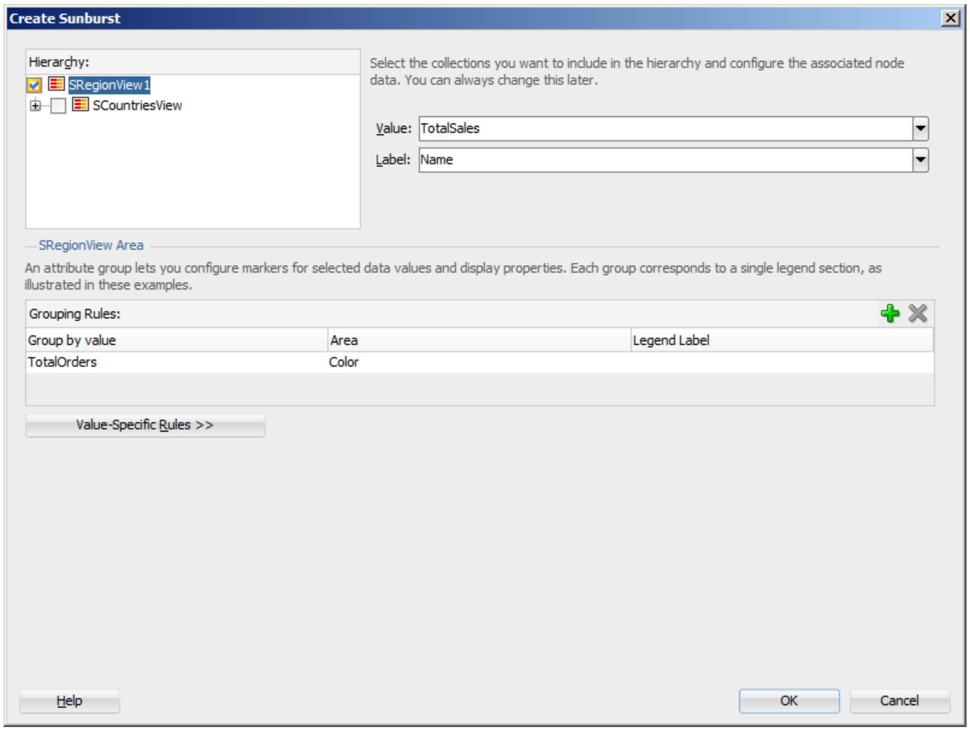
An attribute group lets you configure markers for selected data values and display properties. Each group corresponds to a single legend section, as illustrated in these examples.

Grouping Rules:

Group by value	Area	Legend Label
CountryCount	Color	

Figure 43-29 shows the Create Sunburst dialog completed for the first node in the Summit ADF DVT sample application.

Figure 43-29 Create Sunburst Dialog for a Region Node



Create Sunburst

Hierarchy:

☑ SRegionView1

□ SCountriesView

Select the collections you want to include in the hierarchy and configure the associated node data. You can always change this later.

Value: TotalSales

Label: Name

SRegionView Area

An attribute group lets you configure markers for selected data values and display properties. Each group corresponds to a single legend section, as illustrated in these examples.

Grouping Rules:

Group by value	Area	Legend Label
TotalOrders	Color	

- Optionally, click **Value-Specific Rules** to expand the attribute group dialog to specify a match or exception rule. Use match rules to specify colors or patterns for simple true or false conditions or when you want to match a specific value. Use exception rules when you want to specify a color or pattern when the node's grouped-by value meets a specific condition.

  To specify a match rule, in the **Match Rules** section, click **New** and enter values for the following:

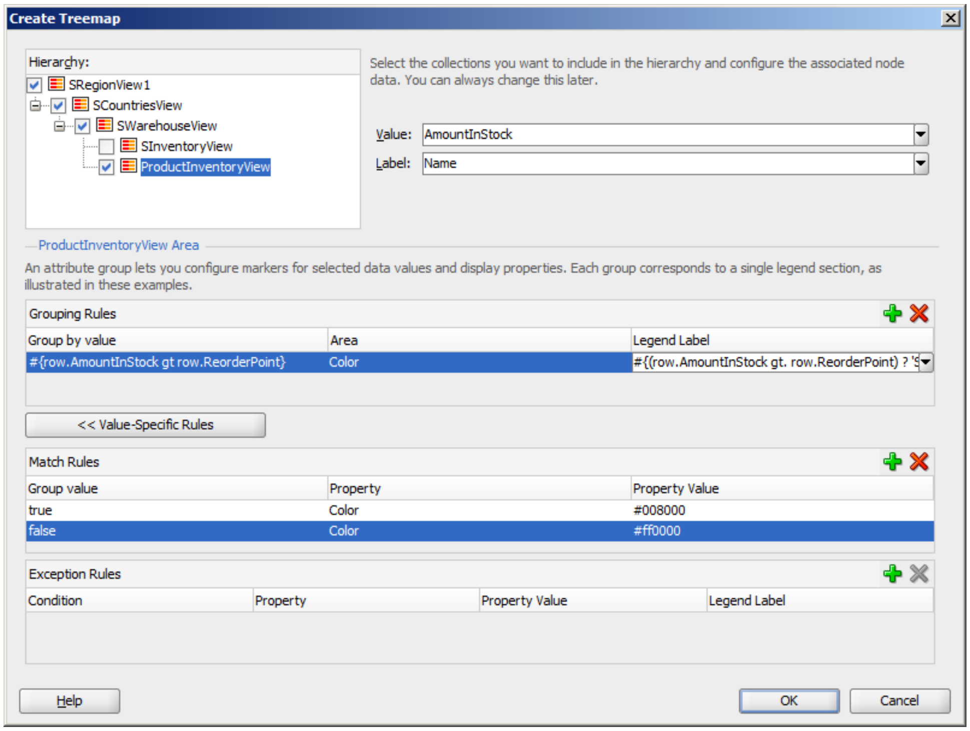
  – **Group Value**: Enter the category value for the match. This can be a string that represents a category or you can set this to `true` or `false`. If you set this to true or false, the **Group by value** field must contain an EL expression that evaluates to true or false as in the following example:`#{row.AmountInStock gt row.ReorderPoint}`.

  – **Property**: From the dropdown list, select **Color** if you want the node to vary by color or select **Pattern** if you want the attribute node to vary by pattern.

  – **Property Value**: From the dropdown list, select the color or pattern to display when the node's value matches the **Group Value**. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.

  Figure 43-30 shows the Create Treemap dialog for a data collection using match rules for the bottom level of the hierarchy.

Figure 43-30 Treemap Showing Match Rules for an Attribute Group



Create Treemap

Hierarchy:

- ☑ SRegionView1
  - ☑ SCountriesView
    - ☑ SWarehouseView
      - □ SInventoryView
      - ☑ ProductInventoryView

Select the collections you want to include in the hierarchy and configure the associated node data. You can always change this later.

Value: AmountInStock

Label: Name

ProductInventoryView Area

An attribute group lets you configure markers for selected data values and display properties. Each group corresponds to a single legend section, as illustrated in these examples.

Grouping Rules

Group by value	Area	Legend Label
#{row.AmountInStock gt row.ReorderPoint}	Color	#{(row.AmountInStock gt. row.ReorderPoint) ? 'S

<< Value-Specific Rules

Match Rules

Group value	Property	Property Value
true	Color	#008000
false	Color	#ff0000

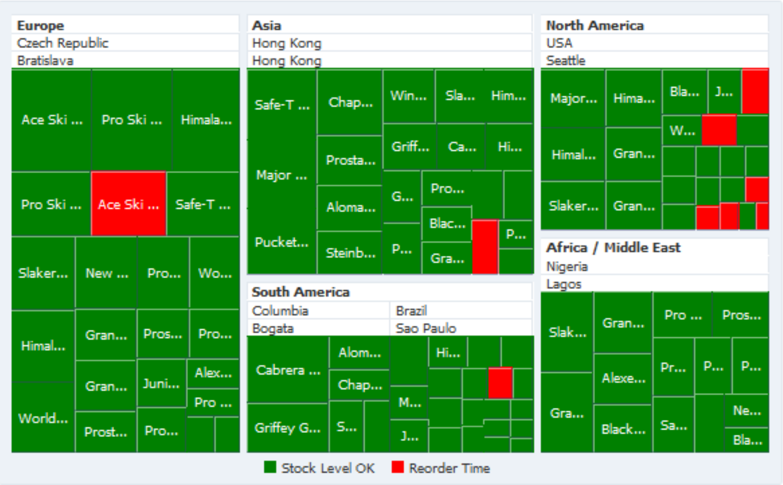
Exception Rules

Condition	Property	Property Value	Legend Label

In this example, the treemap nodes will display in green (RGB hexadecimal `#008000`) when the inventory levels are acceptable and in red (RBG hexadecimal `#ff0000`) when the inventory level is at or below the product's reorder level. The attribute group's **Label** field contains the details for the legend display. In this case, the field contains an expression that determines the legend label based on an item's amount in stock: `#{(row.AmountInStock gt row.ReorderPoint) ? 'Stock Level OK': 'Reorder Time'}`.

Figure 43-31 shows the runtime treemap.

Figure 43-31 Treemap Showing Match Rules at Runtime



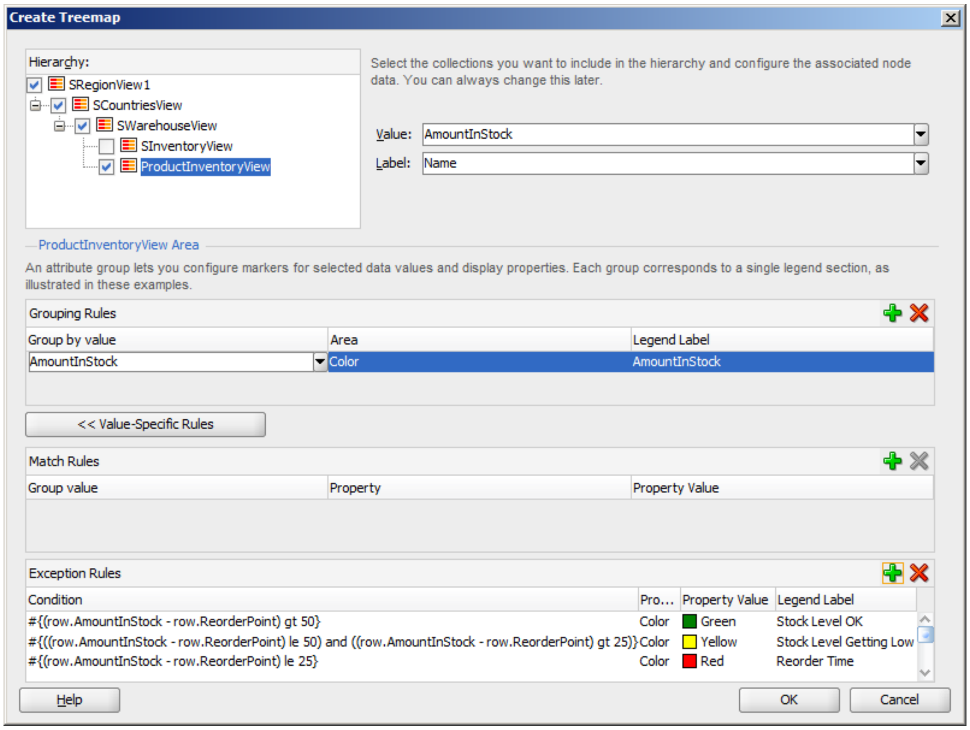
To specify an exception rule, in the **Exception Rules** section, click **New** and enter values for the following:

– **Condition**: Enter a JSF EL expression that evaluates to true or false. You can enter the expression directly in the **Condition** field or select **Expression Builder** to enter the JSF EL expression.

  In the Summit ADF DVT sample application, three exception rules are defined for the bottom level of the hierarchy. When the product's inventory level is well above the reorder level, the treemap node in Figure 43-24 and the sunburst node in Figure 43-25 display in green. The treemap and sunburst node display in yellow when the inventory level is close to the reorder point and display in red when the inventory level is at or very near the reorder point.

  Figure 43-32 shows the Create Treemap dialog for the Summit ADF DVT sample data collection using exception rules for the bottom level of the hierarchy.

Figure 43-32 Treemap Showing Exception Rules Creation Dialog



Create Treemap

Hierarchy:
- ☑ SRegionView1
  - ☑ SCountriesView
    - ☑ SWarehouseView
      - □ SInventoryView
      - ☑ ProductInventoryView

Select the collections you want to include in the hierarchy and configure the associated node data. You can always change this later.

Value: AmountInStock

Label: Name

ProductInventoryView Area

An attribute group lets you configure markers for selected data values and display properties. Each group corresponds to a single legend section, as illustrated in these examples.

Grouping Rules

Group by value	Area	Legend Label
AmountInStock	Color	AmountInStock

<< Value-Specific Rules

Match Rules

Group value	Property	Property Value

Exception Rules

Condition	Pro...	Property Value	Legend Label
#{(row.AmountInStock - row.ReorderPoint) gt 50}	Color	🟩 Green	Stock Level OK
#{((row.AmountInStock - row.ReorderPoint) le 50) and ((row.AmountInStock - row.ReorderPoint) gt 25)}	Color	🟨 Yellow	Stock Level Getting Low
#{(row.AmountInStock - row.ReorderPoint) le 25}	Color	🟥 Red	Reorder Time

> **Note:**
>
> In this example, the condition is referencing the `ReorderPoint` attribute from the data collection. To use this attribute, you must manually add it to the binding for the treemap after the treemap is created. For more information, see What Happens When You Create a Databound Treemap or Sunburst.

- **Property**: From the dropdown list, select **Color** if you want the node to vary by color. Select **Pattern** if you want the node to vary by pattern.
- **Property Value**: From the dropdown list, select the color or pattern to display when the node's value meets the condition you specified in the **Condition** field. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.
- **Legend Label**: From the dropdown list, select **Select Text Resource** to select a text resource to be used for the legend label. You can also enter text in this field or select **Expression Builder** to enter a JSF EL expression.

5. Click **OK**.

What Happens When You Create a Databound Treemap or Sunburst

Creating a treemap or sunburst from Data Controls panel has the following effect:

- Creates the bindings for the sunburst or treemap in the page definition file of the JSF page
- Adds the necessary tags to the JSF page for the `treemap` or `sunburst` component

The example below displays bindings that JDeveloper generated for a `treemap` component using the data collection in Figure 43-26.

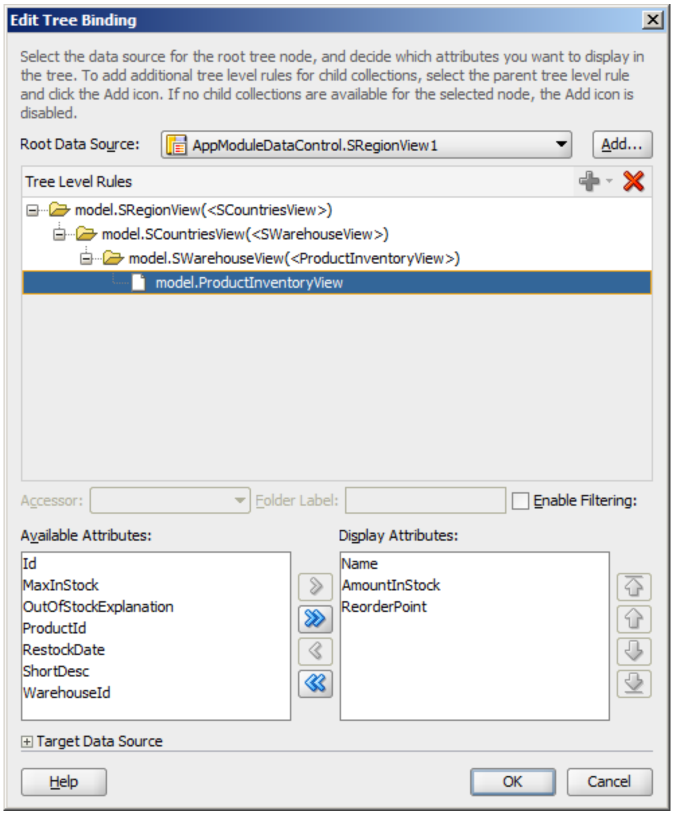
```
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="SRegionView1" RangeSize="-1"
            DataControl="AppModuleDataControl" id="SRegionView1Iterator"/>
</executables>
<bindings>
  <tree IterBinding="SRegionView1Iterator" id="SRegionView1">
    <nodeDefinition DefName="model.SRegionView" Name="SRegionView10">
      <AttrNames>
        <Item Value="CountryCount"/>
        <Item Value="Name"/>
      </AttrNames>
      <Accessors>
        <Item Value="SCountriesView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SCountriesView" Name="SRegionView11">
      <AttrNames>
        <Item Value="WarehouseCount"/>
        <Item Value="Country"/>
      </AttrNames>
      <Accessors>
        <Item Value="SWarehouseView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SWarehouseView" Name="SRegionView12">
      <AttrNames>
        <Item Value="ProductCount"/>
        <Item Value="City"/>
      </AttrNames>
      <Accessors>
        <Item Value="ProductInventoryView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.ProductInventoryView" Name="SRegionView13">
      <AttrNames>
        <Item Value="Name"/>
        <Item Value="AmountInStock"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

The rules for populating the nodes of the treemap or sunburst are defined in node definitions. The example shows that four node definitions were generated, one for each level of the hierarchy. Each of these node definitions references a view object and the attributes specified in the Create Treemap or Create Sunburst dialog. Each node definition also references an accessor for the next level of the hierarchy if the next level exists.

Attributes that were not specified in the **Value**, **Name**, or **Group By Value** fields during creation will not be included in the binding. If you need to reference another attribute in the data collection, you must add it manually to the binding. For example, in the Summit ADF DVT sample, the attribute exception rules calculate the colors based on the difference between the amount in stock (`AmountInStock`) and the reorder point (`ReorderPoint`) for a given product. For the EL expression to evaluate properly, you must add the `ReorderPoint` attribute to the binding definition for the treemap or sunburst.

To add the binding, in the Structure window, right-click the **dvt:treemap** or **dvt:sunburst** component and choose **Go to Binding**. Choose **Edit** in the **Binding** section to add the `ReorderPoint` attribute. Figure 43-33 shows the completed Edit Tree Binding dialog for the Summit ADF DVT treemap with `ReorderPoint` added to the display attributes.

Figure 43-33 Edit Tree Binding Dialog



Select the data source for the root tree node, and decide which attributes you want to display in the tree. To add additional tree level rules for child collections, select the parent tree level rule and click the Add icon. If no child collections are available for the selected node, the Add icon is disabled.

Root Data Source: AppModuleDataControl.SRegionView1

Tree Level Rules

```
model.SRegionView(<SCountriesView>)
  model.SCountriesView(<SWarehouseView>)
    model.SWarehouseView(<ProductInventoryView>)
      model.ProductInventoryView
```

Accessor: Folder Label: □ Enable Filtering:

Available Attributes: Id, MaxInStock, OutOfStockExplanation, ProductId, RestockDate, ShortDesc, WarehouseId

Display Attributes: Name, AmountInStock, ReorderPoint

⊞ Target Data Source

After you click **OK**, the binding will be updated with the added attribute. The example below shows the revised binding for the `SRegionView13` node definition.

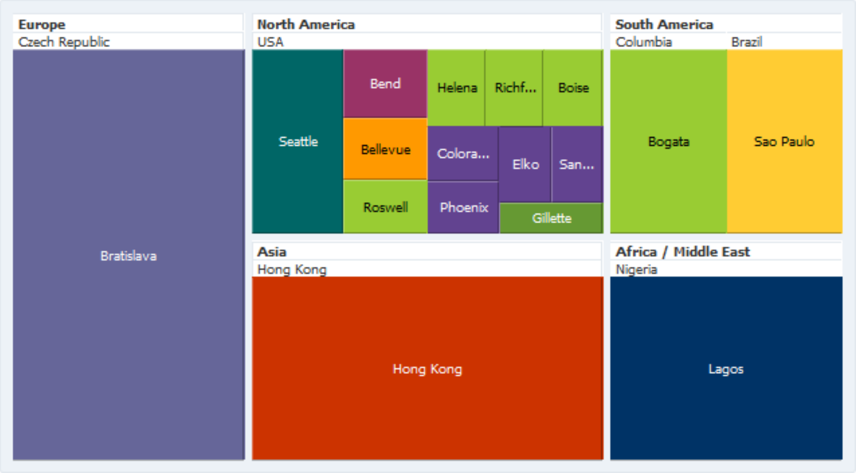
```
<nodeDefinition DefName="model.ProductInventoryView" Name="SRegionView13">
  <AttrNames>
    <Item Value="Name"/>
    <Item Value="AmountInStock"/>
    <Item Value="ReorderPoint"/>
  </AttrNames>
</nodeDefinition>
```

Once you create your treemap or sunburst, you can modify the value, label, and attribute group for each node using the Create Treemap or Create Sunburst dialog. To open the dialog, use the **Edit** icon in the Properties window for the `treemap` or `sunburst` component. You can also customize the values directly in the code or by setting values in the Properties window.

What Happens at Runtime: How Databound Sunbursts or Treemaps Are Initially Displayed

By default, a sunburst or treemap displays only the first two levels of the hierarchy and will not display a legend until you configure the `legendSource` attribute on the sunburst or treemap. Figure 43-34 shows the treemap that is displayed at runtime if you create the treemap using the data collection in Figure 43-26.

Figure 43-34   Databound Treemap Example Before Configuration



After completing the Create Treemap or Create Sunburst dialog, you can use the Properties window to configure the treemap or sunburst level display and `legendSource` attribute. You can also specify settings for other treemap or sunburst attributes and use the child tags associated with the sunburst and treemap tags to customize the components further.

The example below shows the code on the JSF page code for the treemap in Figure 43-24. In this example, the databound treemap is configured to display all levels in the hierarchy, a legend, a tooltip when the user hovers the mouse over a node, and a summary for accessibility. The code related to the additional configuration is highlighted in bold font.

```
<dvt:treemap id="t1" value="#{bindings.SRegionView1.treeModel}"
             var="row" displayLevelsChildren="3"
             legendSource="ag1" summary="Sample Treemap">
  <af:switcher facetName="#{row.hierTypeBinding.name}" id="s1">
    <f:facet name="SRegionView11">
      <dvt:treemapNode value="#{row.WarehouseCount}" label="#{row.Country}"
                       id="tn1">
        <dvt:attributeGroups id="ag2" value="#{row.WarehouseCount}"
type="color"/>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView10">
      <dvt:treemapNode value="#{row.CountryCount}" label="#{row.Name}" id="tn2">
        <dvt:attributeGroups id="ag3" value="#{row.CountryCount}" type="color"/>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView13">
      <dvt:treemapNode value="#{row.AmountInStock}" label="#{row.Name}" id="tn3"
                       shortDesc="Amount in Stock:
                                  #{row.AmountInStock}&lt;br/>Reorder Point:
                                  #{row.ReorderPoint}">
        <dvt:attributeGroups value="#{row.AmountInStock}" type="color" id="ag1">
          <dvt:attributeExceptionRule id="aer1"
                                      condition="#{(row.AmountInStock -
                                                    row.ReorderPoint) gt 50}"
                                      label="Stock OK">
            <f:attribute name="color" value="#008800"/>
          </dvt:attributeExceptionRule>
          <dvt:attributeExceptionRule id="aer2"
                condition="#{((row.AmountInStock - row.ReorderPoint) le 50) and
                             ((row.AmountInStock - row.ReorderPoint) gt 25)}"
                label="Stock Level Getting Low">
            <f:attribute name="color" value="#FFFF33"/>
          </dvt:attributeExceptionRule>
          <dvt:attributeExceptionRule id="aer3"
                condition="#{(row.AmountInStock - row.ReorderPoint) le 25}"
                label="Reorder Time">
            <f:attribute name="color" value="#880000"/>
          </dvt:attributeExceptionRule>
        </dvt:attributeGroups>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView12">
      <dvt:treemapNode value="#{row.ProductCount}" label="#{row.City}" id="tn4">
        <dvt:attributeGroups id="ag4" value="#{row.ProductCount}" type="color"/>
      </dvt:treemapNode>
    </f:facet>
  </af:switcher>
</dvt:treemap>
```

The example below shows the code on the JSF page code for the sunburst in Figure 43-25. In this example, the databound sunburst is configured with a summary and a tooltip that displays when the user hovers the mouse over a node.

```
<dvt:sunburst id="t1" value="#{bindings.SRegionView1.collectionModel}"
              var="row" summary="Sunburst Demo">
  <af:switcher facetName="#{row.hierTypeBinding.name}" id="s1">
    <f:facet name="SRegionView10">
     <dvt:sunburstNode value="#{row.TotalSales}" label="#{row.Name}" id="sn1"
          shortDesc="Sales: #{row.TotalSales}&lt;br/>Orders:
#{row.TotalOrders}">
       <dvt:attributeGroups value="#{row.TotalOrders}" type="color" id="ag2"/>
     </dvt:sunburstNode>
   </f:facet>
   <f:facet name="SRegionView11">
     <dvt:sunburstNode value="#{row.TotalSales}" label="#{row.Country}" id="sn2"
          shortDesc="Sales: #{row.TotalSales}&lt;br/>Orders:
#{row.TotalOrders}">
       <dvt:attributeGroups value="#{row.TotalOrders}" type="color" id="ag1"/>
     </dvt:sunburstNode>
   </f:facet>
 </af:switcher>
</dvt:sunburst>
```

For information about configuring the sunburst or treemap level display, `legendSource` attribute, tooltips, additional attributes, or child tags, see the Using Treemap and Sunburst Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

44

Creating Databound Diagram Components

This chapter describes how to how to create a diagram from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization `diagram` components to create diagrams that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.
If you are designing your page using simple UI-first development, then you can add the diagram to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the diagram component, see Using Diagram Components in *Developing Web User Interfaces with Oracle ADF Faces*.

This chapter includes the following sections:

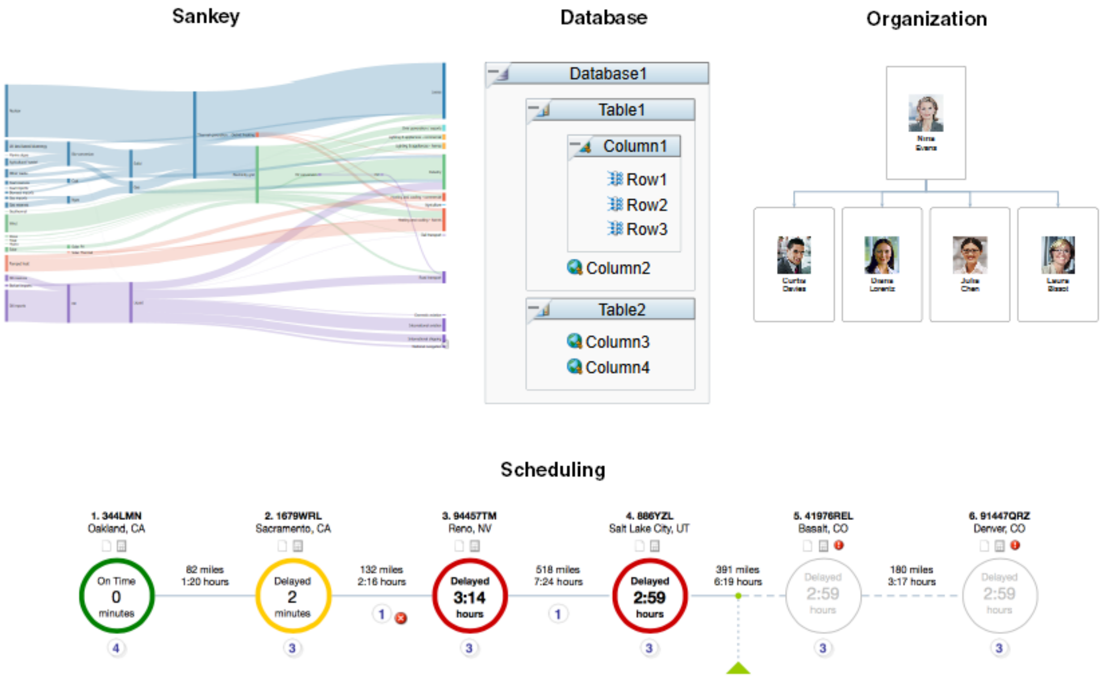
About ADF Data Visualization Diagram Components

The DVT `diagram` component is a versatile tool that produces an interactive component that you can use to model, represent, and visualize information using a shape called a node to represent data and links to represent relationships between the nodes. Use diagrams when you want to highlight both the data objects and the relationship between them.

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

Figure 44-1 shows four runtime images of diagram components: a Sankey flow diagram, database table design, employee organization chart, and a scheduling diagram. In these examples, the nodes are the processes, database objects, employees, and scheduled stops. The links show the relationship between each process in the Sankey flow diagram, employee in the organization chart, and sequence of stops in the scheduling diagram.

Figure 44-1 Diagram Component Examples



The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for the DVT diagram component, see End User and Presentation Features in *Developing Web User Interfaces with Oracle ADF Faces*.

Data Visualization Components Use Cases and Examples

For detailed descriptions of Diagram component use cases and examples, see Diagram Use Cases and Examples in *Developing Web User Interfaces with Oracle ADF Faces*.

Additional Functionality for Data Visualization Components

You may find it helpful to understand other Oracle ADF features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see Rerendering Partial Page Content in *Developing Web User Interfaces with Oracle ADF Faces*.

- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see Allowing User Customization on JSF Pages in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: You can make your data visualization components accessible. For more information, see Developing Accessible ADF Faces Pages in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see Customizing the Appearance Using Styles and Skins in *Developing Web User Interfaces with Oracle ADF Faces*.
- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls.

Creating Databound Diagram Components

Databound DVT diagram components require a collection of node objects to represent the data and, optionally, a collection of link objects to represent the relationships between the nodes.

You can use objects that implement a List interface, such as a `java.util.ArrayList` object, or a collection model, such as a `org.apache.myfaces.trinidad.model.CollectionModel`.

Databound diagrams also require a client layout configuration defined in a JavaScript method that you add to the application as a feature. Client layouts specify how to lay out the nodes and links on a page. The diagram component includes a default layout that you can use and modify as needed. The default `forceDirectedLayout` positions the diagram nodes so that all the links are of more or less equal length, and there are as few crossing links as possible.

> **Note:**
>
> You can also provide your own client layout configuration in a JavaScript object that you add as an application feature. For additional information, see Using the Diagram Layout Framework in *Developing Web User Interfaces with Oracle ADF Faces*.

The Create Diagram wizard provides declarative support for creating the diagram and binding it to data. In the five wizard pages you can:

1. Configure the diagram's client layout.

   You can choose the default client `forceDirectedLayout` feature, specify your own layout, or choose no layout.

2. Specify the node and link data, including:

   - The collections to use for the node and link data
   - The attribute that specifies the node's unique identifier (id)
   - Optionally, the attribute in the node collection that contains the container id to identify child nodes that are contained by the parent node
   - The attributes in the link collection that specify the starting and ending node ids for a link

3. Optionally, configure the display characteristics of the node's label and marker.

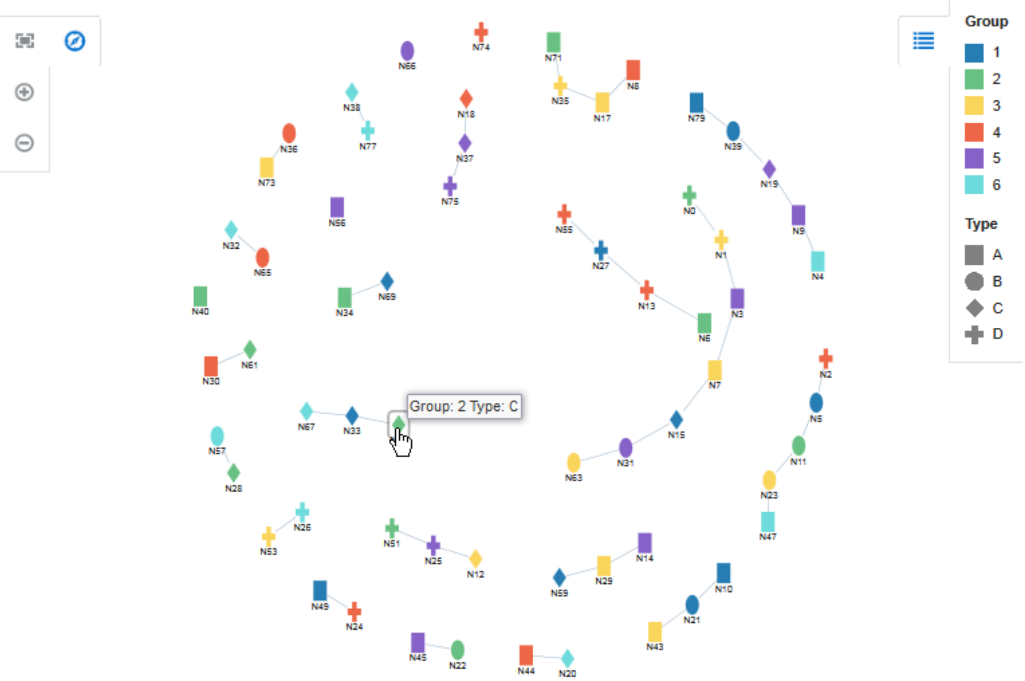
   Diagram nodes use the `dvt:marker` component to configure many of the node's display characteristics, including color, pattern, shape, border style, and color.

4. Optionally, configure attribute groups to group nodes by color, shape, pattern, opacity, scale X, or scale Y according to a specified attribute.

5. Optionally, configure the display characteristics of the link's label, style, color, width, beginning connector, and end connector.

Figure 44-2 shows a diagram configured to use the default client layout. In this example, the diagram is configured to use attribute groups to group the nodes by the values in the node's `NodeGroup` and `NodeType` attributes.

Figure 44-2 Diagram Example With Attribute Groups



After you complete the Create Diagram wizard and the diagram is added to your page, you can further customize the diagram using the Properties window. For additional information, see Using Diagram Components in *Developing Web User Interfaces with Oracle ADF Faces*.

> **Note:**
>
> The ADF Data Visualization Tools (DVT) component collection includes other components that you can also use to model organization charts, time lines, etc.
>
> For example, you can also use the DVT hierarchy viewer component to display an organization chart bound to employee data. Hierarchy viewers also use nodes and links to display data, but the component automatically creates the links based on the values in the node's data collection, and you do not need to supply a separate data collection for the links.
>
> For additional information about other DVT components and typical use cases, see Introduction to Data Visualization Components in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Diagram Using ADF Data Controls

To create a DVT diagram using data controls, bind the `dvt:diagram` component to a collection that contains the node data and a collection that contains the links that represent the relationships between the nodes. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

> **Tip:**
>
> You can also create the diagram by dragging the diagram from the Components window.

Before you begin:

It may be helpful to have an understanding of databound diagrams. For more information, see About ADF Data Visualization Diagram Components.

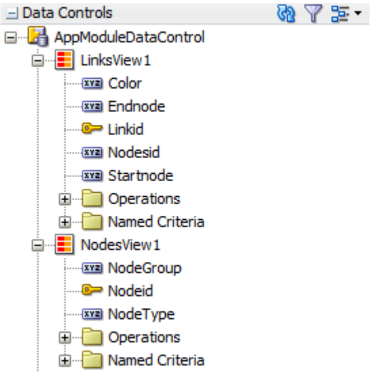
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the diagram, as described in Creating and Modifying an Application Module.

  Figure 44-3 shows the data control for the diagram displayed in Figure 44-2. In this example, `NodesView1` contains the data collection for the diagram nodes, and `LinksView1` contains the data collection for the diagram links.

Figure 44-3 Diagram Node and Link Data Collections Example



The `Startnode` and `Endnode` attributes in the `LinksView1` data collection contain references to the `Nodeid` attribute in the `NodesView1` data collection. Figure 44-4 shows a portion of the link collection's data in the Object Viewer.

Figure 44-4 Diagram Sample Link Data

	LINKID	NODESID	STARTNODE	ENDNODE	COLOR
1	L0	N0	N0	N1	#e61717
2	L1	N1	N1	N3	#e63617
3	L10	N10	N10	N21	#e6b217
4	L11	N11	N11	N23	#e6c117
5	L12	N12	N12	N25	#e6d117
6	L13	N13	N13	N27	#e6e017
7	L14	N14	N14	N29	#dbe617
8	L15	N15	N15	N31	#cce617
9	L16	N16	N16	N33	#bce617
10	L17	N17	N17	N35	#ade617
11	L18	N18	N18	N37	#9de617
12	L19	N19	N19	N39	#8ee617

- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound diagram:

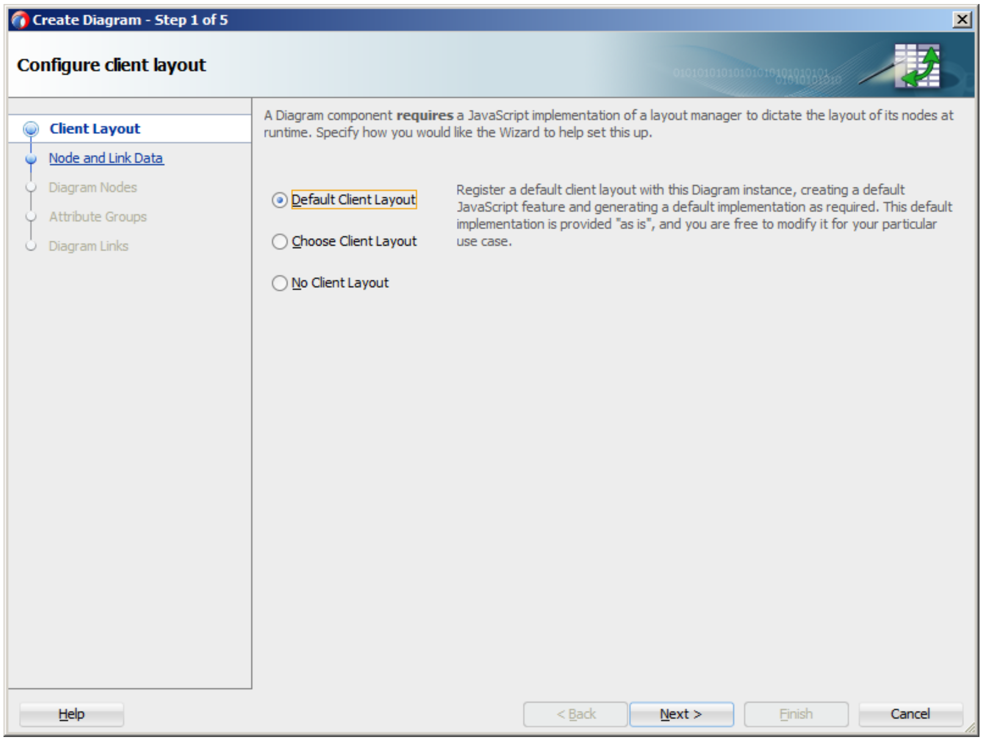
1. From the Data Controls panel, select the data collection that represents the nodes to use for your diagram.

   For example, to use the data collection shown in this section, select `NodesView1`.

2. Drag the collection onto a JSF page and, from the menu, choose **Diagram**.
3. In the Create Diagram - Configure Client Layout dialog, select your client layout.

   You can choose the default client layout, provide your own layout, or choose no layout. To choose the default layout, click **Default Client Layou**t as shown in Figure 44-5.

Figure 44-5 Configure Client Layout Dialog Showing Default Client Layout Selection



Configure client layout

A Diagram component **requires** a JavaScript implementation of a layout manager to dictate the layout of its nodes at runtime. Specify how you would like the Wizard to help set this up.

● Default Client Layout

○ Choose Client Layout

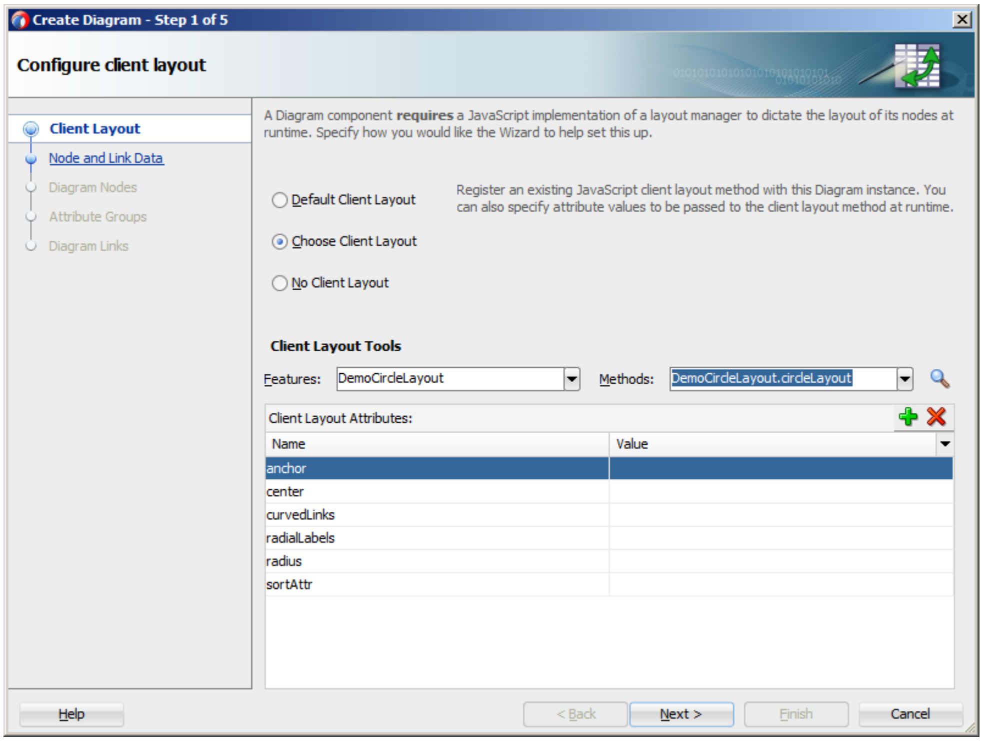
○ No Client Layout

Register a default client layout with this Diagram instance, creating a default JavaScript feature and generating a default implementation as required. This default implementation is provided "as is", and you are free to modify it for your particular use case.

To specify a different layout, click **Choose Client Layout** and select the feature and method that you want to use from the **Features** and **Methods** dropdown menus. After you choose the layout, the layout's optional attributes appear in the dialog, and you can enter values for the attributes as desired.

Figure 44-6 shows the completed Create Diagram - Configure client layout dialog for a custom circle layout. In this example, the selected feature name is `DemoCircleLayout`, and the selected method is `circleLayout`. Optional layout attributes include `anchor`, `center`, `curvedLinks`, `radialLabels`, `radius`, and `sortAttr`.

Figure 44-6 Configure Client Layout Dialog Showing Custom Layout Selection



Create Diagram - Step 1 of 5

Configure client layout

- Client Layout
- Node and Link Data
- Diagram Nodes
- Attribute Groups
- Diagram Links

A Diagram component **requires** a JavaScript implementation of a layout manager to dictate the layout of its nodes at runtime. Specify how you would like the Wizard to help set this up.

○ Default Client Layout

● Choose Client Layout

○ No Client Layout

Register an existing JavaScript client layout method with this Diagram instance. You can also specify attribute values to be passed to the client layout method at runtime.

Client Layout Tools

Features: DemoCircleLayout

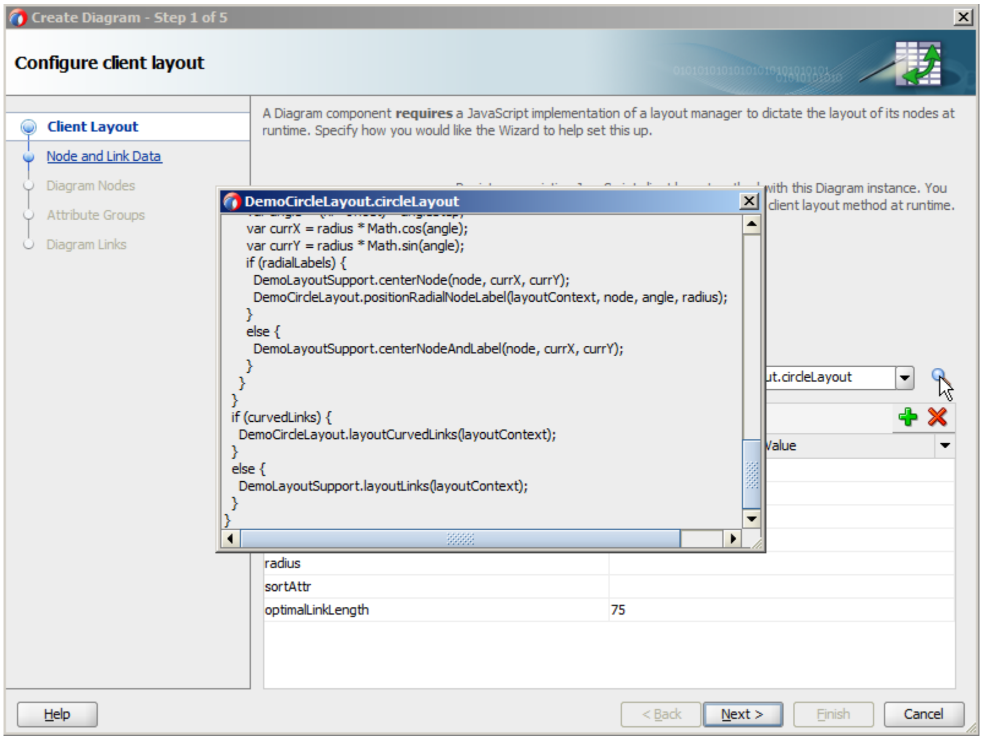
Methods: DemoCircleLayout.circleLayout

Client Layout Attributes:

Name	Value
anchor	
center	
curvedLinks	
radialLabels	
radius	
sortAttr	

If you want to look at the code source for the method you selected, click **Search** to display a popup containing the source code. Figure 44-7 shows the popup that displays the `DemoCircleLayout.circleLayout` method.

Figure 44-7 Configure Client Layout Dialog Showing Method Source Code Popup



A Diagram component **requires** a JavaScript implementation of a layout manager to dictate the layout of its nodes at runtime. Specify how you would like the Wizard to help set this up.

with this Diagram instance. You
client layout method at runtime.

ut.circleLayout

DemoCircleLayout.circleLayout

```
      var currX = radius * Math.cos(angle);
      var currY = radius * Math.sin(angle);
      if (radialLabels) {
        DemoLayoutSupport.centerNode(node, currX, currY);
        DemoCircleLayout.positionRadialNodeLabel(layoutContext, node, angle, radius);
      }
      else {
        DemoLayoutSupport.centerNodeAndLabel(node, currX, currY);
      }
    }
  }
  if (curvedLinks) {
    DemoCircleLayout.layoutCurvedLinks(layoutContext);
  }
  else {
    DemoLayoutSupport.layoutLinks(layoutContext);
  }
}
```

	Value
radius	
sortAttr	
optimalLinkLength	75

4. In the Create Diagram - Specify Node and Link Data dialog, enter values for the following to identify the data sources and link connections:

   - **Collection**: Verify that the correct data collection is displayed for the node collection.

     To change the data collection, click **Add Data Source** and choose another data collection from the list.

   - **Node Id**: Enter a value or use the dropdown menu to select the attribute in the node's data collection that represents the unique identifier of the node in the diagram.

     Alternatively, you can enter an EL expression that returns the value or select **Expression Builder** from the dropdown menu to launch the Expression Builder dialog. For help with the Expression Builder dialog, press **F1** or click **Help**.

   - **Container Id**: Enter or use the dropdown list to select the attribute in the node's data collection that represents the parent node for child nodes in the diagram.

     Alternatively, you can enter an EL expression that returns the value or select **Expression Builder** from the dropdown menu to launch the Expression Builder dialog.

   - **Collection** (Link): Enter the data collection that represents the links, or click **Add Data Source** to choose the data collection from the list.

   - **Start Node Id**: Enter or use the dropdown list to select the attribute in the link's data collection that represents the source node in diagram.

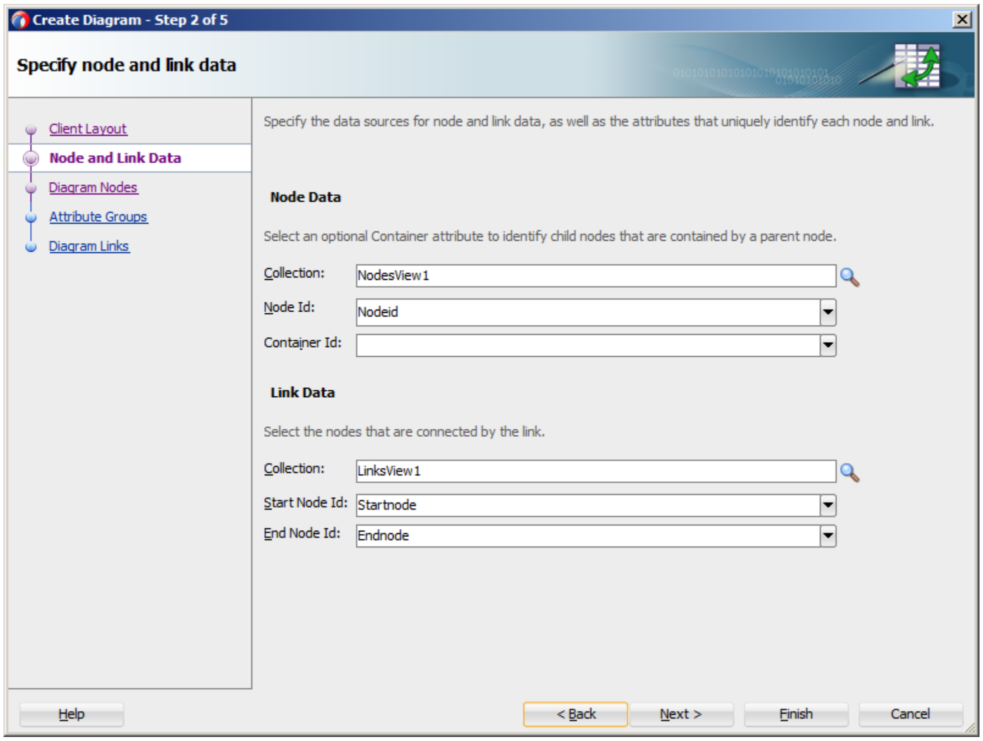
Alternatively, you can enter an EL expression that returns the value or select **Expression Builder** from the dropdown menu to launch the Expression Builder dialog.

- **End Node Id**: Enter or use the dropdown list to select the attribute in the link's data collection that represents the target node in diagram.

  Alternatively, you can enter an EL expression that returns the value or select **Expression Builder** from the dropdown menu to launch the Expression Builder dialog.

Figure 44-8 shows the completed dialog for a diagram using the `NodesView1` and `LinksView1` data collections. In this example, the **Node Id** value is `Nodeid`, and the link's **Start Node Id** and **End Node Id** values are set to the `Startnode` and `Endnode` attributes in the `LinksView1` data collection. In this example, the parent container has no children, and the **Container ID** field is not used.

Figure 44-8 Specify Node and Link Data Dialog Example



Create Diagram - Step 2 of 5

Specify node and link data

Specify the data sources for node and link data, as well as the attributes that uniquely identify each node and link.

Node Data

Select an optional Container attribute to identify child nodes that are contained by a parent node.

Collection: NodesView1
Node Id: Nodeid
Container Id:

Link Data

Select the nodes that are connected by the link.

Collection: LinksView1
Start Node Id: Startnode
End Node Id: Endnode

5. In the Create Diagram - Configure Diagram Nodes dialog, optionally enter values for the following to configure the display characteristics of the node's label and marker:

   - **Node Label**: From the dropdown list, select the attribute in the data collection to use for the node's label. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

     Optionally, you can enter values for the label's width, height, and opacity. For help with the dialog, press **F1** or click **Help**.

> **Tip:**
>
> If you're not sure yet which values make sense for your diagram, you can create the diagram and modify the values after creation.

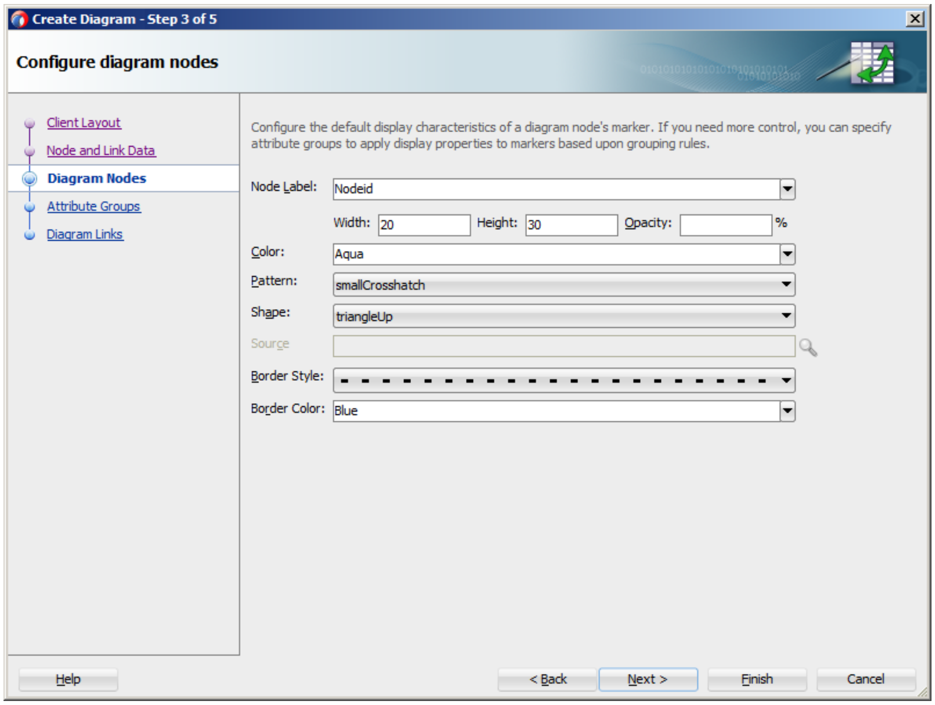
- **Color**: From the dropdown list, select a node color from the provided colors or select **Custom Colo**r to enter the Color Picker dialog. The default node color is `black`.
- **Pattern**: From the dropdown list, select a node pattern. Valid values for pattern include a choice of twelve prebuilt patterns, such as small and large checkers, diamonds, and triangles. If you specified a node color, the pattern will display in the color you chose. The default node pattern is `none`.
- **Shape**: From the dropdown list, select a shape to use for the node. Valid values include: `circle`, `human`, `diamond`, `square`, `triangleDown`, `triangleUp`, and `plus`. The default node shape is `circle`.

> **Note:**
>
> When you specify the node's shape, color, or pattern explicitly, the same value will be used for each node in the diagram. If you want to vary the color, pattern, or shape according to some measure, configure an attribute group in the next page of the Create Diagram wizard instead.

- **Source**: To use a custom node shape, enter the relative path to the SVG file to use for the node image, or use the Search icon to open the Select SVG File dialog to navigate to the image source.
- **Border Style**: From the dropdown list, select a border style for all nodes in the diagram. Valid values include `solid`, `dash`, and `dot`. The default style is a solid line.
- **Border Color**: From the dropdown list, select a border color for all nodes in the diagram or select **Custom Color** to enter the Color Picker dialog. The default border color is `black`.

  Figure 44-9 shows a completed Create Diagram - Configure Diagram Nodes dialog. In this example, the node label is configured with a relative width of 20 and relative height of 30. The node's shape is a triangle pointing up with an aqua-colored small crosshatch pattern.

Figure 44-9   Configure Diagram Nodes Dialog Example



Create Diagram - Step 3 of 5

Configure diagram nodes

Configure the default display characteristics of a diagram node's marker. If you need more control, you can specify attribute groups to apply display properties to markers based upon grouping rules.

Node Label: Nodeid

Width: 20 Height: 30 Opacity: %

Color: Aqua

Pattern: smallCrosshatch

Shape: triangleUp

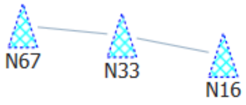
Source

Border Style: -

Border Color: Blue

[Figure 44-10](#) shows the runtime view of three diagram nodes after creation.

Figure 44-10   Diagram Nodes With Optional Display Attributes



6. (Optional) In the Create Diagram - Configure Attribute Groups, to configure one or more attribute groups for the diagram nodes, click **New** in the **Grouping Rules** section and enter values for the following:

   - **Group by value**: From the dropdown list, select the attribute in the data collection to group by in the attribute group. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.
   - **Property**: From the dropdown list, select the property that you want to group by for display. Available options include `Color`, `Opacity`, `Pattern`, `Scale X`, `Scale Y`, and `Shape`.

     To vary the attribute group by more than one property, select **Select Multiple Attributes**. In the Select Multiple Attributes, select the desired properties, and click **OK**.
   - **Legend Label**: From the dropdown list, select the attribute in the data collection to display in the diagram legend. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

- **Section Label**: To use a text resource for the label, select **Select Text Resource** to associate a text resource for the label. If you wish to access data stored in objects, or reference and invoke methods using an EL Expression, select **Expression Builder** to launch the Expression Builder dialog.

  > **Note:**
  >
  > The section label describes the legend content of a sub-section of the legend and is rendered in the legend area. In Figure 44-2, for example, Group and Type are section labels.

- Optionally, click **Value-Specific Rules** to expand the attribute group dialog to specify a match or exception rule. Use match rules to specify colors or patterns for simple true or false conditions or when you want to match a specific value. Use exception rules when you want to specify a color or pattern when the grouped-by value meets a specific condition.

  To specify a match rule, in the **Match Rules** section, click **New** and enter values for the following:

  – **Group Value**: Enter the category value for the match. This can be a string that represents a category or you can set this to `true` or `false`. If you set this to true or false, the **Group by value** field must contain an EL expression that evaluates to true or false as in the following example:`#{row.AmountInStock gt row.ReorderPoint}`.

  – **Property**: From the dropdown list, select the property that you want to group by for display. Available options include `Color`, `Opacity`, `Pattern`, `Scale X`, `Scale Y`, and `Shape`.

  – **Property Value**: From the dropdown list, select the color or pattern to display when the node's value matches the **Group Value**. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.

  To specify an exception rule, in the **Exception Rules** section, click **New** and enter values for the following:

  – **Condition**: Enter a JSF EL expression that evaluates to true or false. You can enter the expression directly in the **Condition** field or select **Expression Builder** to enter the JSF EL expression.

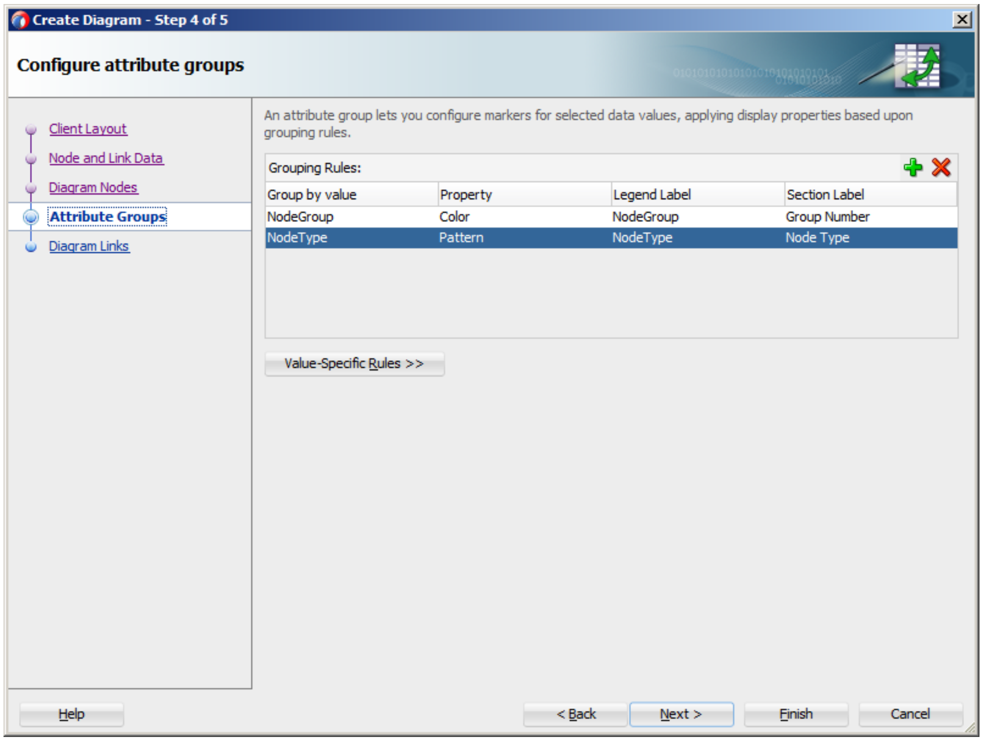
  – **Property**: From the dropdown list, select the property that you want to group by for display. Available options include `Color`, `Opacity`, `Pattern`, `Scale X`, `Scale Y`, and `Shape`.

  – **Property Value**: From the dropdown list, select the color or pattern to display when the node's value meets the condition you specified in the **Condition** field. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.

  – **Legend Label**: From the dropdown list, select **Select Text Resource** to select a text resource to be used for the legend label. You can also enter text in this field or select **Expression Builder** to enter a JSF EL expression.

Figure 44-11 shows the completed Create Diagram - Configure Attribute Groups dialog for the diagram in Figure 44-2. In this example, the diagram is configured for two attributes groups. The first attribute group varies the node's color depending upon the value in the `NodeGroup` attribute, and the second attribute group varies the node's shape depending upon the value in the `NodeType` attribute. The legend will display section labels for both groups.

Figure 44-11   Configure Attribute Groups Dialog Example



An attribute group lets you configure markers for selected data values, applying display properties based upon grouping rules.

Grouping Rules:

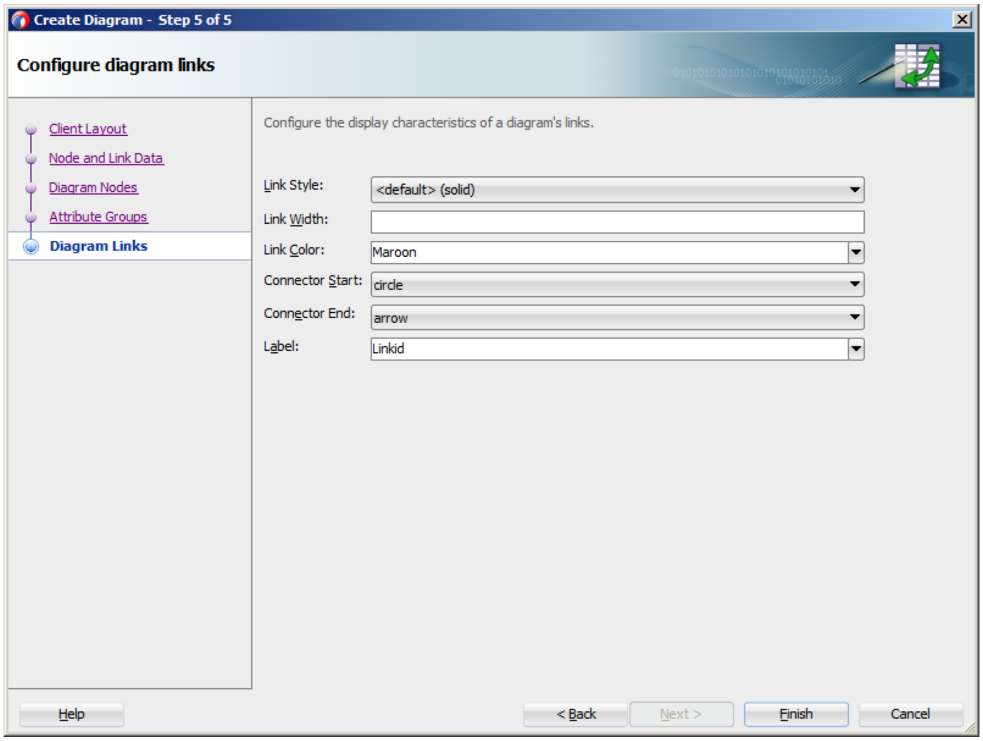
Group by value	Property	Legend Label	Section Label
NodeGroup	Color	NodeGroup	Group Number
NodeType	Pattern	NodeType	Node Type

7. In the Create Diagram - Configure Diagram Links dialog, enter values for the following to configure the display characteristics of the link label, style, and connector:

   - **Link Style**: From the dropdown list, select a border style for all nodes in the diagram. Valid values include `solid`, `dash`, `dot`, and `dashDot`. The default style is a solid line.
   - **Link Width**: Enter the width of the link in pixels. The default value is `1`.
   - **Link Color**: From the dropdown list, select a link color from the provided colors or select **Custom Colo**r to enter the Color Picker dialog. The default link color is `black`.
   - **Connector Start**: Enter a value for the link's start connector. Valid values include `none`, `arrowOpen`, `arrow`, `arrowConcave`, `circle`, `rectangle`, and `rectangleRounded`. The default value is `none`.
   - **Connector End**: Enter a value for the link's end connector. Valid values include `none`, `arrowOpen`, `arrow`, `arrowConcave`, `circle`, `rectangle`, and `rectangleRounded`. The default value is `none`.
   - **Label**: From the dropdown list, select the attribute in the data collection to use for the links's label. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

Figure 44-12 shows a completed Create Diagram - Configure Diagram Links dialog. In this example, the link is configured with a label and the default width and style. The link's color is maroon and will display a circle at the connector's start and an arrow at the connector's end.

Figure 44-12 Configure Dialog Links Dialog Example

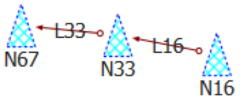


Configure the display characteristics of a diagram's links.

Link Style: <default> (solid)
Link Width:
Link Color: Maroon
Connector Start: circle
Connector End: arrow
Label: Linkid

Figure 44-13 shows the runtime view of three diagram nodes after creation.

Figure 44-13 Diagram Links With Optional Display Characteristics



8. When you have completed the Create Diagram wizard, click **Finish** to exit the wizard and add the diagram to the page.

What Happens When You Create a Databound Diagram

Creating a diagram from the Data Controls panel has the following effect:

- Creates the bindings for the diagram in the page definition file (*pageName*`PageDef.xml`) of the JSF page
- Adds the necessary tags to the JSF page for the `dvt:diagram` component
- If you chose the default client layout during creation, registers the layout with the ADF Faces runtime environment

Bindings for Diagram Components

The following code sample shows the bindings that JDeveloper generated for a `dvt:diagram` component using the data collection shown in Figure 44-3.

```
<executables>
  <variableIterator id="variables"/>
    <iterator Binds="NodesView1" RangeSize="-1"
DataControl="AppModuleDataControl" id="NodesView1Iterator"/>
    <iterator Binds="LinksView1" RangeSize="-1"
DataControl="AppModuleDataControl" id="LinksView1Iterator"/>
</executables>
<bindings>
  <tree IterBinding="NodesView1Iterator" id="NodesView1">
    <nodeDefinition DefName="model.NodesView" Name="NodesView10">
      <AttrNames>
        <Item Value="NodeGroup"/>
        <Item Value="NodeType"/>
        <Item Value="Nodeid"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
  <tree IterBinding="LinksView1Iterator" id="LinksView1">
    <nodeDefinition DefName="model.LinksView" Name="LinksView10">
      <AttrNames>
        <Item Value="Endnode"/>
        <Item Value="Startnode"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

The rules for populating the diagram are defined in a node definition. Each node definition references the node and links view objects and the attributes specified in the Create Diagram dialog. For additional information about the *pageName*`PageDef.xml` file, see pageNamePageDef.xml.

Code on the JSF Page for a Diagram Component

The following example shows the code that is generated on the JSF page for the diagram shown in Figure 44-2.

```
<dvt:diagram id="dg1" layout="DiagramSampleDiagramLayout">
  <dvt:diagramNodes var="node" id="dnodes1"
                    value="#{bindings.NodesView1.collectionModel}">
    <dvt:diagramNode label="#{node.Nodeid}" id="dn1" nodeId="#{node.Nodeid}">
      <f:facet name="zoom100">
        <dvt:marker width="20" id="m1" height="30">
          <dvt:attributeGroups id="ag1" label="#{node.NodeGroup}" type="color"
                               value="#{node.NodeGroup}"/>
          <dvt:attributeGroups id="ag2" label="#{node.NodeType}" type="shape"
                               value="#{node.NodeType}"/>
        </dvt:marker>
      </f:facet>
    </dvt:diagramNode>
  </dvt:diagramNodes>
  <dvt:diagramLinks var="link" value="#{bindings.LinksView1.collectionModel}"
                    id="dl1">
    <dvt:diagramLink startNode="#{link.Startnode}" id="dl2"
```

```
                     endNode="#{link.Endnode}"/>
  </dvt:diagramLinks>
  <dvt:clientLayout method="DiagramSampleDiagramLayout.forceDirectedLayout"
                    featureName="DiagramSampleDiagramLayout"
                    name="DiagramSampleDiagramLayout">
    <f:attribute name="optimalLinkLength" value="75"/>
  </dvt:clientLayout>
  <dvt:legend id="l1">
    <dvt:legendSection label="#{viewcontrollerBundle.GROUP}" source="dnodes1:ag1"
                       id="ls1"/>
    <dvt:legendSection label="#{viewcontrollerBundle.TYPE}" source="dnodes1:ag2"
                       id="ls2"/>
  </dvt:legend>
</dvt:diagram>
```

Default Client Layout Files and Location

When you create a diagram using the default client layout, JDeveloper registers the force directed layout with the ADF runtime environment as a JavaScript (JS) feature. The creation process automatically adds a JS file in the ViewController/src/js/layout directory with the following naming convention:

*ApplicationName*DiagramLayout.js

For example, if your application is named DiagramSample, the JS file is named DiagramSampleDiagramLayout.js. The content of the file contains the forceDirectedLayout method, and you can open the file in JDeveloper. You can also click **Edit Component Definition** in the Properties window to display the Edit Diagram - Configure Client Layout dialog and then click **Search** to display the method popup.

JDeveloper also creates the adf-js-features.xml file if it doesn't already exist and adds the *ApplicationName*DiagramLayout as the feature-name and the path to the JS file as the feature-class. The following example shows the adf-js-features.xml file for an application named DiagramSample.

```
<?xml version="1.0" encoding="UTF-8" ?>
<features xmlns="http://xmlns.oracle.com/adf/faces/feature">
  <feature>
    <feature-name>DiagramSampleDiagramLayout</feature-name>
    <feature-class>js/layout/DiagramSampleDiagramLayout.js</feature-class>
  </feature>
</features>
```

Modifying Diagram Properties and Layout

After you create your diagram, you can specify a different client layout or add additional elements, such as a label, using the Edit Diagram dialog. To open the dialog, use the **Edit** icon in the Properties window for the dvt:diagram component. You can also customize the diagram properties directly in the visual editor or by setting values in the Properties window.

For example, to add the tooltip shown in Figure 44-2 to your diagram, you can enter a value for the diagram node's shortDesc attribute in the Properties window or in the code editor.

```
<dvt:diagramNode label="#{node.Nodeid}" id="dn1" nodeId="#{node.Nodeid}"
                 shortDesc="Group: #{node.NodeGroup} Type:
#{node.NodeType}">
```

```
  <f:facet name="zoom100">
    ... contents omitted
  </f:facet>
</dvt:diagramNode>
```

For additional information and examples for customizing your diagram, see Using Diagram Components in *Developing Web User Interfaces with Oracle ADF Faces*.

45
Creating Databound Tag Cloud Components

This chapter describes how to how to create a tag cloud from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization `tagCloud` components to create tag clouds that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.

If you are designing your page using simple UI-first development, then you can add the tag cloud to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the tag cloud component, see Using Tag Cloud Components in *Developing Web User Interfaces with Oracle ADF Faces*.

This chapter includes the following sections:

- About ADF Data Visualization Tag Cloud Components
- Creating Databound Tag Cloud Components

About ADF Data Visualization Tag Cloud Components

A tag cloud is a visual representation for text data, typically used to visualize free form text or tag metadata for a website. The importance or frequency of each tag is shown with font size or color. This visualization is useful for quickly identifying the most prominent terms in a set.

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component must be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

Data Visualization Components Use Cases and Examples

For detailed descriptions of Tag Cloud component use cases and examples, see Tag Cloud Use Cases and Examples in *Developing Web User Interfaces with Oracle ADF Faces*.

End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support.

For detailed descriptions of the end user and presentation features for the DVT tag cloud component, see End User and Presentation Features of Tag Clouds in *Developing Web User Interfaces with Oracle ADF Faces*.

Additional Functionality for Data Visualization Components

You may find it helpful to understand other **Oracle ADF** features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

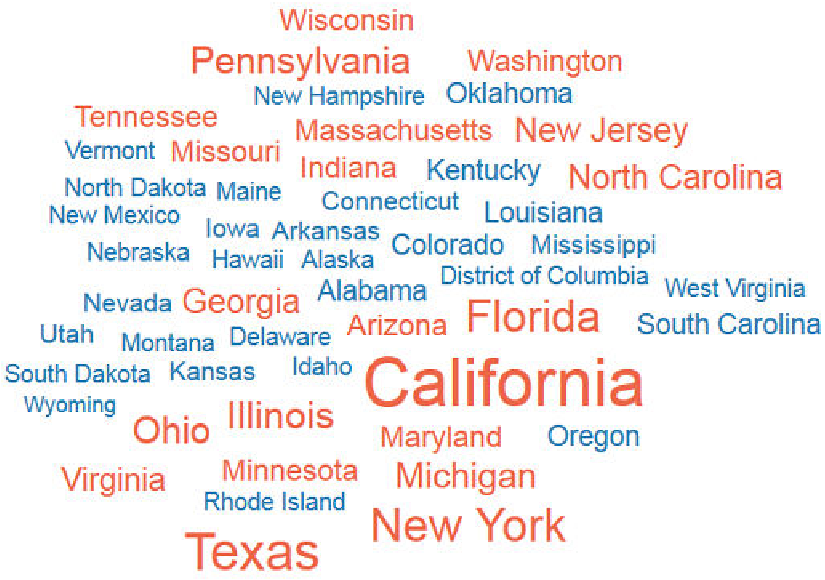
- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the Rerendering Partial Page Content chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the Allowing User Customization on JSF Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: By default, data visualization components are accessible. You can make your application pages available to screen readers. For more information, see the Developing Accessible ADF Faces Pages chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Designing a Page Using Placeholder Data Controls.

Creating Databound Tag Cloud Components

The ADF Tag Cloud component displays tag data in either a rectangular container or in a free-form cloud. Tags represent the actual data and are stamped inside the cloud layout according to their weight, with heavier or more important tags in the middle.

Figure 45-1 shows a tag cloud configured to show all the states in the USA. States with a population of less than 5 million have blue tags and states with a population of 5 million or more have red tags. This tag cloud renders high density tags nearer to the center.

Figure 45-1   Tag Cloud Component showing High and Low Population States in USA



For detailed information about tag cloud end user and presentation features, use cases, tag structure, and adding special features to tag clouds, see the Using Tag Cloud Components chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

How to Create a Databound Tag Cloud

A tag cloud is used to display tag information or website metadata in a free flow format. You can create a tag cloud by using the Data Controls panel.

Before you begin:

It may be helpful to have an understanding of databound tag clouds. For more information, see Creating Databound Tag Cloud Components.

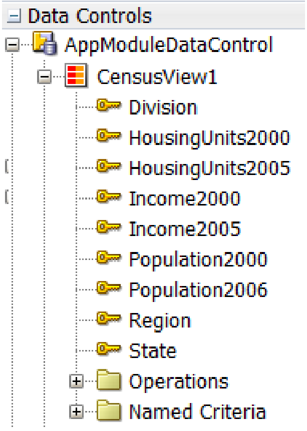
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Additional Functionality for Data Visualization Components.

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the tag cloud, as described in Creating and Modifying an Application Module.

  Figure 45-2 shows the data control for the tag cloud displayed in Creating Databound Tag Cloud Components. In this example, `CensusView1` contains the data collection for the tag cloud. Tags are represented visually as free-form text.. Each tag is sized and stamped according to the values in the tag's `Population2006` attribute.

Figure 45-2 Data Control for Tag Cloud Showing High and Low Population States in the USA



The values of the `Population2006` attribute are checked against Match Rules in the tag cloud. Tags with a value of more than 5 million are rendered in red and the other tags are rendered in blue.

- Create a JSF page as described in the How to Create JSF Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

To create a databound tag cloud:

1. From the Data Controls panel, select a collection.

   For example, to use the data control shown in this section, select `CensusView1`.

2. Drag the collection onto a JSF page and, from the menu, choose **Tag Cloud**.

3. In the Create Tag Cloud dialog, do the following to configure the tag cloud:

   - From the dropdown menu of the **Text Value** field, select an attribute to represent the text that will be shown in the rendered tag cloud.

     For example, to configure the tag cloud in the sample, select the `State` attribute.

   - To configure the tag sizes, select an attribute from the dropdown menu of the **Relative Size** field.

     For example, to configure the tag cloud in the sample, select the `Population2006` attribute

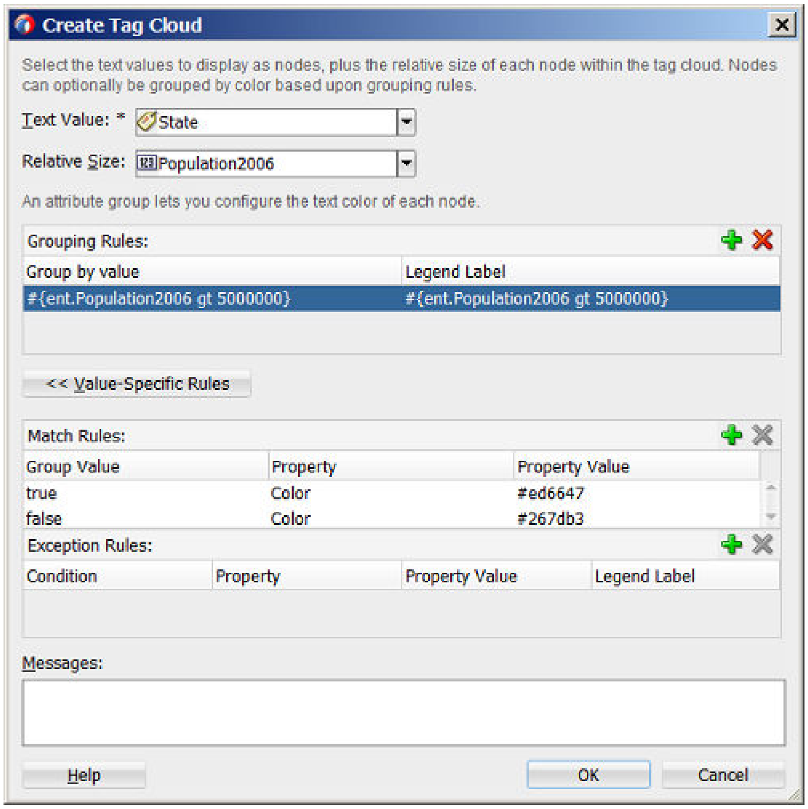
   - To configure tag colors, create a rule under **Grouping Rules** and then create appropriate **Value-Specific Rules**. Use **Match Rules** to specify colors for simple true or false conditions or when you want to match a specific value. Use **Exception Rules** when you want to specify a color when the tag's grouped-by value meets a specific condition.

     For example, to configure the tag cloud in the sample, create a new Grouping rule. Under both **Group by value** and **Legend Label**, provide `#{ent.Population2006 gt 5000000}`.

Then create two new Match Rules. For the first, provide a **Group Value** of `true` and a **Property Value** of `#ed6647`. For the second, provide a **Group Value** of `false` and a **Property Value** of `#267db3`.

Figure 45-3 shows the Create Tag Cloud dialog that generates the sample tag cloud using the `CensusView1` data control.

Figure 45-3 Create Tag Cloud dialog for CensusView1



Create Tag Cloud

Select the text values to display as nodes, plus the relative size of each node within the tag cloud. Nodes can optionally be grouped by color based upon grouping rules.

Text Value: * State

Relative Size: Population2006

An attribute group lets you configure the text color of each node.

Grouping Rules:

Group by value	Legend Label
#{ent.Population2006 gt 5000000}	#{ent.Population2006 gt 5000000}

<< Value-Specific Rules

Match Rules:

Group Value	Property	Property Value
true	Color	#ed6647
false	Color	#267db3

Exception Rules:

Condition	Property	Property Value	Legend Label

Messages:

4. Click **OK**.

After completing the data binding dialog, you can use the Property Inspector to specify settings for the tag cloud attributes and you can also use the child tags associated with the `dvt:tagCloud` tag to customize the tag cloud further. For more information about configuring tag cloud components, see the Using Tag Cloud Components section in the *Developing Web User Interfaces with Oracle ADF Faces*.

What Happens When You Create a Databound Tag Cloud

Dropping a tag cloud from the Data Controls panel has the following effect:

- Creates the bindings for the tag cloud and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

The data binding XML that JDeveloper generates represents the physical model of the tag cloud you create. The example below shows the bindings that JDeveloper generated in the page definition file where a tag cloud was created using data from the `State` and `Population2006` attributes in the `CensusView1` data collection.

```
<tree IterBinding="CensusView1Iterator" id="CensusView1">
    <nodeDefinition DefName="view.CensusView" Name="CensusView10">
        <AttrNames>
            <Item Value="State"/>
            <Item Value="Population2006"/>
        </AttrNames>
    </nodeDefinition>
</tree>
```

The following example shows the code that is generated on the JSF page for the tag cloud:

```
<dvt:tagCloud id="tc1" var="ent"
value="#{bindings.CensusView1.collectionModel}" layout="cloud">
    <dvt:tagCloudItem label="#{ent.State}" id="tci1"
value="#{ent.Population2006}">
        <dvt:attributeGroups value="#{ent.Population2006 gt 5000000}"
type="color"

label="#{ent.Population2006}"    id="ag1">
            <dvt:attributeMatchRule group="true" id="amr1">
                <f:attribute name="color" value="#ed6647"/>
            </dvt:attributeMatchRule>
            <dvt:attributeMatchRule group="false" id="amr2">
                <f:attribute name="color" value="#267db3"/>
            </dvt:attributeMatchRule>
        </dvt:attributeGroups>
    </dvt:tagCloudItem>
</dvt:tagCloud>
```

After you create your tag cloud, you can modify the binding or add additional rules using the Edit Tag Cloud dialog. To open the dialog, use the Edit icon in the Properties window for the tag cloud component. You can also customize the attributes of the tag cloud directly in the code, in the visual editor, or by setting values in the Properties window.

46
Using Contextual Events

This chapter describes how to create, publish, and subscribe to contextual events to facilitate communications between ADF Faces regions in the Fusion web application. It describes how to declaratively create the events, as well as programmatically use managed beans and JavaScript.
This chapter includes the following sections:

About Creating Contextual Events

The Contextual Events feature in Oracle ADF provides a powerful mechanism for passing parameters to share information among pages and regions. You can create contextual events by using managed beans, plain Java objects, and JavaScripts.

The contextual events framework provides the communications between regions within a page. The framework provides the page with the ability to map events that are produced and consumed by the various regions on the page. You can use JDeveloper to declaratively publish events using the page definition file. Similarly, you can declaratively subscribe to those events from the page definition file. You can pass parameters with the event and implement handlers to respond to an event. Other ways to create contextual events include using managed beans and using JavaScript. Note that contextual events do not require regions to be refreshed for the region to uptake parameters.

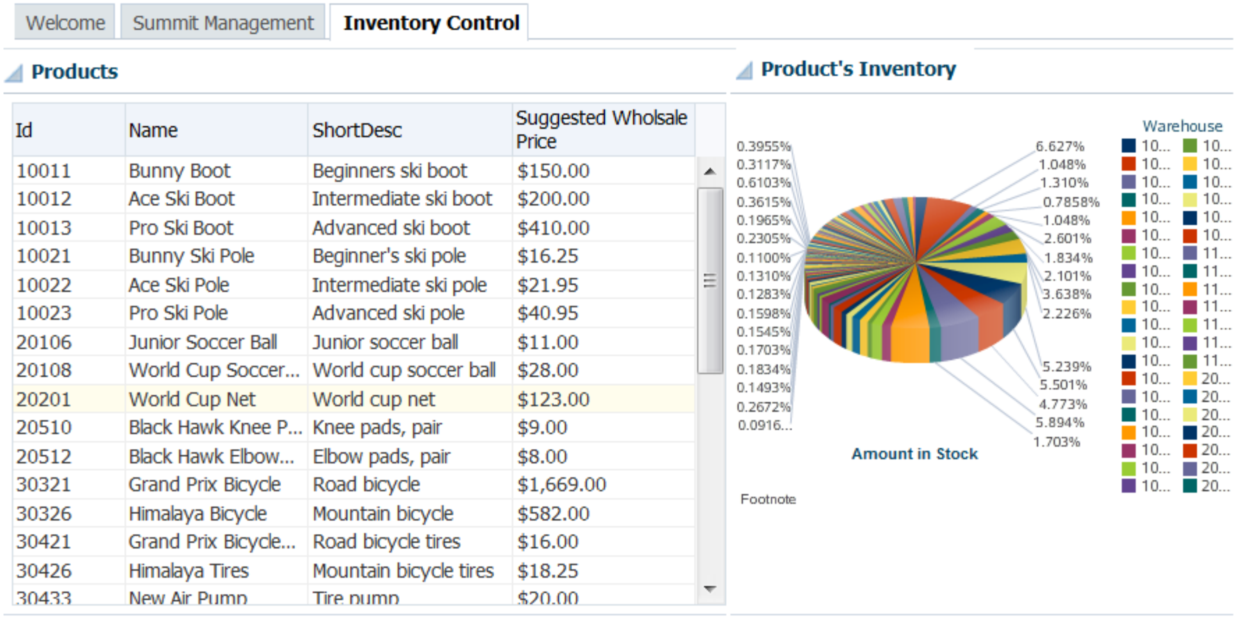
Contextual events are not the same as the business events that can be raised by **ADF Business Components** or the events raised by UI components. For a description of these types of events, see *Developing Web User Interfaces with Oracle ADF Faces*. Contextual events can be used, however, in association with UI events. In this case, an action listener that is invoked due to a UI event can, in turn, invoke a method action binding that then raises the event.

Often a page or a region within a page needs information from somewhere else on the page or from a different region. While you can pass parameters to obtain that information, doing so makes sense only when the parameters are well known and the inputs are EL-accessible to the page. Parameters are also useful when a task flow may need to be restarted if the parameter value changes.

However, suppose you have a task flow with multiple page fragments that contain various interesting values that could be used as input on one of the pages in the flow. If you were to use parameters to pass the value, the task flow would need to surface output parameters for the union of each of the interesting values on each and every fragment. Instead, for each fragment that contains the needed information, you can define a contextual event that will be raised when the page is submitted. The page or fragment that requires the information can then subscribe to the various events and receive the information through the event.

In the Summit sample application for ADF task flows, contextual events are used in the Inventory Control tab of the main page to display the inventory for a selected product. When the Inventory Control tab is selected by the user, it displays two regions side by side. One region contains the `showProducts.jsff` page fragment which contains a table of the products available. The other region contains the `showInventory.jsff` page fragment which contains a DVT chart showing the product inventory percentages for different warehouses. Figure 46-1 shows the Inventory Control tab displaying the products and inventory regions.

Figure 46-1 Inventory Control Tab



Products

Id	Name	ShortDesc	Suggested Wholsale Price
10011	Bunny Boot	Beginners ski boot	$150.00
10012	Ace Ski Boot	Intermediate ski boot	$200.00
10013	Pro Ski Boot	Advanced ski boot	$410.00
10021	Bunny Ski Pole	Beginner's ski pole	$16.25
10022	Ace Ski Pole	Intermediate ski pole	$21.95
10023	Pro Ski Pole	Advanced ski pole	$40.95
20106	Junior Soccer Ball	Junior soccer ball	$11.00
20108	World Cup Soccer...	World cup soccer ball	$28.00
20201	World Cup Net	World cup net	$123.00
20510	Black Hawk Knee P...	Knee pads, pair	$9.00
20512	Black Hawk Elbow...	Elbow pads, pair	$8.00
30321	Grand Prix Bicycle	Road bicycle	$1,669.00
30326	Himalaya Bicycle	Mountain bicycle	$582.00
30421	Grand Prix Bicycle...	Road bicycle tires	$16.00
30426	Himalaya Tires	Mountain bicycle tires	$18.25
30433	New Air Pump	Tire pump	$20.00

Product's Inventory

The products region contains the `show-products-task-flow` task flow which utilizes the `showProducts.jsff` page fragment. The inventory region contains the `product-inventory-task-flow` task flow which utilizes the `showInventory.jsff` page fragment.

The main page `index.jsff` is the parent page for both regions, which are located in a child of the `af:panelTabbed` layout component.

A contextual event is passed from the products region to the inventory region so that the `showInventory-task-flow` can display the DVT chart for the selected product. When you create a event for the producer component using the Properties window, a event is registered in the producer's page definition file. In the Summit ADF sample application, the `productSelected` event is registered in the `showProductsPageDef.xml` file, like this:

```
<tree IterBinding="ProductVO1Iterator" id="ProductVO1">
      <nodeDefinition DefName="oracle.summit.model.views.ProductVO"
         Name="ProductVO10">
        <AttrNames>
          <Item Value="Id"/>
          <Item Value="Name"/>
          <Item Value="ShortDesc"/>
          <Item Value="LongtextId"/>
          <Item Value="ImageId"/>
          <Item Value="SuggestedWhlslPrice"/>
          <Item Value="WhlslUnits"/>
        </AttrNames>
        <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
          <event name="productSelected" eventType="Currency Change Event"
             customPayLoad="#{bindings.Id.inputValue}"/>
        </events>
      </nodeDefinition>
</tree>
```

When you use the overview editor for the page definition file to subscribe to events, an eventMap will be created to map events between producers and consumers.

In the Summit ADF sample application, the eventMap is created in the consumer's page definition file, like this:

```
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
    <event name="productSelected">
      <producer region="*">
        <consumer handler="populateInventoryForProduct" region="">
        <parameters>
        <parameter name="productId" value="${payLoad}"/>
        </parameters>
        </consumer>
      </producer>
    </event>
</eventMap>
```

At runtime, when users enter the `show-products-task-flow-definition` and the `showProducts.jsff` page fragment, they are presented with a table of the products that are available. When the user selects a product from the list, a currency change event is invoked, resulting in the broadcast of the `productSelected` contextual event. In this example, a `payLoad` parameter containing the `productId` of the selected product is passed with the event.

This event is then consumed by the `product-inventory` task flow and its handler, the `populateInventoryForProduct()` method. This method uses the `payLoad` parameter to determine which product's inventory information to be displayed in the DVT component.

You will need to create the code for the event handler. For the Summit ADF sample application, the `populateInventoryForProduct()` handler was added to the `InventoryVOImpl.java` file because the InventoryVO **view object** contains the inventory data, as shown below:

```
public void populateInventoryForProduct( String productId ) {
          applyViewCriteria(getViewCriteria("InventoryVOCriteria"));
          setinputProductId( productId );
          executeQuery();
}
```

```
/**
 * Returns the variable value for Variable.
 * @return variable value for Variable
 */
public String getinputProductId() {
        return
(String)ensureVariableManager().getVariableValue("inputProductId");
}

/**
 * Sets <code>value</code> for variable Variable.
 * @param value value to bind as Variable
 */
public void setinputProductId(String value) {
        ensureVariableManager().setVariableValue("inputProductId", value);
}
```

Events are configured in the page definition file for the page or region that will raise the event (the producer). In order to associate the producer with the consumer that will do something based on the event, you create an event map in the page definition file of the consuming page or the parent page. (The parent page is the page that contains both regions). If the consuming page is in a dynamic region, the event map should be in the page definition file of the consuming page and the producer's attribute region set to "*". The attribute region is set to "*" because at design time, the framework cannot determine the relative path to the producer.

You can raise a contextual event for an action binding, a method action binding, a value attribute binding, or a range binding (table, tree, or list binding). You also can conditionally fire an event and conditionally handle an event using EL expressions.

For action and method action bindings, the event is raised when the action or method is executed. The `payLoad` contains the method return value. You can also raise a contextual event from an ADF Faces event such as clicking a button or selecting from a menu. An `eventBinding` is created in the page definition to define the event.

For a value attribute binding, the event is triggered by the binding container and raised after the attribute is set successfully. The `payLoad` is an instance of `DCBindingContainerValueChangeEvent`, which provides access to the new and old value, the producer iterator, the binding container, and the source. If the `payLoad` property is changed to point to a custom data object, then the `payLoad` reference will return the object instead. An example below shows a value change event inside an attribute value binding associated with an input component. The event, `valueChangeEvent`, will be dispatched when the user changes the value of `LAST_NAME` in the page.

```
<attributeValues IterBinding="DeptView1Iterator" id="Dname"
            xmlns="http://xmlns.oracle.com/adfm/jcuimodel">
    <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
            <event name="valueChangeEvent"/>
    </events>
    <AttrNames xmlns="http://xmlns.oracle.com/adfm/uimodel">
            <Item Value="LAST_NAME"/>
    </AttrNames>
</attributeValues>
</bindings>
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
    <event name="valueChangeEvent">
        <producer region="LAST_NAME">
            <consumer region="" handler="consumeEvent"/>
        </producer>
    </event>
</eventMap>
```

For a range binding (tree, table, list), the event is raised after the currency change has succeeded. The `payLoad` is an instance of `DCBindingContainerValueChangeEvent`, which provides access to the new and old value, the producer iterator, the binding container, and the source. The `eventMap` example above shows the event map for a currency change event associated with a range binding.

Value attribute binding and range binding contextual events may also be triggered by navigational changes. For example, if you create an event inside a tree table binding, the event will be dispatched when the user selects a different node of the tree in the page.

You use the **Contextual Events** section under the **Behavior** section in the Properties window to create and publish contextual events. The Contextual Events panel will only appear when you select eligible components or regions in the page, as shown in Figure 46-2.

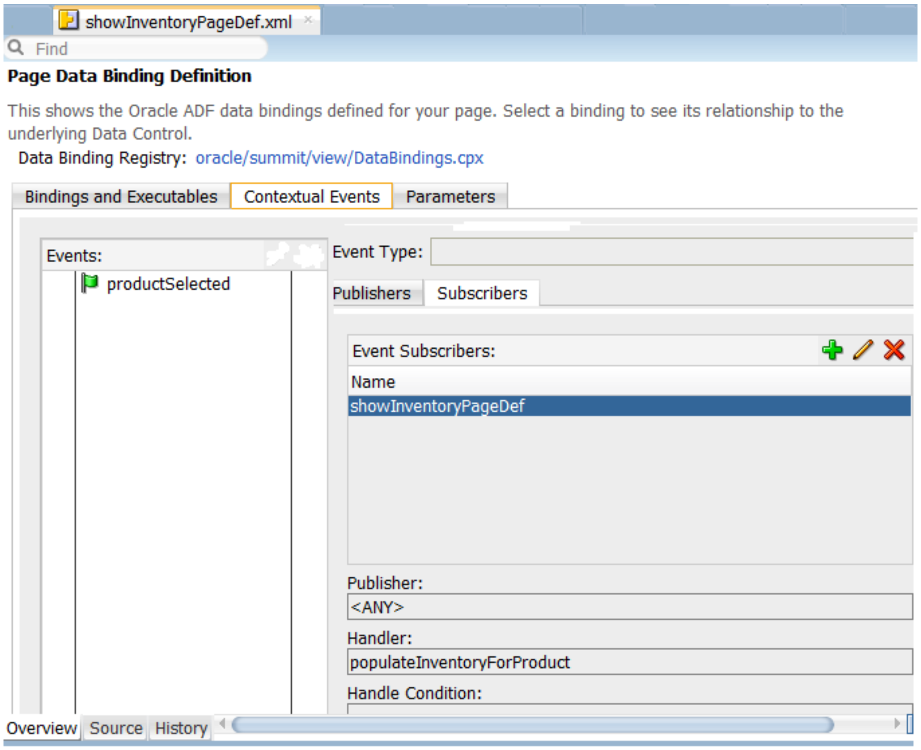
Figure 46-3 Page Definition Contextual Events Tab



Page Data Binding Definition

This shows the Oracle ADF data bindings defined for your page. Select a binding to see its relationship to the underlying Data Control.

Data Binding Registry: oracle/summit/view/DataBindings.cpx

Events:
productSelected

Event Type:

Event Subscribers:

Name
showInventoryPageDef

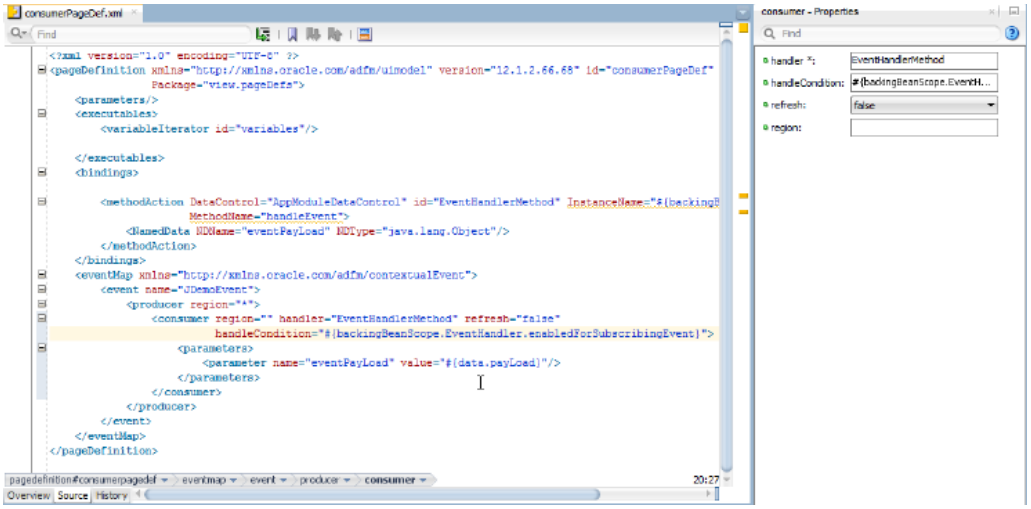
Publisher: <ANY>

Handler: populateInventoryForProduct

Handle Condition:

You can turn off automatic region refresh while consuming a contextual event by adding `refresh="false"` on the consumer element in the `eventMap` of the consuming region's page definition. Setting `refresh` to `false` is useful if you want to take charge of refresh for the event consuming region. The default for the refresh attribute is `true`. Additionally, you can turn off a subscriber region from consuming specific instances of contextual events using an EL binding on the `handleCondition` attribute also present in the consumer element inside the `eventMap` of the consuming region's page definition. The following page definition file source and Property window show a `methodAction` binding and an `eventMap` in a consuming region's page definition, where the addition of the `region` and `handleCondition` attributes control the consuming region's contextual event response.

Figure 46-4   Attributes of Consumer Element in a Consumer EventMap



```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel" version="12.1.2.66.68" id="consumerPageDef"

Contextual Events Use Cases and Examples

There are three kinds of communication patterns between a region and the parent page: parent to region, region to parent, and region to region. The contextual events framework is the most powerful communication implementation that works for all three of these scenarios. Also note that contextual events do not require a region to be refreshed in order to consume input parameters.

You should use contextual events to communicate between ADF regions. While it is possible to use ADF task flow parameters to communicate between regions, doing so may create direct dependencies between the regions. ADF task flow parameters may be fine for static regions, but using contextual events will allow you to implement independent communications between regions.

For example, a page may contain a region with a form for entering employee information. When the user updates the employee Id and presses the submit button, a value change contextual event is raised and the employee Id value is also passed as payLoad. On the same page, another region subscribes to and consumes the event and displays departmental information about the selected employee based on the payLoad information passed with the contextual event.

Additional Functionality for Contextual Events

You may find it helpful to understand other ADF features before you work with contextual events. Following are links to other functionality that may be of interest.

- You can also use ADF task flow parameters to communicate between ADF regions. For more information about using task flows and regions, see Using Task Flows as Regions.

Creating Contextual Events Declaratively

Contextual events in Oracle ADF has two parts, the publisher event (producer) and the handler event (consumer). In the process of creating contextual events declaratively, follow the different procedures to publish, subscribe, and consume an event.

You create contextual events by first creating and publishing the event on the producer based on a method action, action, value attribute, or list binding. On the consumer, you subscribe to the event and create a handler to process the event.

Typically, you create a parent page with regions that contain task flows and view activities. You create contextual events in one region to be published for consumer event handlers in the other region. For more information about using task flows and regions, see Using Task Flows as Regions.

> **Note:**
>
> You can also publish an action contextual event from code (for example, from within a managed bean). You can use `getBindingContainer().getEventDispatcher` which returns an instance of `EventDispatcher`. `EventDispatcher` has public APIs which you can use to programmatically raise contextual events.

How to Publish Contextual Events

You use the Properties window to create contextual events in the page where the contextual event will be produced. That is, the producer's page is the page where the contextual event is generated. The events can be published to either local or remote consumers. By default, all the events are published to local consumer. For instance, clicking a button on a page that would trigger a contextual event to be consumed by another component. The page that contains the button is the producer's page.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. See Creating Contextual Events Declaratively.

You may also find it helpful to understand functionality that can be used with contextual events. See Additional Functionality for Contextual Events.

You will need to complete this task:

> Decide on the type of component you want to use to raise the contextual event. If you plan to use a method action binding, you must have already created the method to be dropped onto the page.

To create a contextual event:

1. In the page where you want to publish the contextual event, drag and drop a component from the Data Controls panel to the page.

   This is the component that will trigger the event. It must have a method action, action, value attribute, or list binding event.

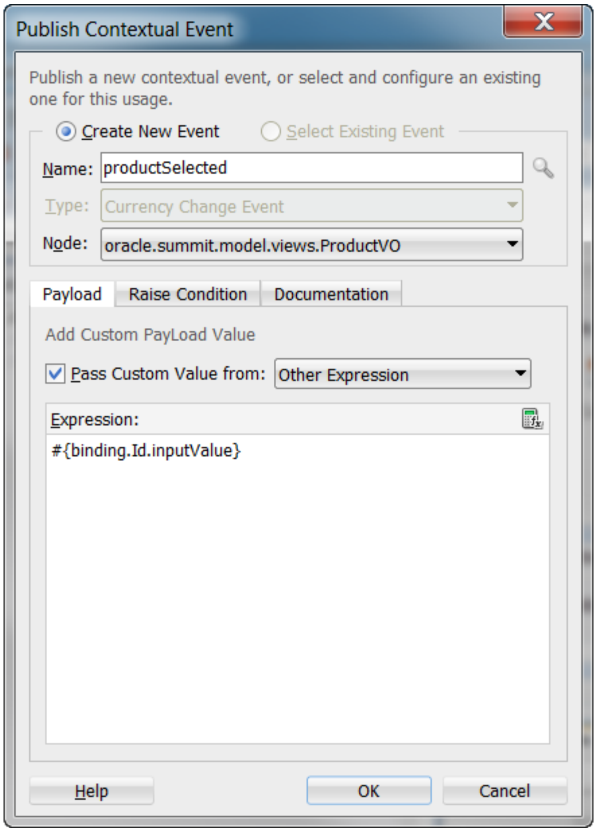
2. In the Properties window, expand the **Behavior** section.
3. In the **Publish Events** section, click the **Add** icon.
4. In the Publish Contextual Events dialog:
   a. Select **Create New Event**.
   b. Enter the name of the event.
   c. If your component is a table, tree, or tree table, a **Node** field appears for you to enter the node that will publish the event upon a change event.
   d. Select **Pass Custom Value From** if you want to pass payload data to the consumer.
   e. If you are passing payload data, select the type of data from the dropdown list. Normally, the parameter is {$payLoad}

      For instance, if you want to pass an attribute value from the producer page to the consumer page, you can select **Page Data** and select the attribute from the tree structure.
   f. You can conditionally raise the event by entering an EL expression in the **Raise Condition** tab.

      For instance, entering an expression such as `${bindings.LAST_NAME.inputValue == 'KING'}` will cause the event to be raised only if the customer's last name is KING.
   g. Click **OK**.

      The event is created on the page, but it is not ready for publishing until it is associated with the component binding.

Figure 46-5 Publish a Contextual Event



Publish Contextual Event

Publish a new contextual event, or select and configure an existing one for this usage.

● Create New Event ○ Select Existing Event

Name: productSelected

Type: Currency Change Event

Node: oracle.summit.model.views.ProductVO

Add Custom PayLoad Value

☑ Pass Custom Value from: Other Expression

Expression:

#{binding.Id.inputValue}

5. By default, all the events are dispatched to the local region. To dispatch the events to a remote region:

   a. In the Source view of the page definition file for the page that generates the event, select the event to see the event properties in the Property window.

   b. Set `dispatchMode` attribute to **remote**.

   > **Note:**
   >
   > If `dispatchMode` attribute is not set to **remote** value when a remote event is raised from a remote region, it might result in an exception, `java.io.NotSerializableException`. In this scenario, it is recommended not to set `dispatchMode` attribute to **local** value.

   c. For `customPayLoad` attribute, write an EL expression that references a serializable object.

   d. For `customPayLoadType` attribute, specify the type of custom payload of the object.

How to Subscribe to and Consume Contextual Events

You use the overview editor for page definition files to subscribe to contextual events. The overview editor displays the current region and its child regions. Only the regions that are shown can subscribe to contextual events.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Creating Contextual Events Declaratively.

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Additional Functionality for Contextual Events.

You will need to complete this task:

> Create a contextual event in the page definition file, as described in How to Publish Contextual Events.

To subscribe and consume the event:

1. Create a handler to process the event and its payload data.

   In the Summit ADF sample application, the `PopulateInventoryForProduct` handler method was created in the `InventoryVO` view object by adding the code to the `InventoryVOImpl.java` file.

   The method appears in the `BackOfficeAppModuleDataControl` **application module**.

2. In the consuming page, add the components that will respond to the event.

   In the Summit ADF sample application, a DVT component is added to the page to display the inventory available in different warehouses.

   The DVT component will receive the data from the `PopulateInventoryForProduct` method.

3. In the Applications window, double-click the page definition file that will contain the event map.

   In the Summit ADF sample application, the `showInventoryPageDef.xml` page definition file will have the event map.

4. In the overview editor, click the **Bindings and Executables** tab and then click the **Add** icon for the **Bindings** section

5. In the Insert Item dialog, select **methodAction** and click **OK**.

6. In the Create Action Binding dialog:

   a. Expand the data collection where you have created your handler.

   b. Select the handler.

   c. Click **OK**.

7. In the overview editor **Contextual Events** tab, click **Subscribers** and click the **Add** icon in the **Event Subscribers** section.

8. In the Subscribe to Contextual Event dialog:

   a. Enter the event name or click the **Search** icon to start the Select Contextual Event dialog.

      If you have started the Select Contextual Events dialog, select the event from the tree and click **OK**.

   b. Select the producer or **<Any>** from the **Publisher** dropdown list. A contextual event can have more than one producer.

Selecting **<Any>** will allow the consumer to subscribe to any producer producing the selected event. In the page definition file, the `producer` attribute will be set to the wildcard "*". If your producer is in a dynamic region, you should set this field to **<Any>** so that the subscriber can consume from any producer.

c. Click the **Search** icon next to the **Handler** field.

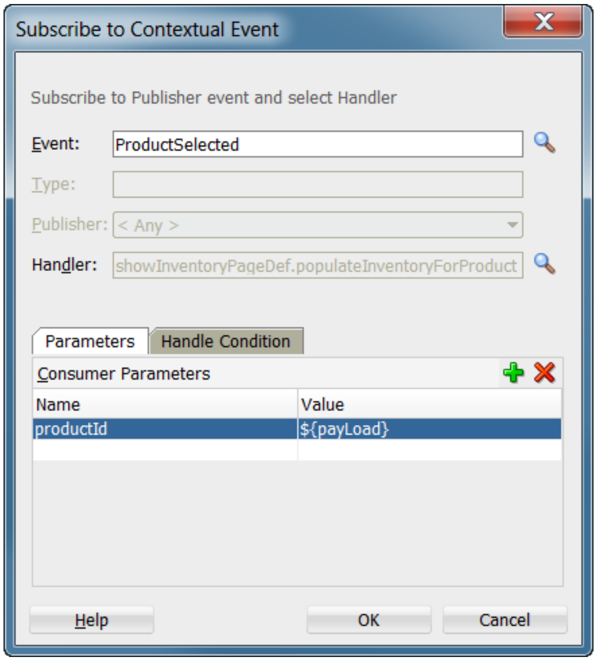
d. In the Select Handler dialog, select the event handler from the tree and click **OK**.

e. If the handler requires parameters, click the **Parameters** tab, click **Add**, and enter name-value pair as parameters.

f. If you want to conditionally handle the event, select the **Handle** tab, and enter an EL Expression that determines the conditions under which the handler will process the event.

g. Click **OK**.

Figure 46-6 Subscribe to a Contextual Event



Subscribe to Contextual Event

Subscribe to Publisher event and select Handler

Event: ProductSelected

Type:

Publisher: < Any >

Handler: showInventoryPageDef.populateInventoryForProduct

Consumer Parameters

Name	Value
productId	${payLoad}

Note:

You can edit the event map by right-clicking the page definition in the Structure window and choosing **Edit Event Map**. You can also edit event attributes in the page definition file or in the Properties window.

What Happens When You Create Contextual Events

When you create an event for the producer, JDeveloper adds an `events` element to the page definition file. Each event name is added as a child. The Event Definition for the

Producer example below shows the `productSelected` event defined in the producer page definition file as a currency change event.

```
<tree IterBinding="ProductVO1Iterator" id="ProductVO1">
      <nodeDefinition DefName="oracle.summit.model.views.ProductVO"
        Name="ProductVO10">
        <AttrNames>
          <Item Value="Id"/>
          <Item Value="Name"/>
          <Item Value="ShortDesc"/>
          <Item Value="LongtextId"/>
          <Item Value="ImageId"/>
          <Item Value="SuggestedWhlslPrice"/>
          <Item Value="WhlslUnits"/>
        </AttrNames>
        <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
          <event name="productSelected" eventType="Currency Change Event"
           customPayLoad="#{bindings.Id.inputValue}"/>
          </events>
      </nodeDefinition>
</tree>
```

In the consumer page definition file, a method action binding is created to respond to the event. The Method Action Definition example below shows the method action binding defined in the `showInventoryPageDef` page definition file.

```
<methodAction id="populateInventoryForProduct" RequiresUpdateModel="true"
          Action="invokeMethod"
          MethodName="populateInventoryForProduct"
          IsViewObjectMethod="true"
                  DataControl="BackOfficeAppModuleDataControl"

InstanceName="data.BackOfficeAppModuleDataControl.InventoryVO1">
      <NamedData NDName="productId" NDType="java.lang.String"/>
</methodAction>
```

When the currency change occurs, the event is broadcasted to its consumers. The method action definition is defined in the consuming page definition file.

When you configure an event map, JDeveloper creates an event map entry in the corresponding page definition file. An example below shows the event map on the `showInventoryPageDef` page definition file that maps the `productSelected` event from the `showproductstaskflowdefinition1` region to the `productinventorytaskflowdefinition1` region. It also maps the `populateInventoryForProduct` handler method bindings that is defined in the `showInventoryPageDef` page definition file. The handler processes the payLoad information (containing the `productID`) and passes it to the DVT component so it can query the warehouse inventory for that product.

```
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
    <event name="productSelected">
      <producer region="*">
        <consumer handler="populateInventoryForProduct" region="">
        <parameters>
        <parameter name="productId" value="${payLoad}"/>
        </parameters>
        </consumer>
      </producer>
    </event>
</eventMap>
```

When you set the value for `dispatchMode` to **remote**, JDeveloper adds the attribute `dispatchMode` to the `event` element in the page definition file. `CustomPayLoadType` will be the type of the payload which is being passed, it will be String if `getCustomPayLoad()` returns String. An example below shows the event element with the `dispatchMode` attribute set to **remote** value and the attributes that specify the custom payload to pass to the remote consumer.

```
<methodAction id="eventProducer" RequiresUpdateModel="true"
Action="invokeMethod" MethodName="eventProducer"
       IsViewObjectMethod="false" DataControl="Class1"
       InstanceName="bindings.eventProducer.dataControl.dataProvider"

ReturnName="data.Class1.methodResults.eventProducer_eventProducer_dataControl_dat
aProvider_eventProducer_result">
 <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
  <event name="teste" eventType="Action Event" dispatchMode="remote"
customPayloadType="java.lang.String"
        customPayLoad="#{testBean.customPayLoad}"/>
 </events>
</methodAction>
```

How to Control Contextual Events Dispatch

You can control the dispatch of contextual events to child regions at the application level or at the page level.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Creating Contextual Events Declaratively.

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Additional Functionality for Contextual Events.

To disable event dispatch:

1. To disable event dispatch at the application level, set the `dynamicEventSubscriptions` property to `false` in the `adf-config.xml` file, as shown in the following example.

   You can disable the event dispatch to regions that have an event map with producers as wildcards.

   ```
   <?xml version="1.0" encoding="windows-1252" ?>
   <adf-config xmlns="http://xmlns.oracle.com/adf/config"
        xmlns:cef="http://xmlns.oracle.com/adfm/contextualEvent">
        <cef:DynamicRegionEventsConfig dynamicEventSubscriptions="false">
        </cef:DynamicRegionEventsConfig>
   </adf-config>
   ```

2. To disable event dispatch at the individual page level, set the `dynamicEventSubscriptions` property to `false` in the associated page definition file, as shown in the following example.

   Contextual events will not be passed to the page and any of its children.

   ```
   <pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
                   version="11.1.1.52.8" id="viewBPageDef"
   Package="view.pageDefs"
                   DynamicEventSubscriptions="false">
   ```

What Happens at Runtime: Contextual Events

If both the event producer and the consumer are defined in the same page definition file, then after the corresponding page is invoked and the binding container is created, the event is raised when:

- The corresponding method or action binding is executed
- A value binding is set successfully
- A range binding currency is set successfully

For a method binding, the result of the method execution forms the payload of the event, and the event is queued. In the Invoke Application phase of the JSF lifecycle, all the queued events will be dispatched. The event dispatcher associated with the binding container checks the event map (also in the binding container, as it is part of the same page definition file) for a consumer interested in that event and delivers the event to the consumer.

When the producer and consumer are in different regions, the event is first dispatched to any consumer in the same container, and then the event propagation is delegated to the parent binding container. This process continues until the parent or the topmost binding container is reached. After the topmost binding container is reached, the event is again dispatched to child-binding containers that have regions with pages that have producer set to wildcard "`*` ".

When you raise a remote event from a remote region to pass a data value by using dataControl, the `dispatchMode` attribute must be set to **remote** value to successfully deliver the data value to the remote region; otherwise, it might result in an exception, `java.io.NotSerializableException`. In this scenario, it is recommended not to set `dispatchMode` attribute to **local** value.

Creating Contextual Events Manually

Contextual events in Oracle ADF has two parts, the publisher event (producer) and the handler event (consumer). In the process of creating contextual events manually, follow a detailed procedure to publish and consume an event.

You create contextual events by first creating the event on the producer. You then determine the consumer of the event, and map the producer to the consumer.

How to Create Contextual Events Manually

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Creating Contextual Events Manually.

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Additional Functionality for Contextual Events.

You will need to complete this task:

> Create a contextual event that has a method binding, action binding, value attribute binding, or list binding on the producer page.

To create a contextual event:

1. In the Applications window, double-click the page definition file that contains the binding for the producer of the event.

   A producer must have an associated binding that will be used to raise the event. For example, if a method or operation will be the producer, the associated action binding or method action binding will contain the event.

2. In the Structure window, right-click the binding for the producer and choose **Insert inside *binding name* > events** or **Insert inside *binding name* > Contextual Events > events**.

3. In the Structure window, right-click the **events** element just created, and choose **Insert inside events > event**.

4. In the Insert event dialog, enter a name for the event in the **name** field, and click **Finish**.

   The event is now created. By default, any return of the associated method or operation will be taken as the payload for the event and stored in the EL-accessible variable `${data.payLoad}`. You now need to map the event to the consumer, and to configure any payload that needs to be passed to the consumer.

5. In the Applications window, double-click the page definition file that contains the binding for the consumer.

   The binding container represented by this page provides access to the events from the current scope, including all contained binding containers (such as task flow regions). If regions or other nested containers need to be aware of the event, the event map should be in the page definition of the page in the consuming region.

6. In the Structure window, right-click the topmost node that represents the page definition, and choose **Edit Event Map**.

   > **Note:**
   >
   > If the producer event comes from a page in an embedded dynamic region, you may not be able to edit the event map using the Event Map Editor. You can manually create the event map by editing the page definition file or use **insert inside** steps, as described in Creating Contextual Events Manually.

7. In the Event Map Editor, click the **Add** icon to add an event entry.

8. In the Add New EventMap Entry dialog, do the following:

   a. Use the **Producer** dropdown menu to choose the producer.

   b. Use the **Event Name** dropdown menu to choose the event.

   c. Use the **Consumer** dropdown menu to choose the consumer. This should be the actual method that will consume the event.

   d. If the consuming method or operation requires parameters, click the **Add** icon.

      In the **Param Name** field, enter the name of the parameter expected by the method. In the **Param Value** field, enter the value. If this is to be the payload from the event, you can access this value using the `${data.payLoad}` expression. If the payload contains many parameters and you don't need them all, use the ellipses button to open the Expression Builder dialog. You can use this dialog to select specific parameters under the **payload** node.

You can also click the **Parameters** ellipses button to launch the selection dialog.

e. Click **OK**.

9. In the Event Map Editor, click **OK**.

Creating Contextual Events Using Managed Beans

Oracle ADF supports publishing an action contextual event from code such as from within a managed bean. You can also dynamically create and handle contextual events using managed beans.

How to Create Contextual Events Using Managed Beans

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Creating Contextual Events Using Managed Beans.

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Additional Functionality for Contextual Events.

To create contextual events using managed beans:

1. Create a method in a managed bean to generate the contextual event.

   As the following example shows managed bean code that perform an action when a button is pressed. The myActionPerformed method is invoked and calls methods to generate the contextual event with "myString" as the payLoad:

```
BindingContainer bc BindingContext.getCurrent().getCurrentBindingsEntry();
JUCtrlActionBinding actionBnd =
  (JUCtrlActionBinding)bc.getControlBinding("eventProducer");
...
((DCBindingContainer)bc).getEventDispatcher().queueEvent(actionBnd.
   getEventProducer(),"myString");
```

2. Bind the producer component to the method in the managed bean.

   As the following example shows code for a producer associated with a command button that invokes an action binding and the consumer is an outputText component that displays a string. They are both on the same page.

```
<af:form id="f1">
     <af:button value="eventProducerButton1" id="cb1"
                action="#{MyBean.myActionPerformed}"/>
     <af:panelLabelAndMessage
label="#{bindings.return.hints.label}"id="plam1">
          <af:outputText value="#{bindings.return.inputValue}" id="ot1"/>
     </af:panelLabelAndMessage>
</af:form>
```

What Happens When You Create Contextual Events Using Managed Beans

The page definition file contains the method action bindings for the producer, the consumer, and the event map, like this:

```
<executables>
    <variableIterator id="variables">
      <variable Type="java.lang.String" Name="eventConsumer_return"
                IsQueriable="false" IsUpdateable="0"
                DefaultValue="${bindings.eventConsumer.result}"/>
    </variableIterator>
</executables>
<bindings>
     <methodAction id="eventProducer"
                  InstanceName="AppModuleDataControl.dataProvider"
                  DataControl="AppModuleDataControl" RequiresUpdateModel="true"
                  Action="invokeMethod" MethodName="eventProducer"
                  IsViewObjectMethod="false"
                  ReturnName="AppModuleDataControl.methodResults.eventProducer_
                       AppModuleDataControl_dataProvider_eventProducer_result">
            <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
                  <event name="myEvent"/>
            </events>
     </methodAction>
     <methodAction id="eventConsumer" RequiresUpdateModel="true"
                  Action="invokeMethod" MethodName="eventConsumer"
                  IsViewObjectMethod="false" DataControl="AppModuleDataControl"
                  InstanceName="AppModuleDataControl.dataProvider"
                  ReturnName="AppModuleDataControl.methodResults.eventConsumer_
                        AppModuleDataControl_dataProvider_eventConsumer_result">
               <NamedData NDName="str" NDValue="test" NDType="java.lang.String"/>
    </methodAction>
    <attributeValues IterBinding="variables" id="return">
        <AttrNames>
             <Item Value="eventConsumer_return"/>
        </AttrNames>
    </attributeValues>
</bindings>
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
    <event name="myEvent">
      <producer region="eventProducer">
        <consumer region="" handler="eventConsumer">
          <parameters>
            <parameter name="test" value="${data.payLoad}"/>
          </parameters>
        </consumer>
      </producer>
    </event>
</eventMap>
```

How to Dynamically Create and Handle Contextual Events Using Managed Beans

You can programmatically create contextual event definitions, register the event producer and even trigger the contextual event. This is useful when you build task flows which need to trigger different events based on the context where the event is used (for example, when the client that hosts the task flow may change).

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Creating Contextual Events Using Managed Beans.

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Additional Functionality for Contextual Events.

To create and handle contextual events dynamically using managed beans:

1. Create a method in a managed bean to generate the contextual event.

   The following sample shows managed bean code that exercises the `EventDispatcher` API to perform an action when a button is pressed.

   ```
   DCBindingContainer bc = (DCBindingContainer)
   BindingContext.getCurrent().getCurrentBindingsEntry();
   bc.getEventDispatcher().queueEvent(new CustomEventProducer(),
   someCustomEventPayLoad);
   bc.getEventDispatcher().processContextualEvents();
   ```

   The event producer class `CustomEventProducer` used in this above sample defines the contextual event `JDemoEvent`.

   ```
   import oracle.adf.model.events.EventProducer;

   public class CustomEventProducer implements EventProducer {
       public CustomEventProducer() {
           super();
       }
       public String getId() {
           return "JDemoEvent";
       }

       public ArrayList getEventDefinitionsList() {
           ArrayList eventDefList = new ArrayList();

           EventDefinitionImpl demoEvent = new EventDefinitionImpl();
           demoEvent.setEventName("JDemoEvent");
           eventDefList.add(demoEvent);
           return eventDefList;
       }

   }
   ```

2. Bind the producer component to the method in the managed bean.

   The following sample shows the producer page source associated with a command button that invokes an action listener method `produceDynamicContextualEvent()` on the above managed bean.

   ```
   <af:panelGroupLayout id="pgl1">
           <af:button text="Produce Contextual Event" id="b5"

   actionListener="#{viewScope.EventProducer.produceDynamicContextualEvent}"/>
   </af:panelGroupLayout>
   ```

3. Bind the consumer component to the event handler method for the contextual event. (This is an alternative to relying on data controls to perform the binding.)

The following sample shows the consumer page source as an outputText component that displays a string set by the event handler method `setOutputTextDeptName()`.

```
<af:panelGroupLayout id="pgl1">
    <af:outputText value="Got the following via Contextual Event :"
id="ot1"/>
    <af:outputText value="#{backingBeanScope.EventHandler.deptName}" id="ot2"

binding="#{backingBeanScope.EventHandler.outputTextDeptName}"
clientComponent="true"/>
</af:panelGroupLayout>
```

Note that when you create a managed bean as event handler for contextual events not using data controls, you may want to create the `methodAction` bindings manually. This will simplify your task when you want to refresh a UI component or invoke some managed bean code as part of the contextual event. The following sample shows a `methodAction` binding and an `eventMap` like the ones that you would create in the consuming region's page definition.

```
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
id="consumerPageDef" Package="view.pageDefs">
     ...
     <bindings>
        <methodAction DataControl="AppModuleDataControl"
id="EventHandlerMethod" InstanceName="${backingBeanScope.EventHandler}"
                      MethodName="handleEvent">
            <NamedData NDName="eventPayLoad" NDType="java.lang.Object"/>
        </methodAction>
    </bindings>
    <eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
        <event name="JDemoEvent">

                <consumer region="" handler="EventHandlerMethod">
                    <parameters>
                        <parameter name="eventPayLoad"
value="#{data.payLoad}"/>
                    </parameters>
                </consumer>
            </producer>
        </event>
    </eventMap>
</pageDefinition>
```

Creating Contextual Events Using Plain Java Objects (POJOs)

Oracle ADF provides bounded task flows that can take any number of parameters and can provide a simple feedback to its caller in the form of an outcome. It also has a return parameter, allowing the task flow to return a Java object.

A bounded task flow embedded in a region may have several views that need to be exposed as possible consumers of an contextual event. Instead of creating a Plain Java Object (POJO), a data control, and an event handler for each view, you can create a single POJO and a single data control to process events for all the views in the task flow.

In this approach, the event receiver method dispatches the contextual event request by using the managed bean reference to invoke the `handleEvent` method and passes the payLoad for processing. The managed bean, defined in backing bean scope, can have JSF component references that allow the bean to refresh the dependent user interface.

The following conditions must be satisfied for this approach to work:

- The event receiver method must pass the payLoad as an argument to the method that handles the message.
- The event receiver method must have a second argument that is used to pass an object reference to a managed bean associated with the subscriber region task flow.
- The managed bean passed as a reference must contain a commonly known public method that accepts the event message as input argument. This method handles the event.

How to Configure a Generic Callback Message Handler for a Task Flow

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Creating Contextual Events Using Plain Java Objects (POJOs).

You may also find it useful to understand functionality that can be used with contextual events. For more information, see Additional Functionality for Contextual Events.

To create the generic event receiver and managed bean event handler:

1. Create a POJO data control.

   The POJO data control should appear in the Data Control panel.

   For more information about data controls, see the Creating and Configuring Bean Data Controls section in *Developing Applications with Oracle ADF Data Controls*.
2. Create an event receiver class (exposed in the POJO data control) with an event handler method that defines two arguments.

   The first argument is for the payLoad delivered by the contextual event. The second argument is callback handler reference to a managed bean that is implementing the contextual event handler interface.
3. Create a managed bean with backing bean scope that implements the `ContextualEventHandler` interface.

   Implementing the `ContextualEventHandler` interface includes defining the call back method, for example, `handleEvent()`, that will be called by the generic contextual event receiver to pass control to the managed bean.
4. Create a method binding in the page definition file of the view within the task flow that will receive the event.

   a. In the Applications window, double-click the page definition file that will contain the event map.

   b. In the overview editor, click the **Bindings and Executables** tab and then click the **Add** icon for the **Bindings** section
   c. In the Insert Item dialog, select **methodAction** in the **Generic Bindings** category, and select the POJO data control that exposes the event receiver method.
   d. Use the EL Expression Builder to reference the managed bean that was created for the `ContextualEventHandler` argument. Leave the `payLoad` argument blank as this will be provided by the contextual event mapper.

5. Subscribe to the contextual event by defining it in the same page definition file where the method binding was declared.

   For general instructions on subscribing to contextual events, follow Step 7 to Step 8 in How to Subscribe to and Consume Contextual Events.

This is an implementation for a generic and reusable contextual event handler that invokes a method on a configured managed bean to have the contextual event payload handled in the context of a view to be changed in response of an event.

Creating Contextual Events Using JavaScript

Every action and method binding that is accessible from a managed bean can be invoked from JavaScript. ADF Faces provides an `af:serverListener` operation component that can be used to call a managed bean method from client-side JavaScript.

To invoke the `af:serverListener` operation component using the referenced managed bean method, use the `BindingContext` object to look up the current `BindingContainer` and to access the `OperationBinding` or a `JUEventBinding` binding. The `af:serverListener` component can also be used to send a message `payload` from the browser client to the managed bean method.

Creating the Event Map Manually

In Oracle ADF, events are configured in the page definition file for the page or region that will raise the event (the producer). To associate the producer with the consumer that will perform some operations based on the event, you create an event map also in the page definition file.

Under most circumstances, you can create the event map using the Event Map Editor as described in Creating Contextual Events Manually. However, in situations such as when the producer event is from a page in an embedded dynamic region, the Event Map Editor at design time cannot obtain the necessary information to create an event map.

How to Create the Event Map Manually

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Creating the Event Map Manually.

You may also find it useful to understand functionality that can be used with contextual events. For more information, see Additional Functionality for Contextual Events.

To create the event map manually:

1. In the Applications window, double-click the page definition file that contains the binding for the consumer.
2. In the Structure window, right-click the topmost node that represents the page definition, and choose **Insert inside *pagedef name* > eventMap**.
3. In the Structure window, select the **eventMap** node, right-click and choose **Insert inside eventMap > event**.
4. In the Insert Event dialog, enter the name of the event and click **OK**.

   Repeat steps 3 and 4 to add more events.
5. Select the **event** node, right-click and choose **Insert inside event > producer**.
6. In the Insert Producer dialog, enter the name of the binding that is producing this event and click OK.

   You can also enter the name of the region which has the event producer, in which case all the consumers specified under this tag can consume the event. You can also enter "*" to denote that this event is available for all consumers under this tag.
7. Select the **producer** node, right-click, and choose **Insert inside producer > consumer**.
8. In the Insert Consumer dialog, enter the name of the handler that will consume the event and click **OK**.

   Repeat steps 7 and 8 to add more consumers.
9. If there are parameters being passed, add the parameter name and value.
   a. Select the **consumer** node, right-click, and choose **Insert inside consumer > parameters**.
   b. Select the **parameters** node, right-click, and choose **Insert inside parameters > parameter**.
   c. In the Insert Parameter dialog, enter the name of the parameter and the value of the parameter and click **OK**. The value can be an EL expression.

      Repeat this step to add more parameters.

Registering a Custom Dispatcher

By default, the contextual event framework uses `EventDispatcherImpl` to dispatch events that would traverse through the regions. You can create a custom event dispatcher to override the default event dispatcher to provide custom behaviors.

After you have created the custom event dispatcher, you must register it in the `Databindings.cpx` file to override the default dispatcher.

How to Register a Custom Dispatcher

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Registering a Custom Dispatcher.

You may also find it useful to understand functionality that can be used with contextual events. For more information, see Additional Functionality for Contextual Events.

To register a custom event dispatcher:

1. Create a custom event dispatcher Java class based on the `EventDispatcher` class.
2. Register the custom event dispatcher in the `Databindings.cpx` file with a fully qualified name using the following format:

   ```
   EventDispatcher="package_name.CustomEventDispatcher_name"
   ```

   As the following example shows the code for a custom event dispatcher called `NewCustomEventDispatcher` created in package `NewPackage`.

   ```
   <Application xmlns="http://xmlns.oracle.com/adfm/application"
                version="11.1.1.51.60" id="DataBindings"
   SeparateXMLFiles="false"
                Package="project3" ClientType="Generic"
                EventDispatcher="NewPackage.NewCustomEventDispatcher">
   ```
3. Create the event in the producer's page definition. For more information, see Creating Contextual Events Declaratively, or Creating Contextual Events Manually.
4. Create the event map in the consumer region if the consumer is in a dynamic region. If the consumer is not in a dynamic region, you can also specify the event map in the parent page which holds both the producer and consumer regions. For more information, see Creating the Event Map Manually.

Part VI
Completing Your Application

This part describes tasks that developers can perform to secure, refine, test, and deploy Fusion web applications.

Part VI contains the following chapters:

- Enabling ADF Security in a Fusion Web Application
- Testing and Debugging ADF Components
- Refactoring a Fusion Web Application
- Reusing Application Components
- Customizing Applications with MDS
- Allowing User Customizations at Runtime
- Using the Active Data Service
- Configuring High Availability for Fusion Web Applications
- Deploying Fusion Web Applications
- Using State Management in a Fusion Web Application
- Tuning Application Module Pools

47

Enabling ADF Security in a Fusion Web Application

This chapter describes how you can enable ADF Security in the Fusion web application to define resource grants for Oracle ADF resources and to restrict the user's ability to view web pages associated those resources.
This chapter includes the following sections:

About ADF Security

Security is an important part of any enterprise application. Security implementation in an ADF application decides who can access the application and what they can do once they are logged in. You can visually enable security in the different layers of your Fusion web application.

The ADF Security framework is the preferred technology to provide authentication and authorization services to the Fusion web application. ADF Security is built on top of the Oracle Platform Security Services (OPSS) architecture, which itself is well-integrated with Oracle WebLogic Server. While other security-aware models exist that can handle user login and resource protection, ADF Security is ideally suited to provide declarative, permission-based protection for **ADF bounded task flows**, for top-level web pages that use **ADF bindings** (pages that are not contained in a bounded task flow), and at the lowest level of granularity, for rows of data defined by ADF **entity objects** and their attributes. In this document, these specific resources that the ADF Security framework protects are known as **ADF security-aware resources**.

You enable ADF Security for Fusion web applications when you run the Configure ADF Security wizard, as described in Enabling ADF Security. The wizard configures ADF Security for the entire Fusion web application, so that any web page associated with an ADF security-aware resource is protected by default. This means that after you enable ADF Security, your application is locked down so that the pages are considered secure by default.

After you enable ADF Security you must grant users access rights so that they may view the web pages of the Fusion web application. Access rights that you grant users are known as a **security policy** that you specify for the page's corresponding ADF security-aware resource. Ultimately, it is the security policy on the ADF resource that controls the user's ability to enter a task flow or view a web page.

Because ADF Security is based on Java Authentication and Authorization Service (JAAS), security policies identify the principal (the user or application role), the ADF resource, and the permission (an operation defined by the resource's ADF permission class). For example, the Summit sample application for ADF task flows secures the web pages contained by the `customer-task-flow` task flow to grant access only to logged-in users (also known as **authenticated users**). At runtime, the ADF Security framework performs authorization checking against the task flow's security policy to determine the user's right to complete the view operation. In this case, the security policy must grant the view permission to the user if they are to complete the checkout process.

To simplify the task of defining security policies for users and ADF resources, ADF Security defines a containment hierarchy that lets you define one security policy for the ADF bounded task flow and its contains web pages. In other words, when you define the security policy at the level of the bounded task flow, you protect the flow's entry point and then all pages within that flow are secured by the policy it defines. Additionally, instead of granting access to individual users, you group users into application roles and grant the view permission to the role.

Specifically, you will define security policies in the Fusion web application for the following ADF security-aware resources to make web pages accessible to users:

- **ADF bounded task flow** protects the entry point to the task flow, which in turn controls the user's access to the pages contained by the flow

  For example, a series of web pages may guide new customers through a registration process and the bounded task flow controls page navigation for the process. For a description of bounded task flows, see About Bounded Task Flows.

  The **ADF unbounded task flow** is not an ADF security-aware component and thus does not participate in authorization checks. When you need to protect the constituent pages of an unbounded task flow, define grants for the page definition files associated with the pages instead.

- ADF **page definition files** associated with web pages not contained by a bounded task flow

  For example, a web page may display a summary of best selling products with data coordinated by the ADF bindings of the page's associated ADF page definition file. For a description of page definitions and ADF bindings, see Working with Page Definition Files.

- ADF **entity objects** and attributes of entity objects that reference rows of data and help define collections for display in the user interface

  For example, a web page may display an **ADF Faces** table component that displays columns that ADF bindings map to the attributes of an entity object as its data source. In the case of entity objects, enabling ADF Security does not automatically secure entity objects rows. The data will remain accessible to users until you define a security policy to explicitly protect the entity object or its attributes. For a description of entity objects, see About Entity Objects.

JDeveloper tools support iterative development of security so you can easily create, test, and edit security policies that you create for ADF resources. You can proceed to create test users in JDeveloper and run the application in Integrated WebLogic Server to simulate how end users will access the secured resources. This chapter describes how to configure the repository of user identities and login credentials known as the **identity store**.

> **Note:**
>
> References to the identity store in this chapter are always in the context of *test* user identities that you create for the purpose of running in Integrated WebLogic Server. Typically, you would not migrate these users to the staging environment when you deploy to Oracle WebLogic Server, as described in Preparing the Secure Application for Deployment.

To avoid a situation where you have enabled ADF Security but have not yet defined security policies to grant access to test users, the Configure ADF Security wizard lets you grant temporary view rights to all existing ADF resources (a view permission grant will be added to the security policy for each ADF resource). This wizard option gives you the choice to disable automatic grants and proceed to define security policies for ADF resources as you create each resource or to enable automatic view grants and gradually replace these grants with security policies that you define. To understand iterative security development choices, see ADF Security Process Overview.

> **Tip:**
>
> Before you enable ADF Security and define security policies for the ADF security-aware resources, you will want to understand the rules that govern ADF authorization checking. Understanding these rules will help you to implement the security you intend. For a discussion of these rules, see ADF Security Use Cases and Examples.

Integration of ADF Security and Java Security

The ADF Security model for securing Fusion web application resources is not based on the URL mapping of a security constraint as exemplified by the Java EE security model. In actual practice, security constraints are not feasible for securing a JavaServer Faces (JSF) web application where page navigation is not supported by specific page URLs. For example, when the user navigates to the next page in a task flow, the URL remains the same throughout the flow. As each new page is displayed, there is no means to trigger a URL-based security constraint.

Instead, ADF Security implements a Java Authentication and Authorization Service (JAAS) security model. The JAAS model is policy-based since JAAS is built on the existing Java security model and integrates with any JAAS implementation, including the Oracle Platform Security Services (OPSS) implementation of the JAAS service. Whereas applications that utilize URL security constraints are security-unaware because they rely on the Java EE container to manage security, Fusion web applications require an explicit call to the ADF Security framework to authorize access to resources based on user-defined policies. Thus, when you enable ADF Security and define access policies for ADF resources, your application is security-aware.

ADF Security simplifies the implementation of a JAAS authorization model. This implementation minimizes the work needed to create a security-aware application by exposing security policies on ADF resources in a declarative fashion and performing authorization checks on these resources at runtime.

The policy store in JDeveloper is file-based and contains a list of entries known as **grants**, which define the security policy for the ADF resource. The grant entry includes all the permissions granted to the user to perform operations on the protected resource, for instance, accessing a web page associated with an ADF bounded task flow. Permissions are granted in the policy store to an application role principal.

ADF Security expands on the JAAS model by allowing you to define grants using the actions specified by the ADF Security framework permission classes. These classes are specific to the ADF resource and map the actions to an operation supported by the resource. The policy store for the Fusion web application therefore contains grants that specify:

- One or more permissions that associate an action defined by the resource's permission class with an instance of the ADF resource in the application (currently, only the `view` action is supported for bounded task flows and page definitions resources)
- The grantee, which is an application role defined by your application that you populate with member users or, optionally, enterprise roles for whom you wish to confer the same access rights

In the case of entity objects, the permission class defines `read`, `delete`, and `update` actions that correspond to the `read`, `removeCurrentRow`, and `update` operations of the entity object.

For a description of the ADF permission classes and supported actions, see ADF Security Permission Grants.

ADF Security Use Cases and Examples

The use of ADF Security enables web applications to easily adjust to real-world business security requirements, because rather than securing paths to application resources, you secure the view operation on ADF resources with JAAS. JAAS-based ADF Security provides:

- Declarative security support for ADF resources, such as the bounded task flow

  Because Java EE security is URL-based or page-based, it is not possible to have a navigation control without custom code. With ADF Security, you can control whether or not the user can enter a task flow. Thus, a single security policy for a task flow can control access to multiple web pages. Additionally, because declarative security lets you secure the ADF resource, not the access path, you can reuse the ADF resource elsewhere in the application and it will remain secured.

- Simplified permission assignment by using application roles that allow for the inheritance of permissions

  While Java EE security roles that are used by Java EE security constraints are flat, JAAS permissions are granted to application roles, which can be nested and may be mapped to enterprise roles that the Oracle WebLogic Server domain defines.

- Utility methods for use in EL expressions to access ADF resources in the security context

You can use the ADF Security EL expression utility methods to determine whether the user is allowed to perform a known operation. For example, you can determine whether the user is allowed to view a particular task flow.

Additionally, JDeveloper enables you to quickly create test users and passwords to test security in Integrated WebLogic Server. When you are ready to deploy to Oracle WebLogic Server, you can migrate the application-specific authorization policies to the server and the administrator can configure the application to use an LDAP user repository.

Table 47-1 summarizes the effect that enabling ADF Security has on the application and the various ADF security-aware resources. For further discussion about how you can work most effectively with ADF Security, see Best Practices for Working with ADF Security.

Table 47-1 Summary of ADF Security-Aware Resources

ADF Resource	How ADF Enforces Security	How to Grant Access
Bounded task flows in all user interface projects	Protected by default. Requires a grant to allow users to enter the bounded task flow.	Define the grant for the task flow. Do *not* define grants for individual page definition files associated with the web pages of the bounded task flow.
Page definition files in all user interface projects	Protected by default. Requires a grant to allow users to view the page associated with the page definition.	If the web page is contained by a bounded task flow, define the grant for the task flow. Define the grant for the page definition *only* when the web page is not contained by a bounded task flow or when the page is contained by an unbounded task flow. Note that the unbounded task flow is not an ADF security-aware component and allows no grants.
Entity objects in the data model project	Not protected by default. Requires a grant to prevent access by users.	Define a grant on the entity object to protect data only if you need to control access at the level of the entire data collection. The data displayed by *all* components in the user interface that reference the protected entity object will be protected. Use entity-level security carefully. Instead, consider defining security at the level of the entity attribute. Note that grants in the data model project are saved as metadata on the entity object itself and do not appear in the ADF policy store.

Table 47-1 (Cont.) Summary of ADF Security-Aware Resources

ADF Resource	How ADF Enforces Security	How to Grant Access
Attributes of entity objects in the data model project	Not protected by default. Requires a grant to prevent access by users.	Define a grant on the entity object attribute to protect data when you need to control access at the level of the columns of the data collection. The data displayed by *all* components in the user interface that reference the protected entity attribute will be protected. Note that grants in the data model project are saved as metadata on the entity object itself and do not appear in the ADF policy store.

Additional Functionality for ADF Security

You may find it helpful to understand other **Oracle ADF** features before you start working with ADF Security. Following are links to other functionality that may be of interest.

- To understand the security features of Oracle Platform Security Services, see Introduction to Oracle Platform Security Services in *Securing Applications with Oracle Platform Security Services*.

ADF Security Process Overview

The Oracle ADF Security framework provides several out-of-the-box features to make it easier for developers to code secure ADF applications. ADF Security settings are stored in the application-wide jazn-data.xml data file.

You work in JDeveloper when you want to secure the ADF resources of your Fusion web application. ADF Security will protect your application's bounded task flows and any web pages contained in an unbounded task flow. You enable this protection by running the Configure ADF Security wizard and later by defining ADF security policies to define user access rights for each resource.

As you create the user interface for your application, you may run the Configure ADF Security wizard at any time. You may choose to:

- Iterate between creating web pages in the UI project and defining security policies on their associated ADF resources
- Complete all of the web pages in the UI project and then define security policies on their associated ADF resources

> **Note:**
>
> Before you proceed to secure the Fusion web application, you should become familiar with the ADF security model, as described in ADF Security Use Cases and Examples.

The iterative design and test process is supported by a variety of design time tools.

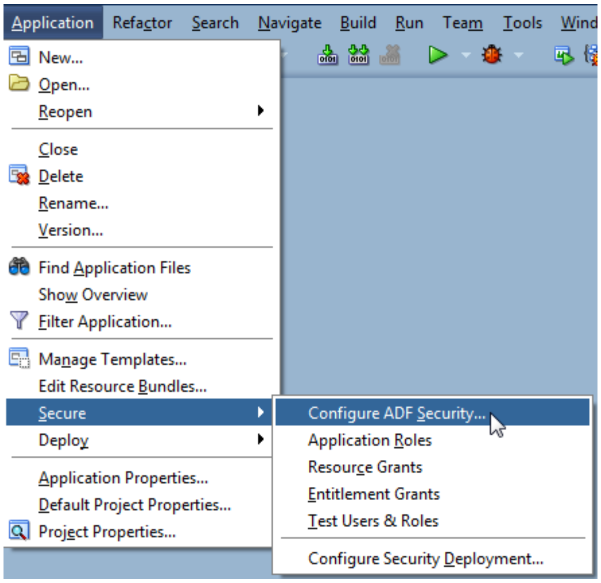
Each time you create a new bounded task flow or ADF page definition file in your user interface projects, the new ADF resource will be visible in the overview editor for the `jazn-data.xml` file. This editor is also called the overview editor for security policies. You use the overview editor to define security policies for ADF resources associated with web pages for the entire application. You can also use the overview editor to sort ADF resources and easily view those that have no security policy yet defined.

You use another editor to provision a few test users in the ADF identity store. The identity store you create in JDeveloper lets you define user credentials (user ID and password). The editor also displays the relationship between users you create and the application roles that you assign them to for the purpose of conferring the access rights defined by ADF security policies.

At design time, JDeveloper saves all policy store and identity store changes in a single file for the entire application. In the development environment, this is the `jazn-data.xml` file. After you configure the `jazn-data.xml` file using the editors, you can run the application in Integrated WebLogic Server and the contents of the policy store will be added to the domain-level store, the `system-jazn-data.xml` file, while the test users will be migrated to the embedded LDAP server that Integrated WebLogic Server uses for its identity store. The domain-level store allows you to test the security implementation by logging on as test users that you have created.

You access all design time tools for security under the main menu, using the **Application > Secure** menu, as shown in Figure 47-1.

Figure 47-1 Accessing the ADF Security Design Time Tools



Design Phase

To enable ADF Security and set up the policy store for the application that you will run in JDeveloper:

1. Enable ADF Security to allow dynamic authentication and enforce authorization by running the Configure ADF Security wizard.

When you run the wizard, if you choose to enable *only* dynamic authentication, skip the remaining design phase steps. The wizard configures files that integrate the security framework with OPSS on Oracle WebLogic Server.

2. Create an ADF security-aware resource, such as a bounded task flow with constituent web pages (or regions) or a top-level web page (or **region**) that is designed using ADF bindings.

   Note: After you run the Configure ADF Security wizard, any web page associated with an ADF security-aware resource will be protected. This means that you must define security policies to make the web pages accessible *before* you can run the application and test security.

3. Associate the ADF security-aware resource with one or more application roles that you create.

   Application roles you create are specific to the application and let you confer the same level of access to a set of users (also known as *member users*). In the test phase you will create some users and add them as members to the application roles you created.

4. Grant view permission to the ADF security-aware resource and each of its associated application roles.

   The grant confers access rights to the application role's member users. Without the grant, the user would not be able to access the ADF security-aware resource. In the test phase, you will create some users and add them to your application roles.

Testing Phase

To provision the identity store and test security using Integrated WebLogic Server:

1. Create some users and, optionally, create their enterprise roles.

   You will log in to the application using the user ID and password you define. An **enterprise role** is a logical role that lets you group users and associate these groups with application roles. The enterprise role is not needed for testing. For more information, see What You May Need to Know About Enterprise Roles and Application Roles.

2. Associate the users you created and, optionally, the enterprise roles, with one or more application roles.

   A member user may belong to more than one application role when you wish to confer the access right granted to multiple application roles.

3. Optionally, replace the default login page with a custom login page.

   The default login page generated by the Configure ADF Security wizard cannot utilize ADF Faces components. It is provided only as a convenience for testing ADF security policies. Your custom login page may be designed with ADF Faces components.

4. Run the application in JDeveloper and access any ADF security-aware resource.

   The first time you attempt to access an ADF security-aware resource, the security framework will prompt you to log in.

5. Log in and check that you are able to access the page and its resources as you intended.

   After you log in, the security framework checks the user's right to access the resource. For example, if you receive an unexpected 401 unauthorized user error, verify that you have created grants as suggested in Best Practices for Working with ADF Security.

Preparation for Staging

To prepare the secure application for deployment to Oracle WebLogic Server in a staging or production environment:

1. Remove any grants to the `test-all` role for all ADF security-aware resources and replace with grants that you define.

   Because ADF resources are secure by default, developers testing the application will be granted view access only after security policies are defined. The Configure ADF Security wizard gives you the option to generate grants to the `test-all` role that will make all ADF resources accessible. To avoid compromising enterprise security, you must eventually replace all temporary grants to the `test-all` role with explicit grants that you define.

2. Remove all user identities that you created.

   JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, rely on the system administrator to configure user identities through the tools provided by the domain-level identity management system.

3. Confirm that the application roles shown in the policy store are the ones that you want an administrator to eventually map to domain-level groups.

4. Decide whether or not you what to define a security constraint to protect ADF Faces resource files.

   Resource files including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the application. These files are not secured by ADF Security, but you can secure their Java EE access paths if you require all users to be authenticated before they can access the application.

5. Migrate the finalized policy store and credentials store to the target server.

   Application policies and credentials can be automatically migrated to the domain policy store when the application is deployed to a server in the Oracle WebLogic environment. Support to automatically migrate these stores is controlled by the target server's configuration. If Oracle Enterprise Manager is used to perform the deployment outside of JDeveloper, then the migration configuration settings can be specified in that tool. For information about migrating the `jazn-data.xml` security policies and the `cwallet.sso` credentials, see the Configuring the OPSS Security Store chapter in *Securing Applications with Oracle Platform Security Services*.

Enabling ADF Security

The Configure ADF Security wizard allows you to enable authentication and authorization separately.

To simplify the configuration process which allows ADF Security to integrate with OPSS, JDeveloper provides the Configure ADF Security wizard. The wizard is the starting point for securing the Fusion web application using ADF Security. The wizard is an application-level tool that, once run, will enable ADF Security for all user interface projects that your application contains.

> **Note:**
>
> Because the Configure ADF Security wizard enables ADF Security for all user interface projects in the application, after you run it, users will be required to have authorization rights to view any web page contained by a bounded task flow and all web pages associated with an ADF page definition. Therefore, after you run the wizard, the application is essentially locked down until you define security policies to grant view rights to the user. For an overview of the process, see ADF Security Process Overview.

How to Enable ADF Security

The Configure ADF Security wizard allows you to choose to enable authentication and authorization separately. You may choose to:

- Enable *only* user authentication.

  Although ADF Security leverages Java EE container-managed security for authentication, enabling only authentication means that you want to use the ADF authentication servlet to support user login and logout, but that you intend to define container-managed security constraints to secure web pages.

- Enable user authentication and also enable authorization.

  Enabling authorization means you intend to control access to the Fusion web application by creating security policies on ADF resources.

The ADF Security framework supports these two choices to give you the option to implement Java EE Security and still be able to support login and logout using the ADF authentication servlet. The benefit of enabling the ADF authentication servlet is that the servlet will automatically prompt the user to log in the first time the application is accessed. The ADF authentication servlet also allows you to redirect the user to a defined start page after successful authentication and does not require passing the target page on the request URL. You will also be able to manage the page redirect when the user logs out of the application. These redirect features provided by ADF Security are not available using only container-managed security.

Note that ADF Security does not perform authentication, but relies on the Java EE container to invoke the configured login mechanism, as described in What Happens at Runtime: How ADF Security Handles Authentication.

> **Best Practice:**
>
> Because Java EE security constraints cannot interact with the task flow to secure the current page of a task flow, container-managed security is not a useful solution when your application is designed with **ADF task flows**. When you use ADF task flows, select the **ADF Authentication and Authorization** option in the Configure ADF Security wizard. This option will allow you to define security policies to protect the task flows of your application.

Because ADF Security delegates authentication to the web container, when you run the Configure ADF Security wizard, the wizard prompts you to configure the authentication method that you want the web container to use. The most commonly used types of authentication are HTTP Basic Authentication and Form-Based Authentication. Basic authentication uses the browser login dialog for the user to enter a user name and password. Note that with basic authentication, the browser caches credentials from the user, thus preventing logout. Basic authentication is useful when you want to test the application without requiring a custom login page. Form authentication allows the application developer to specify a custom login UI. If you choose Form-based authentication, you can also use the wizard to generate a simple login page. The default login page is useful for testing your application with Integrated WebLogic Server.

> **Note:**
>
> Because the generated login page is a simple JSP or HTML file, you will not be able to modify it with ADF Faces components. For information about replacing the default login page with a custom login page that uses ADF Faces components, see Creating a Login Page.

Before you begin:

It may be helpful to have an understanding of the Configure ADF Security wizard. For more information, see Enabling ADF Security.

To enable ADF Security for the application:

1. In the main menu, choose **Application** and then **Secure > Configure ADF Security**.
2. In the ADF Security page, leave the default **ADF Authentication and Authorization** option selected. Click **Next**.

   When you run the wizard with the default option selected, your application will enforce authorization for ADF security-aware resources. Enforcing authorization for ADF resources means that you intend to define security policies for these resources to make the web pages of your application accessible. Until you do so, all pages that rely on the ADF bounded task flows and ADF page definitions will remain protected.

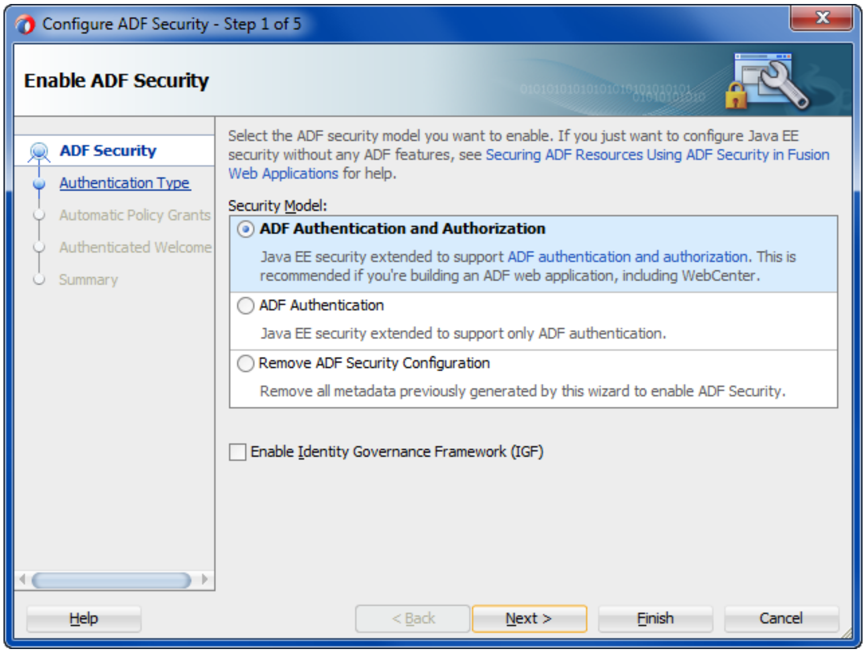
   The other two wizard options to configure ADF Security should not be used when you want to enable ADF Security. Those options allow you to temporarily disable

ADF Security and run your application without security protection, as described in Disabling ADF Security.

Specifically, the first page of the wizard lets you choose among three options, with the default option set to enable **ADF Authentication and Authorization**, as shown in Figure 47-2:

- **ADF Authentication and Authorization** (default) enables the ADF authentication servlet so that you can redirect to a configured web page when the user logs in and logs out. This option also enables ADF authorization to enforce authorization checking against security policies that you define for ADF resources. This option assumes that you will define application roles and assign explicit grants to those roles to manage access to ADF security-aware resources.
- **ADF Authentication** enables the ADF authentication servlet to require the user to log in the first time a page in the application is accessed and supports page redirect by mapping the Java EE application root "/" to the a Java EE security constraint that will trigger user authentication. Since the wizard disables ADF authorization, authorization checking is not performed, whether or not security policies exist for ADF resources. Once the user is logged in, all web pages containing ADF resources will be available to the user.
- **Remove ADF Security Configuration** disables the ADF authentication servlet and prevents ADF Security from checking policy grants without altering the existing policy store. In this case, you may require users to log in, become authenticated, and test access rights against URL security constraints using standard Java EE security. Note that running the wizard with this option disables fine-grained security against ADF resources.

Figure 47-2 Using the Configure ADF Security Wizard to Enable Security-Aware Resources



Configure ADF Security - Step 1 of 5

Enable ADF Security

Select the ADF security model you want to enable. If you just want to configure Java EE security without any ADF features, see Securing ADF Resources Using ADF Security in Fusion Web Applications for help.

Security Model:

● ADF Authentication and Authorization

Java EE security extended to support ADF authentication and authorization. This is recommended if you're building an ADF web application, including WebCenter.

○ ADF Authentication

Java EE security extended to support only ADF authentication.

○ Remove ADF Security Configuration

Remove all metadata previously generated by this wizard to enable ADF Security.

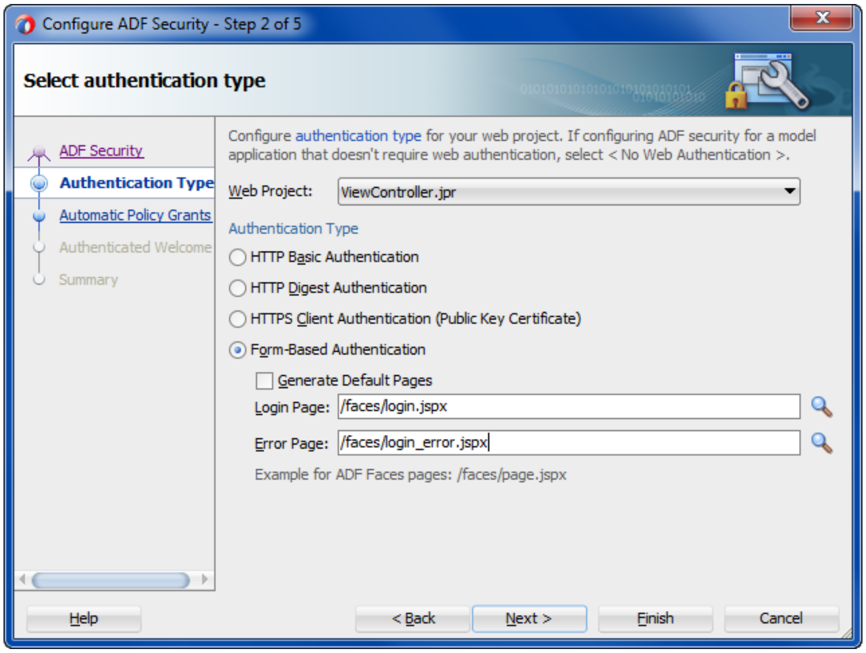
□ Enable Identity Governance Framework (IGF)

3. In the Authentication Type page, select the authentication type that you want your application to use when the user submits their login information. Click **Next**.

A known issue prevents the ADF authentication servlet from working with Basic type authentication and allows a user to access resources after logout. Use form-based authentication instead of basic authentication. For details about this issue, see What You May Need to Know About Fusion Web Application Logout and Browser Caching.

If you select **Form-based Authentication**, you can also select **Generate Default Pages** to allow the wizard to generate a default login and error page. By default the wizard generates the login and error pages at the top level of the user interface project, as shown in Figure 47-3. If you want to change the location, specify the full path relative to the user interface project.

Figure 47-3 Using the Configure ADF Security Wizard to Generate a Simple Login Page



Configure ADF Security - Step 2 of 5

Select authentication type

Configure authentication type for your web project. If configuring ADF security for a model application that doesn't require web authentication, select < No Web Authentication >.

Web Project: ViewController.jpr

Authentication Type

○ HTTP Basic Authentication

○ HTTP Digest Authentication

○ HTTPS Client Authentication (Public Key Certificate)

● Form-Based Authentication

□ Generate Default Pages

Login Page: /faces/login.jspx

Error Page: /faces/login_error.jspx

Example for ADF Faces pages: /faces/page.jspx

4. In the Automatic Policy Grants page, leave the default **No Automatic Grants** option selected. Click **Next**.

   When you select **No Automatic Grants**, you must define explicit grants that are specific to your application. The `test-all` application role provides a convenient way to run and test application resources without the restricted access that ADF authorization enforces. However, it increases the risk that your application may leave some resources unprotected.

   Alternatively, you can use the wizard to grant to the `test-all` application role. When you enable grants to the `test-all` role, you can postpone defining explicit grants to ADF resources until you are ready to refine the access policies of your application. If you decide to enable automatic grants, do not let application development progress too far and the content of the application become well-established before you replace grants to the `test-all` role with the your application's explicit grants. The explicit grant establishes the necessary privilege (for example, `view` on a page) to allow users to access these resources. For more information about the `test-all` role, see How to Use the Built-In test-all Application Role.

5. In the Authenticated Welcome page, select **Redirect Upon Successful Authentication** to direct the user to a specific web page after they log or to define a default destination page after the session is lost due to session timeout. Click **Next**.

   If you leave the **Redirect Upon Successful Authentication** option unselected and your application does not explicitly handle login redirect through the `AuthenticationService` API, then by default the user will be returned to the page from which the login was initiated. However, when the user presses Ctrl-N or Ctrl-T to open a new browser window or tab, they will receive a 403 or 404 error unless a welcome page definition appears in the application's `web.xml` file. You can use this option to specify a welcome page so the definition appears in the application's `web.xml` file.

   Note that if the web page you specify contains ADF Faces components, you must define the page in the context of `/faces/`. For example, the path for `adffaces_welcome.jspx` would appear in the **Welcome Page** field as `/faces/adffaces_welcome.jspx`.

   For details about specifying other redirect options, see How to Redirect a User After Authentication.

6. In the Summary page, review your selections and click **Finish**.

What Happens When You Enable ADF Security

After you run the Configure ADF Security wizard with the default **ADF Authentication and Authorization** option selected in the ADF Security page, you will have:

- Enabled ADF authentication to prompt the user to log in and to allow page redirects
- Enabled ADF authorization checking so that only authorized users will have access to ADF resources

The wizard updates all security-related configuration files and ensures that ADF resources are secure by default. Table 47-2 shows which files the Configure ADF Security wizard updates.

Table 47-2 Files Updated for ADF Authentication and Authorization

File	File Location	Wizard Configuration
web.xml	/public_html/WEB-INF directory relative to the user interface project And, in JDeveloper, in the user interface project under the **Web Content-WEB-INF** node	• Defines the Oracle JpsFilter filter to set up the OPSS policy provider. The filter defines settings that indicate that your servlet has special privileges. It is important that the JpsFilter be the first filter definition in the web.xml file. • Adds the Oracle adfAuthentication servlet definition to require the user to log in the first time ADF resources are accessed. Note that ADF Security does not itself perform authentication, but leverages Java EE container-managed security for this purpose. • When you select the **ADF Authentication and Authorization** option in the wizard, the web.xml maps the adfAuthentication servlet to a security constraint that will trigger user authentication dynamically. • When you select the **ADF Authentication** option in the wizard, the web.xml maps the Java EE application root "/" to the allPages security constraint that will trigger user authentication dynamically. • Sets the authentication method for the Login configuration to handle user login. • When you select the **Redirect Upon Successful Authentication** option in the wizard, the web.xml defines the success_url servlet initialization attribute (init-param element), which whitelists the redirect destination to use upon successful login and provides 1. a single, fixed fallback for the application that does not handle login redirects using the AuthenticationService API or 2. a default destination page after the session is lost due to session timeout. • Defines required security roles, including the role valid-users, which is used to trigger the security constraint that enables dynamic authentication.
adf-config.xml	/.adf/META-INF directory relative to the web application workspace And, in JDeveloper, in the Application Resources panel of the Applications window under the **Descriptors-ADF META-INF** node	• Defines the JAAS security context. • Enables the use of ADF Security security policies for authorization checking (the authorizationEnforce parameter in the <JaasSecurityContext> element is set to true). • Enables triggering a login dialog in Java SE applications, (the authenticationRequire parameter in the <JaasSecurityContext> element is set to true). This parameter is not used in Fusion web applications. Fusion web applications rely on settings in the web.xml file to enable authentication.

Table 47-2 (Cont.) Files Updated for ADF Authentication and Authorization

File	File Location	Wizard Configuration
jps-config.xml	/src/META-INF directory relative to the web application workspace And, in JDeveloper, in the Application Resources panel of the Applications window under the **Descriptors-META-INF** node	• Enables OPSS security services specifically within the JDeveloper design time. When you test data model projects using the Oracle ADF Model Tester or run unit tests for security validation this workspace-specific file must be present. Note that this file is not used in the deployed Fusion web application. For example, when you deploy to Integrated WebLogic Server, OPSS security services are enabled by the DefaultDomain/config/fmwconfig/jps-config.xml file.
weblogic.xml	/public_html/WEB-INF directory relative to the web application workspace And, in JDeveloper, in the user interface project under the **Web Content-WEB-INF** node	• Maps the valid-users security role to an implicit group called users. Oracle WebLogic Server configures all authenticated users to be members of the users group.
jazn-data.xml	./src/META-INF directory relative to the web application workspace And, in JDeveloper, in the Application Resources panel of the Applications window under the **Descriptors-META-INF** node	• Sets the default jazn.com realm name for the XML identity store that you configure for use with Integrated WebLogic Server. You will use this file to store user identities, user groups, and security policies for the ADF Security-enabled application. This file is used during development and enables support for security when running the Oracle ADF Model Tester. However, when you deploy your application, for example, to Integrated WebLogic Server, security policies will be migrated into the configured policy store in the DefaultDomain/config/fmwconfig/system-jazn-data.xml file.

Because authentication is delegated to the web container, the wizard only updates the web.xml file to enable the ADF authentication servlet to trigger authentication dynamically. It defines servlet mapping for the ADF authentication servlet and adds two Java EE security constraints, allPages and adfAuthentication, to the web.xml file, as shown in the following example.

```
<servlet>
   <servlet-name>adfAuthentication</servlet-name>
   <servlet-class>
        oracle.adf.share.security.authentication.AuthenticationServlet
   </servlet-class>
   <init-param>
      <param-name>success_url</param-name>
      <param-value>faces/welcome</param-value>
   </init-param>
   <init-param>
      <param-name>end_url</param-name>
      <param-value>faces/welcome</param-value>
   </init-param>
   <init-param>
```

```
      <param-name>disable_url_param</param-name>
      <param-value>true</param-value>
   </init-param>
   <load-on-startup>1</load-on-startup>
</servlet>
...
<servlet-mapping>
   <servlet-name>adfAuthentication</servlet-name>
   <url-pattern>/adfAuthentication</url-pattern>
</servlet-mapping>
...
<security-constraint>
   <web-resource-collection>
        <web-resource-name>allPages</web-resource-name>
        <url-pattern>/</url-pattern>
   </web-resource-collection>
   <auth-constraint>
        <role-name>valid-users</role-name>
   </auth-constraint>
</security-constraint>
<security-constraint>
   <web-resource-collection>
        <web-resource-name>adfAuthentication</web-resource-name>
        <url-pattern>/adfAuthentication</url-pattern>
   </web-resource-collection>
   <auth-constraint>
        <role-name>valid-users</role-name>
   </auth-constraint>
</security-constraint>
```

The servlet initialization attributes defined by the `init-param` elements shown in the example control redirects for successful login and logout (respectively, `success_url` and `end_url`). These `init-param` elements provide a default or fallback destination when the application does not specify the redirect target during login and logout. In this sense, they define a fixed destination whitelist on the ADF authentication servlet that prevents unvalidated redirects from occurring. The servlet initialization attribute `disable_url_param` may be optionally added to the `web.xml` servlet `init-param` list to block passing `success_url` and `end_url` on the browser URL and provides a level of protection against malicious redirect attacks that might exploit these parameters on the browser URL. This redirect protection works especially well when the application uses the `AuthenticationService` API to support login and logout redirects, which stores the redirect URL parameters as session attributes that may not be changed by the user.

Note that the protection provided by the servlet `init-param` element `disable_url_param` must be opted into and is not enabled by default. Existing applications that rely on the legacy approach of passing redirect parameters on the browser URL Request should not enable the `disable_url_param` attribute. For new applications, it is recommended that you opt in as the example shows (`disable_url_param` set to `true`), to block the usage of `success_url` and `end_url` on the browser URL.

Because the `allPages` constraint maps to the '/' URL, it protects the Java EE application root. This mapping enables the Oracle WebLogic Server web container to trigger user authentication dynamically even before ADF Security is accessed. When the user first accesses the application, it forces the container to challenge the user for the user name and password. Then when the user accesses a page protected by ADF Security, there is no longer a need to authenticate the user and no need to redirect to the ADF authentication servlet.

> **Note:**
>
> You can remove the allPages constraint from the web.xml file if you prefer to provide a login link or button to explicitly trigger login. You could also have a link or button to perform logout. For details about creating a custom component to perform login and logout, see Creating a Login Page. If you keep the constraint to allow dynamic authentication, because it covers everything under the Java EE application root, your login page may not display supporting resources at runtime, as described in How to Ensure That the Custom Login Page's Resources Are Accessible for Explicit Authentication.

Because every user of the application is required to be able to log in, the security constraint defined against the adfAuthentication resource allows all users to access this web resource. As such, the security role associated with the constraint must encompass all users. To simplify this task, the Java EE valid-users role is defined. The weblogic.xml file maps this role to an implicit users group defined by Oracle WebLogic Server. This mapping ensures that every user will have this role because Oracle WebLogic Server configures all properly authenticated users as members of the users group, as described in What You May Need to Know About the valid-users Role.

> **Note:**
>
> The adfAuthentication resource constraint provides the definition of a single standard URL pattern against the ADF authentication servlet. Your web pages can provide an explicit login or logout link that references the ADF authentication servlet URL pattern. This explicit login scenario is an alternative to generating a simple login form in the Configure ADF Security wizard and relying on ADF authentication to prompt the user to log in. For details about handling the explicit login scenario, see Creating a Login Page.

To enable authorization, the wizard updates the adf-config.xml file and sets the authorizationEnforce parameter in the <JaasSecurityContext> element to true, as shown in the following example.

```
<JaasSecurityContext

initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
  jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
                             authorizationEnforce="true"
                             authenticationRequire="true"/>
```

When authorization is enabled, the ADF Security Context gets the user principal from the HttpServletRequest once the user is authenticated by the container. The user submits a user name and password and that data is compared against the data in the identity store where user information is stored. If a match is found, the originator of the request (the user) is authenticated. The user principal is then stored in the ADF Security Context, where it can be accessed to obtain other security-related information (such as the group the user belongs to) in order to determine authorization rights. For details about accessing the ADF Security Context, see Getting Information from the ADF Security Context.

What Happens When You Generate a Default Form-Based Login Page

The wizard-generated login and error pages are simple HTML pages that are added to the top-level folder of your user interface project. The generated login page defines an HTML form that will submit the user's login request with the standard `j_security_check` action. This action together with form-based authentication, which is the default option for container authentication provided by the wizard, allows the web container to authenticate users from many different web application resources.

The wizard updates the `web.xml` file to specify form-based authentication and identify the location of the pages, as shown in the following example.

```
<login-config>
   <auth-method>FORM</auth-method>
   <form-login-config>
       <form-login-page>/login.html</form-login-page>
       <form-error-page>/error.html</form-error-page>
   </form-login-config>
</login-config>
```

Your application will display the wizard-generated login page from a server-side redirect in response to the unauthenticated user attempting to access a protected resource. This is known as implicit authentication because the redirect to the login page only occurs when user navigates to a page that contains an ADF security-aware resource.

Note that web applications also have a notion of public pages and allow for explicit, as well as implicit authentication. This means that users should be able to log in to the application by clicking a login link before they navigate to secured content. For information about creating and using a login link, see Creating a Login Page.

What You May Need to Know About the Configure ADF Security Wizard

The first time you run the Configure ADF Security wizard and enable authentication and authorization, you secure ADF resources at the level of the application. Additionally, you select specific project-level settings for the user interface project, including the authentication type and the authentication welcome. The wizard adds these web application settings to the `web.xml` file in the project you select. When your application contains multiple user interface projects and `web.xml` files, you can return to the wizard and configure these settings in the `web.xml` file for another user interface project that you select.

What You May Need to Know About ADF Authentication

Fusion web applications that use Java EE container-managed authentication for login and ADF authentication for logout integrate with Oracle Single Sign-On (Oracle SSO) with no special requirements. The ADF authentication servlet handles the details of logout and invalidates the user session. However, when the application uses login and logout methods provided by Servlet 3.0, Oracle SSO is not supported. Additionally, Servlet 3.0 login and logout is only compatible with application servers that fully support Java EE 6 or later.

On the first access to a page that relies on an ADF security-aware resource, when the user is not yet logged in, the application server creates a session and the `JpsFilter`, configured in the `web.xml` when you run the Configure ADF Security wizard, creates a subject containing the `anonymous` user principal and the `anonymous-role` role principal. With this role principal, the anonymous user session allows the unauthenticated user to access public web pages that are not associated with any ADF security-aware resources (including ADF bounded task flows or page definitions). Upon login, WebLogic Server does not invalidate the existing anonymous user session, and for security reasons, only creates a new session ID for the authenticated user session.

The authenticated user session behavior enforced by WebLogic Server preserves the user's ability to view public pages that had previously been visited by cloning the anonymous user session data to the authenticated user session with the new ID. While this behavior differs from the way HTTP sessions are created on WebLogic Server, there is no security risk involved in carrying anonymous user session data into the authentication user session.

> **Note:**
>
> In the Fusion web application, the session bean is initialized only when the session is established. If the session is created as `anonymous`, the session bean will not get re-initialized when the user logs in even though WebLogic Server creates a new session. This is the case when going from a public page to a secured page. However, when the user enters the application on a secured page, the session bean does get initialized upon user login.
> For this reason, Fusion web applications should not rely on session-scoped managed beans to get the current user data from the authenticated session. The correct way for the application to obtain the current user is from the ADF Security Context. For details about the API to work with the ADF Security Context, see Getting Information from the ADF Security Context.

In the case of pages associated with ADF security-aware resources, you must explicitly grant `view` permission to `anonymous-role` to make the page accessible to the anonymous user. For details about granting privileges to the anonymous user, see How to Make an ADF Resource Public.

What You May Need to Know About the Built-In test-all Role

The Configure ADF Security wizard lets you enable automatic grants to the built-in `test-all` application role for the purpose of granting view permission to all ADF security-aware resources in your application. Without a permission grant, either an automatic view grant or an explicit grant that you define, ADF Security authorization checking enforcement would prevent you from being able to run the application and access its resources. You can run the wizard with the `test-all` application role feature enabled and then gradually replace automatic view grants with explicit grants. Be aware that you must not deploy the application with grants to the `test-all` application role in place, since this feature makes all ADF resources public. If you choose to enable the built-in `test-all` application role in the wizard, see How to Remove the test-all Role from the Application Policy Store, before deploying your application.

What You May Need to Know About the valid-users Role

The valid-users role is a Java EE security role defined by ADF Security to ensure that all users will access the adfAuthentication servlet web resource defined in the web.xml file. The Configure ADF Security wizard updates the weblogic.xml file to map this ADF Security role to the users principal, as shown in the following example. This mapping ensures that every user will have this role, because Oracle WebLogic Server configures all properly authenticated users as members of the users group.

```
<security-role-assignment>
   <role-name>valid-users</role-name>
   <principal-name>users</principal-name>
</security-role-assignment>
```

At runtime, the users principal is added automatically to a successfully authenticated subject by OPSS. From a security perspective, the valid-users role supports ADF authentication only in the case where you need to control access to web resources using security constraints alone. The end result of this mapping relies entirely on Java EE security and does not involve JAAS Permissions.

Creating Application Roles

To grant permissions to ADF objects, you need to create application roles that are mapped to enterprise groups. When you define roles, you have two options. You can define them either as application roles or as enterprise roles. Application roles are local to an application and it can contain only users and roles defined in the application, whereas enterprise roles are available to all applications deployed in the domain.

You create application roles to represent the policy requirements of the application and to define groups of users with the same view permission rights. The application roles that you create in the application policy store are specific to your application. For example, in the context of the work flow, there may be application roles such as Application Customer Role and Application Employee Role, defined in the SummitADF_TaskFlows workspace of the Summit ADF sample applications.

At runtime, the access rights are conferred on the user through the application role for which the user is defined as a member. Thus, before you can define security policies, the policy store must contain the application roles that you intend to issue grants to. This can be an application role that you define (such as Application Customer Role) or it can be one of the two built-in application roles defined by OPSS: authenticated-role or anonymous-role. JDeveloper provides the built-in application roles to let you make ADF resources public, as described in How to Make an ADF Resource Public.

After you create the application role, you will:

- Grant permissions to the application roles, as described in Defining ADF Security Policies.
- Associate test users with each application role, as described in Creating Test Users.

Best Practice:

The ADF Security framework enforces a role-based access control mechanism with permissions granted either to application roles or to individual users. Although you may only need to test security and therefore might not need to create groups of users, you should still create application roles (with at least one user member). Later when you define security polices on the ADF resources, the overview editor for the application policy store will allow you to select an application role for the grant.

How to Create Application Roles

JDeveloper lets you add application roles to the policy store of the `jazn-data.xml` file, which appears in the **Descriptors/META-INF** node of the Application Resources panel.

Note:

When you create application roles, be sure to add the new application roles to the policy store, not the identity store. Roles that you add to the identity store define enterprise security roles and provide a way to conveniently group users in the identity store. For more details about enterprise roles, see What You May Need to Know About Enterprise Roles and Application Roles.

To create application roles in the policy store of the `jazn-data.xml` file, you use the Application Roles page of the overview editor for the `jazn-data.xml` file. This editor lets you view the relationship between identity store members and the application roles you create.

Before you begin:

It may be helpful to have an understanding of application roles. For more information, see Creating Application Roles.

To create application roles:

1. In the main menu, choose **Application** and then **Secure > Application Roles**.
2. In the Application Roles page of the `jazn-data.xml` overview editor, select the policy store for your application from the **Security Policy** dropdown list.

   The policy store that JDeveloper creates in the `jazn-data.xml` file is automatically based on the name of your application.
3. In the **Roles** list, click the **New** icon.
4. In the **Name** field, enter the name of the role and click any other field to add the application role to the policy store.
5. If you have already set up test users in the identity store, you can map users and roles, as described in How to Associate Test Users with Application Roles.

What Happens When You Create Application Roles

When you add an application role to the policy store, JDeveloper updates the `jazn-data.xml` file located in the `src/META-INF` directory relative to the application workspace. Application roles are defined in `<app-role>` elements under `<policy-store>`, as shown in the following example. Because the policy store `<application>` element names the application, at runtime all application roles that you create will be visible to your application only. Other web applications may define a policy store with their own set of application roles.

```
<policy-store>
     <applications>
         <application>
            <name>SummitADFTaskFlows</name>
            <app-roles>
               <app-role>
                  <name>Application Employee Role</name>
                  <display-name>Application Employee Role</display-name>
                  <class>oracle.security.jps.service.policystore.
                                                      ApplicationRole</class>
               </app-role>
               ...
            </app-roles>
            <jazn-policy>
              ...
            </jazn-policy>
         </application>
    </applictions>
</policy-store>
```

What You May Need to Know About Enterprise Roles and Application Roles

An **enterprise role** is a role that is maintained in the domain identity store (as opposed to an application identity store). Enterprise roles are available to every application deployed in the domain and are therefore also called external roles.

An **application role** is a role used by a Fusion web application. It is specific to the application, defined by the application policy, and not necessarily known to the Java EE container. Application roles are scoped in the sense that they can contain only users and roles defined in the application. Application roles must be mapped to enterprise roles.

You use the overview editor for the `jazn-data.xml` file to create enterprise roles to group users that you add to the identity store. You can use this mechanism to assign entire groups of users to application roles that you have defined for the purpose of conferring access rights defined by ADF security policies, as described in How to Associate Test Users with Application Roles.

However, Integrated WebLogic Server does not require you to create enterprise roles to run the application within JDeveloper. For the purpose of testing the application, it may be sufficient to create a few test users and assign them directly to application roles. When you run the application in JDeveloper, the users and any enterprise roles you defined will be created in the default security provider (which is embedded LDAP for Integrated WebLogic Server).

Typically, when you deploy the application for staging, you will migrate only the policy store to the target server. You can configure JDeveloper deployment options so that the identity store, including test users and enterprise roles, is not migrated, as described in How to Configure, Deploy, and Run a Secure Application in JDeveloper.

After you deploy the secure application, Oracle Fusion Middleware will merge your application's policy store with the policies of the domain-level policy store. To complete this task, the administrator for the Oracle WebLogic Server will eventually map the application roles of your policy store to the existing domain-level enterprise roles. This application role mapping at the domain level allows enterprise users to access application resources according to the ADF security policies you have defined. The domain-level application role mapping by the administrator also allows you to develop the ADF security policies of your application without requiring any knowledge of the identity store in the production environment.

Defining ADF Security Policies

The ADF security implementation consists of two main concepts; authentication and authorization. Authentication ensures the identity of the user based on the identity store and authorization ensures that the user only has access to resources they have been granted access to in the policy store.

Authorization relies on a policy store that is accessed at runtime and that contains permissions that grant privileges to execute predefined actions, like `view`, on a specified object. Initially, after you run the Configure ADF Security wizard, the policy store defines no grants. And, because the default wizard option **ADF Authentication and Authorization** enables authorization checking, the web pages of your application that rely on the ADF security-aware resources will be inaccessible to users. You must use JDeveloper to define explicit grants for the resources that you want to permit users to access.

> **Best Practice:**
>
> When you run the Configure ADF Security wizard with the default option **ADF Authentication and Authorization** selected, you will lock down the web pages of your application. This affords the most protection to the Fusion web application possible since you will define explicit grants to allow users to access only the pages you intend. For a discussion of this guideline and others, see Best Practices for Working with ADF Security.

Before you can define security policies, the policy store for your application must contain the application roles that you intend to issue grants to. This can be an application role that you define (such as `Application Customer Role`) or it can be one of the two built-in application roles defined by OPSS: `authenticated-role` or `anonymous-role`. You use application roles to classify users, so that each member of the same role possesses the same access rights. As such, the security policy names the application role as the principal of the grant, rather than specific users. For details about defining application roles, see Creating Application Roles.

For the user interface project, you use the overview editor for security policies to secure ADF resources, including ADF task flows and ADF page definitions. You open the editor on the `jazn-data.xml` file by double-clicking the `jazn-data.xml` file (located in the Application Resources panel) or by choosing **Secure > Resource Grants** from the **Application** menu in the main menu.

Note that when you open the `jazn-data.xml` file, the overview editor provides additional editor pages that you use to create test users, enterprise roles, and application roles.

For the data model project, you do not secure entity objects or their attributes using the overview editor for security policies. Instead, you set metadata directly on these objects to manage whether or not the databound UI component displays the data. For details about granting permissions for row-level security, see How to Define Policies for Data.

How to Make an ADF Resource Public

It is a common requirement that some web pages be available to all users, regardless of their specific access privileges. For example, the home page should be seen by all visitors to the site, while a corporate site should be available only to those who have identified themselves through authentication.

In both cases, the page may be considered public, because the ability to view the page is not defined by the users' specific permissions. Rather, the difference is whether the user is anonymous or a known identity.

In the ADF security model, you differentiate between the absence of security and public access to content by granting access privileges to the `anonymous-role` principal. The anonymous role encompasses both known and anonymous users, thus permission granted to `anonymous-role` allows access to a resource by unauthenticated users, for example, guest users. To provide access to authenticated users only, the policy must be defined for the `authenticated-role` principal.

> **Note:**
>
> For details about creating a public home page which contains links to other pages in the application, see How to Create a Public Welcome Page.

Before you begin:

It may be helpful to have an understanding of ADF security policies. For more information, see Defining ADF Security Policies.

You will need to complete these tasks:

1. Create bounded task flows, as described in Creating a Task Flow.
2. Create web pages with an ADF page definition file, as described in Working with Page Definition Files.
3. Run the Configure ADF Security wizard, as described in Enabling ADF Security.
4. Create application roles, as described in Creating Application Roles.

To grant public access to ADF security-aware resources:

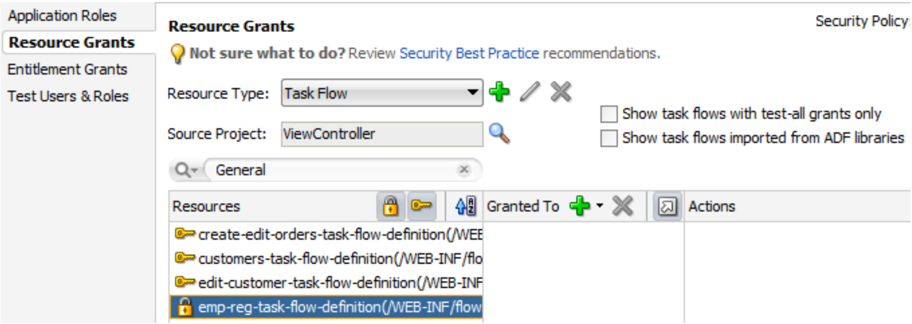
1. In the main menu, choose **Application** and then **Secure > Resource Grants**.

2. In the Resource Grants page of the overview editor for security policies, select one of the following resources from the **Resource Type** dropdown list:
   - **Task Flow** when you want to make a bounded task flow public. The application displays the web pages under the permission you define for the task flow itself. Thus, all constituent web pages of the bounded task flow will become public.
   - **Web Page** when you want to make individual web pages public. Typically, these pages are defined by an unbounded task flow and are top-level pages in the application, such as a home page.
3. In the **Resources** column, select the ADF resource for which you want to grant access rights.

   The resource you select should display the lock icon in the first column next to the resource name. The lock icon indicates that the resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant. For example, in Figure 47-4, the ADF resource `customer-registration-task-flow` (a bounded task flow) shows the lock icon since no grant has been made.

   > **Tip:**
   >
   > Click the key toggle icon in the header for the overview editor's first column to hide or show resources that already have grants and display only the resources without grants. The key icon indicates that the resource has a grant that will make the resource accessible to users with sufficient access rights.

Figure 47-4 Selecting an ADF Security-Aware Resource in the Overview Editor



Resource Type: Task Flow

Source Project: ViewController

□ Show task flows with test-all grants only

□ Show task flows imported from ADF libraries

General

create-edit-orders-task-flow-definition(/WEE
customers-task-flow-definition(/WEB-INF/flo
edit-customer-task-flow-definition(/WEB-INF
emp-reg-task-flow-definition(/WEB-INF/flow

4. In the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.
5. In the Select Application Roles dialog, select one of these built-in application roles:
   - **anonymous-role** means the resource will be accessible to anyone who visits the site. A grant to this role is necessary if you want to make a web page associated with an ADF security-aware resource accessible before a user logs in. For example, you would grant to `anonymous-role` for a task flow that manages customer registration.

- **authenticated-role** means the resource will be accessible only to authenticated users (ones who visit the site and log in). For example, you would grant to `authenticated-role` for an employee registration task flow.

6. In the Select Application Roles dialog, click **OK**.
7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **view** action selected.

   By default, the overview editor shows **view** selected, as shown in Figure 47-5. The view action is the only action currently supported for Fusion web applications.

What Happens When You Make an ADF Resource Public

When you define a security policy, the overview editor for security policies updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The overview editor writes the policy information to the `<policy-store>` section of the file. The security policy, or grant, contains both a grantee and one or more permissions. The grantee is the application role that the policy is being defined for—in this case, the anonymous role. Each permission defines the resource being secured and the action that can be performed against that resource.

The following example shows a security policy in the `jazn-data.xml` file that makes a customer registration task flow public. The grant to `anonymous-role` contains a single view permission for a bounded task flow, `customer-registration-task-flow`. With this grant, all users will be able to enter the customer registration task flow and complete the customer registration process. Additional grants to the anonymous role may be made and will appear in the `<permissions>` section of the anonymous role grant.

```
<policy-store>
   ...
   <jazn-policy>
      <grant>
         <grantee>
            <principals>
               <principal>
                  <class>oracle.security.jps.internal.core.
                                      principals.JpsAnonymousRoleImpl</class>
                  <name>anonymous-role</name>
               </principal>
            </principals>
         </grantee>
         <permissions>
            <permission>
                  <class>oracle.adf.controller.security.TaskFlowPermission</
class>
                  <name>/WEB-INF/customer-registration-task-flow.xml#
                                         customer-registration-task-flow</name>
                  <actions>view</actions>
            </permission>
            ...
         </permissions>
      ...
      </grant>
      ...
   </jazn-policy>
</policy-store>
```

What Happens at Runtime: How the Built-in Roles Are Used

The `anonymous-role` and `authenticated-role` names are special roles defined by Oracle Platform Security Services (OPSS).

When you run the Configure ADF Security wizard, the wizard configures the `JpsFilter` definition in the `web.xml` file to enable support for the anonymous role. The enabled anonymous role allows ADF Security to support browsing of the site by anonymous users—those users who have not yet logged in. In contrast, the authenticated role is not declared and is always recognized by default. ADF Security supports both of these roles.

When an end user first accesses an ADF security-aware resource, the system creates a subject and populates it with the anonymous role principal. As long as the ADF security-aware resource being accessed has the view grant to anonymous role, the user is permitted access. If the anonymous role is not a grantee of the ADF resource, the user is prompted to log in. After logging in, the authenticated role is added to the subject. The wizard also adds the `JpsFilter` definition to the `web.xml` file, where `remove.anonymous.role` set to `false` ensures that the anonymous role principal is available even after the user logs in. With the authenticated role principal, the user may access resources that have an explicit grant to the authenticated role.

How to Define Policies for ADF Bounded Task Flows

You define the access policy for an ADF bounded task flow by creating permission grants in the Resource Grants page of the overview editor for security policies. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines a permission target (in this case, the bounded task flow definition name) for which you have issued grants to authorize the members of a specific application role.

Best Practice:

Do not create permission grants for the individual web pages of a bounded task flow. When the user accesses the bounded task flow, security for all pages will be managed by the permissions you grant to the task flow. And, because the contained web pages (with associated page definitions) will be inaccessible by default, ADF Security prevents users from directly accessing the pages of the task flow. This supports a well-defined security model for task flows that enforces a single entry point for all users. For further information about implementing security policies, see Best Practices for Working with ADF Security.

You can sort the task flows in the overview editor by clicking the toggle buttons in the **Task Flow** header, as described in Table 47-3.

Table 47-3 Resource Grant Toggle Buttons for Bounded Task Flows

Button	Toggle Action	Description
🔒	Shows/hides bounded task flows with no grants	Represents a bounded task flow with no permission grants defined. The web pages that the task flow calls will not be accessible to any user.
🔑	Shows/hides bounded task flows with grants	Represents a bounded task flow with one or more permission grants defined. The web pages that the task flow calls will be accessible to users who are members of the application role that received the grant.

The list of available actions displayed by the overview editor is defined by the task flow permission class (`oracle.adf.controller.security.TaskFlowPermission`). The permission class maps these actions to the operations supported by the task flow. Table 47-4 shows the actions displayed by JDeveloper for ADF bounded task flows.

Note that the `view` action is the only action currently supported for Fusion web applications. Do not select `customize`, `grant`, or `personalize` actions—they are reserved for future use in task flow security.

Table 47-4 Secured Actions of ADF Bounded Task Flows

Grantable Action	Effect on the User Interface
`view`	Controls who can read and execute a bounded task flow in a Fusion web application. This is the only operation that the task flow supports.
`customize`	Reserved for future use. This action is not checked at runtime.
`grant`	Reserved for future use. This action is not checked at runtime.
`personalize`	Reserved for future use. This action is not checked at runtime.

To define a grant for the task flow security policy, use the Resource Grants page of the overview editor for the `jazn-data.xml` file.

Before you begin:

It may be helpful to have an understanding of ADF security policies. See Defining ADF Security Policies.

You will need to complete these tasks:

1. Create bounded task flows, as described in Creating a Task Flow.

> **Best Practice:**
>
> If you are creating bounded task flows in separate UI projects of the same application, you will want to assign unique task flow definition names. This is necessary because a grant's task flow definition name is scoped in the `jazn-data.xml` policy store by path (for example, `/WEB-INF/`*`mytaskflow`*`-definition.xml#`*`mytaskflow`*`-definition`). Therefore creating bound task flows with unique definition names is the only way to impose project-level scoping of the grants.

2. Run the Configure ADF Security wizard, as described in Enabling ADF Security.
3. Create application roles, as described in Creating Application Roles.

To define a permission grant on an ADF bounded task flow:

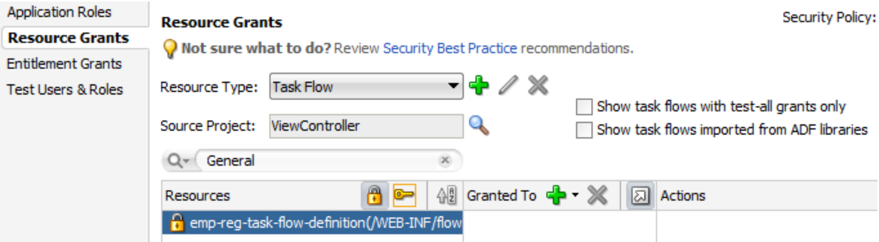
1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select **Task Flow** from the **Resource Type** dropdown list.

   The overview editor displays all the task flows that your application defines. Task flows are defined by task flow definition files (`.xml`) that appear in the Web Content/Page Flows node of the user interface project.
3. In the **Resources** column, select the task flow for which you want to grant access rights.

   The first time you make a grant to a bounded task flow, the first column should display the **Resources without any grants** icon (represented by a "lock") next to the task flow name. The overview editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant.

   > **Tip:**
   >
   > Click the **Resources with grants** icon (represented by a "key") in the header for the **Resources** column to hide all task flows that already have grants. This will display only task flows without grants, as shown in Figure 47-6. Additionally, you can type a partial task flow name in the search field to display only the task flows with character-matching names.

Figure 47-6 Hiding Task Flows with Grants in the Overview Editor



Resource Type: Task Flow

Source Project: ViewController

□ Show task flows with test-all grants only

□ Show task flows imported from ADF libraries

4. In the **Granted to** column, click the **Add Grantee** icon and select **Add Application Role**.

5. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

   The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, `anonymous-role` and `authenticated-role`, as described in What Happens at Runtime: How the Built-in Roles Are Used.

   If you do not see application roles that are specific to your application, create the role, as described in Creating Application Roles.

6. In the Select Application Roles dialog, click **OK**.

7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **view** action selected.

   By default, the overview editor shows the **view** action selected, as shown in Figure 47-7. The view action is the only action currently supported for Fusion web applications. Do not select **customize**, **grant**, or **personalize** actions—they are reserved for future use and will not be checked by ADF Security at runtime.

   The `TaskFlowPermission` class defines task flow—specific actions that it maps to the task flow's operations, as described in Table 47-4.

□ personalize
☑ view

8. You can repeat these steps to make additional grants as desired.

   The same task flow definition can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in What Happens When You Define the Security Policy.

How to Define Policies for Web Pages That Reference a Page Definition

You define the access policy for an ADF page definition by creating permission grants in the Resource Grants page of the overview editor for security policies. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines a permission target (in this case, the page definition name) for which you have issued grants to authorize the members of a specific application role.

> **Best Practice:**
>
> Create permission grants for the individual web page only when the page is not a constituent of a bounded task flow. Page-level security is checked for pages that have an associated page definition binding file *only* if the page is directly accessed or if it is accessed in an *unbounded* task flow. For further information about implementing security policies, see Best Practices for Working with ADF Security.

You can sort the web page definition resources in the overview editor by clicking the toggle buttons in the **Resources** header, as described in Table 47-5.

Table 47-5 Resource Grant Toggle Buttons for Web Page Definitions

Button	Toggle Action	Description
🔒	Shows/hides top-level pages with no grants	Represents a page definition with no permission grants defined for a web page that is contained in an unbounded task flow. The web page will not be accessible to any user.
🔑	Shows/hides top-level pages with grants	Represents a page definition with one or more permission grants defined for a web page that is contained in an unbounded task flow. The web page will be accessible to users who are members of the application role that received the grant.
📄	Shows/hides pages included in a bounded task flow	Represents a page definition associated with a web page that also is contained in a bounded task flow. Do not grant to these web page definitions. Instead, define a security policy for the bounded task flow.

Table 47-5 (Cont.) Resource Grant Toggle Buttons for Web Page Definitions

Button	Toggle Action	Description
🔑	Shows/hides unsecurable pages (with no page definition)	Represents a web page with no page definition defined that is contained in an unbounded task flow. (Pages like this that are contained by a bounded task flow are secured by the bounded task flow's permission.) The web page will be accessible to all users since it is not secured by an associated ADF security-aware resource. Optionally, you can secure the page by adding an empty page definition file, as described in What You May Need to Know About Defining Policies for Pages with No ADF Bindings.

The list of available actions displayed by the overview editor is defined by the region permission class (`oracle.adf.share.security.authorization.RegionPermission`). The permission class maps these actions to the operations supported by the ADF page definition for the web page. Table 47-6 shows the actions displayed by JDeveloper for ADF page definitions.

Note that the `view` action is the only action currently supported for Fusion web applications.

Do not select `customize`, `grant`, or `personalize` actions—they are implemented for page definition security only in WebCenter Portal: Framework applications.

Table 47-6 Securable Actions of ADF Page Definitions

Grantable Action	Effect on the User Interface
`view`	Controls who can view the page. This is the only operation that the page definition supports. All other operations support Oracle WebCenter Portal: Framework.
`customize`	Controls who can make implicit changes (such as minimize/restore, delete, or move) to a WebCenter Portal customizable component (in a Panel Customizable or Show Detail Frame) contained in a page of a custom application (one enabled to use Oracle WebCenter Portal's Composer) or a WebCenter Portal application. For details, see Introduction to WebCenter Portal Assets in *Developing for Oracle WebCenter Portal*.
`grant`	Confers the rights specified by all WebCenter Portal-specific actions combined; it is equivalent to granting all other actions. It also controls who can make grants to other users and who can change security settings on the page using Oracle WebCenter Portal's Composer. For details, see Introduction to WebCenter Portal Assets in *Developing for Oracle WebCenter Portal*.
`personalize`	Controls who can make implicit changes (such as minimize/restore, delete, or move) to a WebCenter Portal customizable component (in a Panel Customizable or Show Detail Frame) contained in a page of a custom application (one enabled to use Oracle WebCenter Portal's Composer) or a WebCenter Portal application. For details, see Introduction to WebCenter Portal Assets in *Developing for Oracle WebCenter Portal*.

To define a grant for the page definition security policy, use the Resource Grants page of the overview editor for security policies.

Before you begin:

It may be helpful to have an understanding of ADF security policies. See Defining ADF Security Policies.

You will need to complete these tasks:

1. Create the top-level web pages with an ADF page definition file, as described in Working with Page Definition Files.

> **Best Practice:**
>
> If you are creating top-level web pages in separate UI projects of the same application, you will want to assign unique page file names. This is necessary because a grant's page definition name is scoped in the `jazn-data.xml` policy store by package (for example, `view.pageDefs.`*`mytoppage`*`PageDef`). Therefore creating top-level pages with unique file names is the only way to impose project-level scoping of the grants.

2. Run the Configure ADF Security wizard, as described in Enabling ADF Security.
3. Create application roles, as described in Creating Application Roles.

To define a permission grant on an ADF page definition:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select **Web Page** from the **Resource Type** dropdown list.

   The Resource Grants page of the overview editor displays all web pages, including those that have an associated ADF page definition. This includes any web page that uses ADF bindings or any web page for which you have created an empty page definition. Page definitions are defined by `PageDef.xml` files that appear in the Application Sources node of the user interface project.
3. In the **Resources** column, select the page definition for which you want to grant access rights.

   The first time you make a grant to a page definition, the first column should display the **Resource without any grants** icon (represented by the "lock" icon) next to the page definition name. The editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant. For example, the page definition `account_updateUserInfo` shown in Figure 47-8 displays the lock icon since no grant has been made. Other page definitions in Figure 47-8 show the **Page included in bounded task flow** icon because they are not top-level pages and thus are securable by the containing bounded task flow.

   Do not create grants for individual web page definitions that display the **Page included in bounded task flow** icon. Security policies for the associated web pages are secured by their bounded task flow. For example, in Figure 47-8, the page definition associated with the `account_addressDetails.jsff` region will be secured by the containing bounded task flow.

> **Tip:**
>
> You can type a partial page definition name in the search field to display only the page definitions with character-matching names. For example, a search on the word `general` would display only the page definitions that begin with the word `general`, as shown in Figure 47-8.

   The same page definition can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in What Happens When You Define the Security Policy.

How to Define Policies to Control User Access to ADF Methods

ADF methods that your application defines may be dropped into the user interface as command components. By default, users who have access to the page that displays the command component for the method will also have rights to execute the method. When you want to create additional security to restrict access to the method operation, you must create a resource grant and test the permission at the level of the user interface. ADF Security does not perform authorization checking for ADF methods; you must enable authorization checking in your application. Based on a resource permission you have granted to the user for the ADF method, the user interface will either enable or disable the command component.

To control user access to a method that your page displays as a command component, you complete these steps:

1. Create a resource grant for a custom resource type and resource.

2. Enforce the permission grant in the user interface.

Creating a Resource Grant to Control Access to ADF Methods

The resource type that you create will be set to the matcher class `oracle.security.jps.ResourcePermission`, which will allow you to grant permission to parts of the application that are not protected by ADF Security. For example, your page may display a button that lets users cancel a product shipment to customers. However, only members of a specific application role may be allowed to cancel a shipment. To enforce this rule, you can create a resource permission that may be checked declaratively in the user interface at runtime to enable or disable the button.

To create a resource permission for user interface components that you want to protect, use the overview editor for security policies.

Before you begin:

It may be helpful to have an understanding of how ADF Security handles ADF methods. For more information, see How to Define Policies to Control User Access to ADF Methods.

You will need to complete these tasks:

1. Create the command component that executes the method that you want secure, as described in Creating Command Components to Execute Methods.
2. Run the Configure ADF Security wizard, as described in Enabling ADF Security.
3. Create application roles, as described in Creating Application Roles.

To grant a resource permission on a custom resource type:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, next to the **Resource Type** dropdown list, click the **New Resource Type** button.
3. In the Create Resource Type dialog, enter the name of the resource type, a display name to display when granting resource permissions in JDeveloper, and a description.

   Enter a resource type and display name that is appropriate for the user interface resource that needs to be protected. For example, if you want to protect a method button that cancels a product shipment, you might enter the resource type `CancelShipment` and display name `Cancel Shipment`.
4. Next to the **Actions** list, click the **Add Action** button and enter the name of the action that you want to protect. Click **OK**.

   The action name can be any name that you want to associate with the custom resource type. For example, if you want to protect a button that invokes a method, you might enter the action name `invoke`. You can add multiple actions to the list when you need to support granting instances of the resource permission to separate application roles.
5. In the Resource Grants page of the overview editor for security policies, in the **Resources** column, click the **Add Resource** icon.

   The first time you make a grant to a custom resource type, no resource will be defined. You must create a custom resource for the policy that will be used to check user permissions in the user interface at runtime.

6. In the Create Resource dialog, enter the name of the resource and a display name to display when granting resource permissions in JDeveloper, and then click **OK**.

   Enter a resource name and a display name that describes the user interface resource that you want to protect. For example, if you want to protect a method button that cancels a product shipment, you might enter the resource name `CancelShipmentButton` and display name `Cancel Shipment Button`.

7. In the **Granted to Roles** column, click the **Add Grantee** icon and select **Add Application Role**.

8. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

   The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, **anonymous-role** and **authenticated-role**, as described in What Happens at Runtime: How the Built-in Roles Are Used.

   If you do not see application roles that are specific to your application, create the role, as described in Creating Application Roles.

9. In the Select Application Roles dialog, click **OK**.

10. In the Resource Grants page of the overview editor, in the **Actions** column, select the desired action.

    By default, the overview editor shows all actions of the custom resource type unselected. The available actions are defined by the resource type.

11. You can repeat these steps to make additional grants as desired.

    The same ADF method resource can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in What Happens When You Define the Security Policy.

Enforcing the Resource Grant in the User Interface

You use the Expression Builder dialog that you display for the UI component display property to define an EL expression that checks the user's access rights to a previously defined custom resource type. When you run the application, the component will appear either enabled or disabled based on the outcome of the EL expression resource permission evaluation.

For example, you can define the `userGrantedPermission` expression on the `disabled` attribute of the `af:button#cb1` button, as shown in the following example. In this case, the expression tests whether the user has permission and then either enables the button or, when the user does not have permission, disables the button. Because the expression is not defined on the button's `rendered` attribute, the page always displays the button.

```
<af:button actionListener="#{bindings.myMethodName.execute}"
     text="myMethodName"
     disabled="#{!securityContext.userGrantedPermission
       ['resourceName=CancelShipmentButton,resourceType=CancelShipment,
             action=invoke']}
     id="cb1"/>
```

Before you begin:

It may be helpful to have an understanding of the limitations of ADF method authorization checking. For more information, see How to Define Policies to Control User Access to ADF Methods.

You will need to complete this task:

> Create the resource grant for a custom resource type, as described in Creating a Resource Grant to Control Access to ADF Methods.

To check the resource permission using an expression:

1. In the Applications window, double-click the page that contains the command component bound to the ADF method.
2. In the visual editor for the page, select the command component that is used to execute the ADF method.
3. In the Property window, click the **Property Menu** dropdown menu next to the **Disabled** field and choose **Expression Builder**.
4. In the Expression Builder, expand the **ADF Bindings - securityContext** node and select **userGrantedPermission**, and then, in the **Expression** field, enter a concatenated string that defines the permission.

   Enter the permission string as a semicolon-separated concatenation of `resourceName=`*`aResourceName`*`;resourceType=`*`aResourceType`*`;action=`*`actionName`*. For example, to enable or disable a command button used to invoked the method in a page, you would enter an expression similar to the one shown in the above example.

   In the example, the expression determines whether a resource policy grants invoke privileges for the resource type named `CancelShipment` to the user's defined application role. The resource policy must exist in the application policy store to test the expression at runtime.
5. Click **OK**.

What Happens When You Define the Security Policy

When you define a security policy, the overview editor for security policies updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The overview editor writes the policy information to the `<policy-store>` section of the file. The security policy, or grant, contains both a grantee and one or more permissions. The grantee is the application role that the policy is being defined for. Each permission defines the resource being secured and the action that can be performed against that resource.

The following example shows a security policy in the `jazn-data.xml` file that grants unauthenticated users access to an employee registration task flow and a top-level web page used to access the task flow. The grant to the `anonymous-role` application role contains a view permission for a bounded task flow, `emp-reg-task-flow`, and a view permission on the web page with the `indexPageDef` page definition. With this grant, unauthenticated users will be able to enter the employee registration task flow and view the welcome page.

For the web page, notice that permission has been defined on the `indexPageDef` page definition created for the welcome page (`index.jsf`). Also, note that this is a top-level web page that is not already secured by a bounded task flow.

```
<policy-store>
    ...
    <jazn-policy>
        <grant>
            <grantee>
                <principals>
                    <principal>
                         <name>anonymous-role</name>
                         <class>oracle.security.jps.internal.core.principals.
                                       JpsAnonymousRoleImpl</class>
                     </principal>
                 </principals>
             </grantee>
             <permissions>
                  <permission>
                      <class>oracle.adf.controller.security.TaskFlowPermission</
class>
                      <name>/WEB-INF/flows/emp-reg-task-flow-definition.xml#
                                                  #emp-reg-task-flow-definition</
name>
                      <actions>view</actions>
                  </permission>
                   <permission>

<class>oracle.adf.share.security.authorization.RegionPermission</class>
                        <name>oracle.summit.view.pageDefs.indexPageDef</name>
                        <actions>view</actions>
                  </permission>
                  ...
             </permissions>
        </grant>
        ...
    </jazn-policy>
</policy-store>
```

What Happens at Runtime: How ADF Security Policies Are Enforced

Grants that you make for ADF resources are standard JAAS Permissions. When you enable ADF Security in your application, Oracle Platform Security Service (OPSS) running in Oracle WebLogic Server will utilize the grants to allow authorization. In authorization mode, ADF Security uses fine-grained authorization, implemented with JAAS Permissions to perform security checks for access rights to pages. The ADF Security enforcement logic checks to see whether the user, represented by the JAAS subject, has the right permissions to access the resource.

The subject contains the user's principals, which include a user principal that contains their name (could be anonymous, before logging on, or some user name after logging on), and their list of role principals, which would include `authenticated-role` and some number of other roles that are obtained from the policy and identity stores. The principal is created to represent all of the user's memberships in application roles defined in the policy store. In turn, each application role may have multiple Permissions associated with them. These are the ADF security policies that are created through the overview editor for the `jazn-data.xml` file.

> **Note:**
>
> ADF security policies are scoped by application. This scoping allows two applications to refer to the same permission target, without producing unintentional results. You are not required to name application resources to impose application scoping of the policy store information.

Before you run the application using Integrated WebLogic Server, you will need to provision the identity store with test users and add these users to the application roles that you want to configure. The application roles can define members that are specific users or groups of users (also known as **enterprise roles**), as described in Creating Test Users.

Then at runtime, whether the current user has view permission on the page they are trying to access will be determined by the context of the page:

- If the page is an activity of a bounded task flow, the task flow controller determines the permission.
- If the page is a top-level page with an associated page definition file, the **ADF Model** layer determines the permission.

Oracle Platform Security Services then checks to see whether the subject contains the roles that have the corresponding permissions needed to access the page. If the user is authorized, then the task flow is entered.

In the case of a bounded task flow and top-level pages (defined by an unbounded task flow), if the user is not authorized, **ADF Controller** throws an exception and passes control to an exception handler that the task flow configuration specifies. For details about specifying an error page, see How to Redirect a User After Authentication.

What You May Need to Know About Defining Policies for Pages with No ADF Bindings

The default Configure ADF Security wizard option **ADF Authentication and Authorization** enables authorization checking and secures a web page whenever the page is associated with an ADF security-aware resource. Therefore, after you run the wizard, a web page will not be secured if both of these conditions exist:

- The page does not display databound ADF Faces components and therefore no ADF page definition exists for the page.
- The page is not a constituent page of a bounded ADF task flow. (Any page that the user accesses as a process of a bounded task flow is checked under the permission of the task flow.)

JDeveloper will generate an ADF page definition file for you whenever you design a web page using the **Data Controls panel** to create databound ADF Faces components. However, if your web page does not use ADF bindings, you can still create an *empty* page definition file by right-clicking the web page in the user interface project and choosing **Go to Page Definition**. The page definition file can remain empty because the page does not need to work with ADF bindings to support databound ADF Faces components.

Once you associate a web page with an ADF page definition file, empty or not, authorization checking will be enforced when the user accesses the associated web page. You can define security policies for the page as you would any other ADF page definition. For details about making grants to an empty ADF page definition, see How to Define Policies for Web Pages That Reference a Page Definition.

Before you begin:

It may be helpful to have an understanding of security for individual page definition files. For more information, see How to Define Policies for Web Pages That Reference a Page Definition.

You may also find it helpful to understand how JDeveloper normally generates page definition files. For more information, see Working with Page Definition Files.

To create an empty page definition that you can define security policies for:

1. In the Applications window, locate the web page you want to secure, right-click the node and choose **Go to Page Definition**.
2. In the confirmation dialog, click **Yes** to create a new page definition for the page.

   The page definition will be added to the `pageDefs` package.

How to Use Regular Expressions to Define Policies on Groups of Resources

When you want to define a grant that applies to multiple resources at once, you can create patterns as defined by the `java.util.regex.Pattern` class to form a regular expression that gets evaluated at runtime. For example, to match a grant to a set of resources, you can enter the expression `.*` (specifies any character zero or more times) on the name of the permission. ADF Security does not support the use of regular expressions on other security objects, such as the principal name.

You might use this feature to group bounded task flows that would have the same permissions into their own subfolders of `WEB-INF` and define the grant for the entire folder, as shown in the following example. In this case, the expression uses the dot character (defined as, any character) followed by the asterisk quantifier (defined as, zero or more times).

```
...
<grant>
   <grantee>
      <principals>
         <principal>
            <class>oracle.security.jps.service.policystore.ApplicationRole</
class>
            <name>anonymous-role</name>
         </principal>
      </principals>
   </grantee>
   <permissions>
       <permission>
          <class>oracle.adf.controller.security.TaskFlowPermission</class>
          <name>/WEB-INF/.*</name>
          <actions>view</actions>
       </permission>
   </permissions>
</grant>
```

As the overview editor for the jazn-data.xml file does not support the use of regular expressions in the user interface, you must edit the file directly. Do not edit the policy store of the system-jazn-data.xml file directly. Instead, add grants using regular expressions to the jazn-data.xml file. These grants will then be merged to the policy store when you run or deploy the application.

The use of more complex regular expressions enables you to define business rules in the policy, thus creating a very targeted set of permissions. For example, you can grant the view permission on all page definitions and deny specific page definitions at the same time by defining an exclusion set in your regular expression. The following example shows how the view permission is granted to anonymous-role for all pages except those for which the page definition name starts with custom.

```
<grant>
   <grantee>
      <principals>
         <principal>
            <class>oracle.security.jps.service.policystore.ApplicationRole</
class>
            <name>anonymous-role</name>
         </principal>
      </principals>
   </grantee>
   <permissions>
      <permission>
         <class>oracle.adf.share.security.authorization.RegionPermission</class>
         <name>[^(custom)].*</name>
         <actions>view</actions>
      </permission>
   </permissions>
</grant>
```

Table 47-7 shows some of the basic regular expression metacharacters that you can use in your policy definitions.

Table 47-7 Description of Metacharacters

Metacharacter	Description
[abc]	a, b, or c (included in list)
[^abc]	Any character except a, b, or c (negation)
[a-zA-Z]	a to z or A to Z, inclusive (range)
[a-d[m-p]]	a to d, or m to p ~= [a-dm-p](union)
[a-z&&[def]]	d, e, or f (intersection)
[a-z&&[^bc]]	a through z, without b and c: [ad-z] (subtraction)
[a-z&&[^m-p]]	a through z, and not m through p
.*	Any number of arbitrary characters (note this expression uses a dot and an asterisk together)

How to Define Policies for Data

ADF entity objects in the data model project are security-aware, meaning that predefined resource-specific permissions exist that a developer can grant. Additionally, you can secure just the individual attributes of entity objects.

Entity objects that you secure restrict users from updating data displayed by any web page that renders a UI component bound by an ADF binding to the data accessed by the secured entity object. Additionally, when you secure an entity object, you effectively secure any **view object** in the data model project that relies on that entity object. As such, entity objects that you secure define an even broader access policy that applies to all UI components bound to this set of view objects.

To secure row data using ADF entity objects:

1. Define a permission map for the specific actions of the entity object or the attributes of the entity object that you want to secure.
2. Grant the permission to an application role that you have added to the policy store.

Defining Permission Maps on ADF Entity Objects

In the data model project, you use the overview editor for the entity object to define a permission map for the specific actions allowed by the entity object. The metadata consists of a permission class, a permission name, and a set of actions mapped to binding operations.

The list of available operations displayed by the overview editor is defined by the entity object permission class (`oracle.adf.share.security.authorization.EntityPermission`). The permission class maps the operations supported by the entity object to actions. Table 47-8 shows the securable operations of the entity object.

Table 47-8 Securable Operations of ADF Entity Objects

Securable Operation	Expected Mapped Action	Corresponding Implementation
`read`	`read`	View the rows of a result set that has been restricted by a `WHERE` clause fragment.
`update`	`update`	Update any attribute of the bound collection.
`removeCurrentRow`	`delete`	Delete a row from the bound collection.

> **Note:**
>
> Unlike `read` and `update` operations, the securable operation that maps to the `delete` action is defined with the unique identifier, `removeCurrentRow`. Because authorization checks in Fusion web applications rely on the operation name and not the action name, you must test the `removeCurrentRow` operation name rather than the `delete` privilege name. For details about the entity row API and EL expressions that allow you to test entity permissions, see How to Perform Authorization Checks for Entity Object Operations.

To secure all row-level data that the entity object accesses, use the overview editor for the entity object.

Before you begin:

It may be helpful to have an understanding of ADF security for entity objects. For more information, see How to Define Policies for Data.

You will need to complete this task:

> Create entity objects in the data model project, as described in Creating a Business Domain Layer Using Entity Objects.

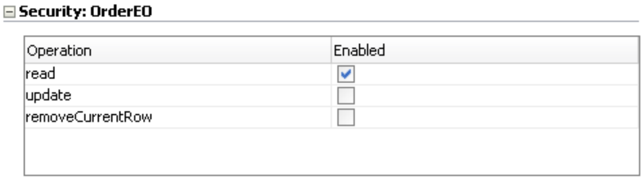
To secure an operation on an entity object:

1. In the Applications window, double-click the entity object that you want to secure.
2. In the overview editor, click the **General** navigation tab.
3. In the General page, expand the **Security** section and select the operations you want to secure for the entity object.

   The **Security** section displays the securable operations that the `EntityPermission` class defines. The class maps the entity object—specific actions to the entity object's operations, as described in Table 47-8.

   For example, to enable **read** permission, select it as shown in Figure 47-11. The permissions appear in the XML definition of the entity object.

Figure 47-11   Permission Enabled on read Operation for an ADF Entity Object



⊟ Security: OrderEO

Operation	Enabled
read	☑
update	□
removeCurrentRow	□

Defining Permission Maps on ADF Entity Object Attributes

In the data model project, you use the overview editor for the entity object to define a permission map for the specific actions allowed by the entity object attribute. The metadata consists of a permission class, a permission name, and a set of actions mapped to binding operations.

The list of available operations displayed by the overview editor is defined by the entity object permission class (`oracle.adf.share.security.authorization.EntityPermission`). The permission class maps the operations supported by entity object attributes to actions. Table 47-9 shows the securable operations of entity object attributes.

Table 47-9   Securable Operations of ADF Entity Object Attributes

Securable Operation	Expected Mapped Action	Corresponding Implementation
`update`	`update`	Update a specific attribute of the bound collection.

To secure individual columns of data that the entity object accesses, use the Attributes page of the overview editor for the entity object.

Before you begin:

It may be helpful to have an understanding of ADF security for entity objects. For more information, see How to Define Policies for Data.

You will need to complete this task:

> Create entity objects in the data model project, as described in Creating a Business Domain Layer Using Entity Objects.

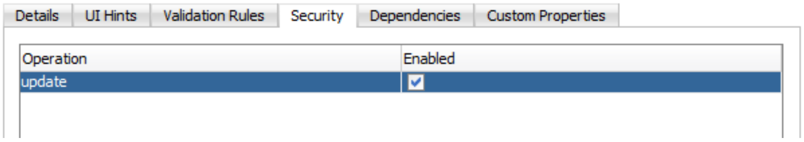
To secure an operation on an entity object attribute:

1. In the Applications window, double-click the entity object that defines the attribute you want to secure.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute to secure, and then click the **Security** tab and select the **update** operation.

   The **Security** tab displays the securable operations that the `EntityAttributePermission` class defines. The class maps the entity object-specific actions to the entity object's operations, as described in Table 47-9.

   For example, to enable **update** permission, select it as shown in Figure 47-12. The permission map appears in the XML definition of the entity object.

Figure 47-12 Permission Enabled on update Operation for an ADF Entity Object Attribute



Operation	Enabled
update	☑

Granting Permissions on ADF Entity Objects and Entity Attributes

Once a permission target is configured, any data that derives from entity objects or their attributes remains unsecured until you explicitly define policy grants for the entity object's permission target.

To define the access policy for an existing entity object or entity attribute permission target, use the overview editor for security policies.

Before you begin:

It may be helpful to have an understanding of ADF security for entity objects. For more information, see How to Define Policies for Data.

You will need to complete these tasks:

1. Run the Configure ADF Security wizard, as described in Enabling ADF Security.
2. Create application roles, as described in Creating Application Roles.
3. Define the permission target for the entity object or the attributes of the entity object, as described in Defining Permission Maps on ADF Entity Objects.

To define the access policy for an entity object or entity attribute:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.

2. In the Resource Grants page of the overview editor for security policies, select **ADF Entity Object** or select **ADF Entity Object Attribute** from the **Resource Type** dropdown list.

   The Resource Grants page of the overview editor displays all entity objects (or entity attributes) for which you previously defined permission targets.

3. In the **Resources** column, select the ADF entity object or entity attribute for which you want to grant access rights.

   The first time you make a grant to an ADF entity object or entity attribute, the first column displays the **Resource without any grants** icon (represented by the "lock" icon) next to the method name, as shown in Figure 47-13. The editor displays the lock icons to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant.

Figure 47-13 Entity Objects Without Grants in the Overview Editor

ItemEO(oracle.summit.model.entities)
OrdEO(oracle.summit.model.entities)

4. In the **Granted to Roles** column, click the **Add Grantee** icon and select **Add Application Role**.

5. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

   The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, **anonymous-role** and **authenticated-role**, as described in What Happens at Runtime: How the Built-in Roles Are Used,

   If you do not see application roles that are specific to your application, create the role, as described in Creating Application Roles.

6. In the Select Application Roles dialog, click **OK**.

7. In the Resource Grants page of the overview editor, in the **Actions** column, select the action that you want to grant to a specific application role.

   For entity objects, the overview editor shows **read** action selected by default. You may select the **update** action and **delete** action if you have configured their corresponding permission targets, as described in Table 47-8.

   For entity object attributes, the overview editor shows the **update** action selected by default, corresponding to the permission target described in Table 47-9. No other actions are supported for entity object attributes.

   Figure 47-14 shows the **delete**, **read**, and **update** privileges granted to the **Application Employee Role** application role for an entity object.

ItemEO(oracle.summit.model.entities)	Application Employee Role	☑ read
OrdEO(oracle.summit.model.entities)		☑ update

8. You can repeat these steps to make additional grants as desired.

   The same ADF entity object or entity attribute can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in What Happens When You Define the Security Policy.

How to Aggregate Resource Grants as Entitlement Grants

You define end user access for individual securable Oracle ADF artifacts by creating resource grants. However, for ease of administration and maintenance, resource grants can also be defined as entitlement grants, in which case multiple securable application artifacts are aggregated into a named security group that can be granted to application roles using a single statement. For example, when you want to authorize access to the data exposed in the application by an ADF Business Components **entity object**, multiple entity objects may require the same security policy. Instead of individually granting access privileges to each entity object, you can group the privileges as a set in an entitlement and grant them all at once.

You create entitlement grants in the Entitlements Grants page of the overview editor for security policies. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines an entitlement (identified in the XML definition as `<permission-set>`) comprised of resource instance /action pairs that you select. This entitlement is a grantable entity that you then grant to an application role.

The list of resource types appears in the overview editor for security policies. The resource type you select filters the resource instances defined within the projects of your application's workspace. The resource type selection also determines the list of available actions displayed by the overview editor. For example, when you select the **Task Flow Permission** resource type, the overview editor will display all of the task flows in the user interface projects that you select and also displays the **view** action that you can associate with the available ADF bounded task flow resources.

Table 47-10 lists the resource types displayed in JDeveloper and identifies the associated resource and supported actions for each type.

Table 47-10 Resource Types of Securable Oracle ADF Artifacts

Resource Type	Supports These Resources and Actions
`Task Flow`	Defines view actions on ADF bounded task flows in a user interface project that you select.
`Web Page`	Defines view actions on regions and web pages backed by ADF page definition files in a user interface project that you select.
`ADF Entity Object`	Defines read, update, and delete actions on entity objects in a data model project that you select.
`ADF Entity Object Attribute`	Defines update actions on entity object attributes of a specific entity object in a data model project that you select.

To define an entitlement grant for a securable Oracle ADF artifact, use the Entitlement Grants page of the overview editor for security policies.

Before you begin:

It may be helpful to have an understanding of ADF security for entity objects. For more information, see How to Aggregate Resource Grants as Entitlement Grants.

You will need to complete this task:

- Create application roles, as described in Creating Application Roles.

To define an entitlement grant for an Oracle ADF artifact:

1. In the main menu, choose **Application** and then **Secure > Entitlement Grants**.
2. In the Entitlement Grants page of overview editor for security policies, click the **Add Entitlements** icon in the **Entitlements** section.

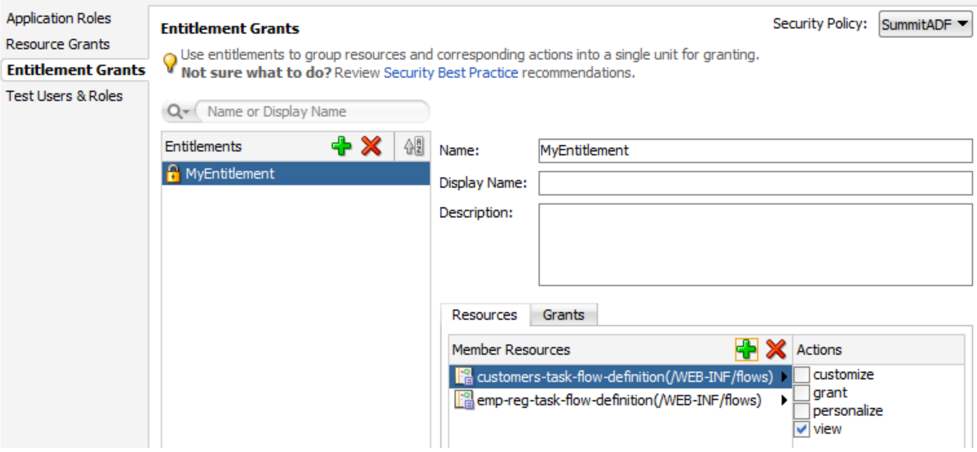
   The overview editor displays all the resources that your application defines.
3. In the Entitlement Grants page, click the **Resources** tab and then click the **Add Member Resource** icon to add a member resource to the entitlement.
4. In the Select Resources dialog, select the resource from the **Resource Type** dropdown and then select the desired project in the **Source Projects** section.

   The dialog displays all the projects in your application workspace.
5. In the **Available Resources** section, select the resource and click the **Add** icon.

   The dialog displays all the resources define by your selected project.
6. In the **Actions** lists, select the desired action for the selected resource.

   Figure 47-15 shows the overview editor with the **View** action selected for the task flow and added to **MyEntitlement**.

Figure 47-15 Adding a Bounded Task Flow as a Resource in an Entitlement Grant



Security Policy: SummitADF

Use entitlements to group resources and corresponding actions into a single unit for granting.
Not sure what to do? Review Security Best Practice recommendations.

MyEntitlement

Name: MyEntitlement
Display Name:
Description:

customers-task-flow-definition(/WEB-INF/flows)
emp-reg-task-flow-definition(/WEB-INF/flows)

□ customize
□ grant
□ personalize
☑ view

7. Add other desired resources to the list.
8. In the Entitlement Grants page, click the **Grants** tab and then click the **Add Role Grants** icon to grant the entitlement to an application role.
9. In the Select Application Roles dialog, select one or more custom application roles.

   The dialog displays all the application roles from the `jazn-data.xml` file. You must not add a grant to a predefined application role (also called **duty roles** in the terminology of Oracle Fusion Applications). Only select custom application roles that either you created in JDeveloper or that were created by an IT security manager for this purpose.
10. Click **OK**.
11. You can repeat these steps to add other resources and make grants on those resources to the same entitlement for the same custom application role.

What Happens After You Create an Entitlement Grant

When you use the security policy editor in JDeveloper to create an entitlement grant, JDeveloper modifies the source for the application policy store in the `jazn-data.xml` file. The policy store section of the file contains a `<resource-type>` definition (that identifies the actions supported for resources of the selected type), a `<resource>` definition (to identify the resource instance that you selected from your application and mapped to a resource type), a `<permission-set>` definition (to define the resources and actions to be granted as an entitlement), and a `<grant>` definition with one or more entitlements (defined in the XML as a permission set) granted to the desired application roles (the grantee).

As the following example illustrates, entitlement-based security policies in the Oracle Fusion application are defined in the `<jazn-policies>` element and consist of one or more entitlements granted to a single application role.

```
<?xml version="1.0" ?>
<jazn-data>
  <policy-store>
    <applications>
      <application>
  <name>MyApp</name>

<app-roles>
  <app-role>
    <name>AppRole</name>
    <display-name>AppRole display name</display-name>
    <description>AppRole description</description>
    <guid>F5494E409CFB11DEBFEBC11296284F58</guid>
    <class>oracle.security.jps.service.policystore.ApplicationRole</class>
  </app-role>
</app-roles>

<role-categories>
  <role-category>
    <name>MyAppRoleCategory</name>
    <display-name>MyAppRoleCategory display name</display-name>
    <description>MyAppRoleCategory description</description>
  </role-category>
</role-categories>

<!-- resource-specific OPSS permission class definition -->

  <!-- function security policy is a grantee and permission set -->
```

```
        <grant>
          <!-- application role is the recipient of the privileges -->
          <grantee>
            <principals>
              <principal>
                <class>
                   oracle.security.jps.service.policystore.ApplicationRole
                </class>
                <name>AppRole</name>
                <guid>F5494E409CFB11DEBFEBC11296284F58</guid>
              </principal>
            </principals>
          </grantee>

          <!-- entitlement granted to an application role -->
          <permission-set-refs>
            <permission-set-ref>
              <name>MyEntitlement</name>
            </permission-set-ref>
          </permission-set-refs>
        </grant>
      </jazn-policy>
    </application>
  </applications>
 </policy-store>
</jazn-data>
```

Creating Test Users

For testing purpose, ADF Security allows developers to create users in the jazn-data.xml file.

JDeveloper provides editors to help you create both the identity and the policy stores. You create both repositories in an application-specific `jazn-data.xml` file. The editor for the identity store section of the file lets you enter the list of valid user IDs and their assigned passwords. The same editor lets you create application roles and assign the test users or enterprise roles as members of the application roles. Once defined, this information appears in the policy store section of the `jazn-data.xml` file.

How to Create Test Users in JDeveloper

You seed the identity store of your application with a temporary set of users to simulate the actual users' experience in your production environment. When you run the application in Integrated WebLogic Server, you can log in as any test user and be conferred access rights to view the secure ADF resources of your application.

You can use the identity store to organize users into enterprise roles. Because you typically will configure JDeveloper's deployment options to prevent migrating the identity store to a staging environment, enterprise roles that you create in the `jazn-data.xml` file are for convenience only. For more details about the use of enterprise roles, see What You May Need to Know About Enterprise Roles and Application Roles.

> **Caution:**
>
> If you choose to deploy the identity store to your standalone server, you must not create users and enterprise roles in your local identity store that are already configured for Oracle WebLogic Server. For example, if you were to deploy the identity store with the user `weblogic` and enterprise role `Administrators`, you would overwrite the default administration configuration on the target server. For a complete list of global roles that Oracle WebLogic Server installs by default, see the Users, Groups, and Security Roles chapter in *Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

To enable the user to view resources, you make grants against application roles rather than against the users who are the members of those roles. Therefore, after you seed the identity store with test users, you must associate each user or enterprise role group with an application role. This association confers the access rights defined by ADF security policies to users. For details about conferring access rights to users, see How to Associate Test Users with Application Roles.

You should avoid choosing a user name already configured for Oracle WebLogic Server (for example, do not enter `webcenter`). For the list of user names installed by Oracle WebLogic Server, see the Users, Groups, and Security Roles chapter in *Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

Before you begin:

It may be helpful to have an understanding of the identity store. See Creating Test Users.

To create test users and groups:

1. In the main menu, choose **Application** and then **Secure > Test Users & Roles**.
2. In the Test Users & Roles page of the overview editor for security policies, select the realm for your application from the **Realm** dropdown list and perform the following steps.

   JDeveloper uses the realm `jazn.com` by default.

   a. In the **Users** list, click the **New User** icon.
   b. In the **Name** field, enter the user name.
   c. In the **Password** field, enter the password for the user and click any other field to add the password to the identity store.

      The password must contain at least eight characters and at least one of the characters must be a special character (such as !, %, ^, &, $ and so on).
3. Optionally, in the overview editor for security policies, click the **Enterprise Roles** navigation tab, select the realm for your application from the **Realm** dropdown list, and perform the following steps.

   You create enterprise roles only when you want to organize users into groups that you will add to an application role. For the purpose of creating test users to run the application using Integrated WebLogic Server, you do not need to create enterprise role groups.

   a. In the **Enterprise Roles** list, click the **New Role** icon.

b. In the **Name** field, enter the name of the enterprise role and click any other field to add the role to the identity store.

   If you create enterprise role groups, you should avoid choosing a role name that is already configured for Oracle WebLogic Server (for example, do not enter `Administrators`). For a complete list of the default group names installed by Oracle WebLogic Server, see Users, Groups, and Security Roles in *Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

What Happens When You Create Test Users

When you provision the identity store with user identities and enterprise role groups, JDeveloper updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The dialog writes the user information to the `<jazn-realm>` section of the file corresponding to the identity store. Each user identity has a user name and a user login password. Each enterprise role contains one or more member users.

The following example shows the identity store in the `jazn-data.xml` file with two users and two enterprise roles. The user `cmagee` is a member of the `Enterprise Employee Group` enterprise role, while user `214` is a member of the `Enterprise Customer Group` enterprise role.

```
<jazn-data>
   <jazn-realm default="jazn.com">
      <realm>
         <name>jazn.com</name>
         <users>
            <user>
               <name>cmagee</name>
               <display-name>Colin Magee</display-name>
               <description>Sales Rep</description>
               <credentials>{903}5AUHlE+qvDxxAhxIMoXJ/WLhMF0ynue7</credentials>
            </user>
            <user>
               <name>214</name>
               <display-name>Ojibway Retail</display-name>
               <description>Customer</description>
               <credentials>{903}rijN2KQCBSeBQ/JNZlv8GwwUiGWk5IQa</credentials>
            </user>
            ...
         </users>
         <roles>
            <role>
               <name>Enterprise Employee Group</name>
               <members>
                  <member>
                     <type>user</type>
                     <name>cmagee</name>
                  </member>
               </members>
            </role>
            <role>
               <name>Enterprise Customer Group</name>
               <members>
                  <member>
                     <type>user</type>
                     <name>214</name>
```

```
                        </member>
                        ...
                    </members>
                </role>
                ...
            </roles>
        </realm>
        ...
    </jazn-realm>
</jazn-data>
```

How to Associate Test Users with Application Roles

Because the ADF Security framework enforces a role-based access control mechanism with permissions granted to application roles, you define a set of roles in the policy store that are specific to your application. For example, in the context of the work flow, there may be roles such as customer, product specialist, supervisor, and administrator.

After you create an application role, you can proceed to associate users that you created in the identity store with one or more roles. At runtime, users who are members of an application role will be conferred the access rights of their application roles. You can assign a user to more than one application role when you want to confer the right of multiple resource grants to a particular user.

For example, one authenticated user might belong to the supervisor role and an employee role, while another user might belong only to the employee role. The security policy for a bounded task flow that permits customer records to be browsed and edited may confer view permission to the supervisor role and limit view permission to the browse page for the employee role. Thus, grants to application roles support multiple levels of access. If the authenticated user is not a member of an application role with a view permission grant for the target ADF resource, the security framework will return an unauthorized user message.

Before you begin:

It may be helpful to have an understanding of the identity store. For more information, see Creating Test Users.

You will need to complete these tasks:

1. Run the Configure ADF Security wizard, as described in Enabling ADF Security.
2. Create application roles, as described in Creating Application Roles.
3. Define security policies for ADF security-aware resources, as described in Defining ADF Security Policies.
4. Create test users, and, optionally, create enterprise role groups, as described in How to Create Test Users in JDeveloper.

To associate users with application roles:

1. In the main menu, choose **Application** and then **Secure > Application Roles**.
2. In the Application Roles page of the overview editor for security policies, select the policy store for your application from the **Security Policy** dropdown list.

   The policy store that JDeveloper creates in the `jazn-data.xml` file are automatically based on the name of your application.

3. In the **Roles** list, select an existing application role and complete these tasks as appropriate:
   a. In the **Mappings** section, click the **Add User or Role** icon dropdown menu and choose **Add User**, then in the Select Users dialog select the previously created user from the list and click **OK**.
   b. Optionally, if you have defined enterprise roles in the identity store, in the **Mappings** section, click the **Add User or Role** icon dropdown menu and choose **Add Enterprise Role**, then in the Select Enterprise Roles dialog select the previously created enterprise role from the list and click **OK**.

What Happens When You Configure Application Roles

When you associate users with application roles, JDeveloper updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The dialog writes the user information to the `<policy-store>` section of the file. Each application role contains one or more member users or enterprise roles.

The following example shows the policy store in the `jazn-data.xml` file with the `Application Employee Role` application role, which contains two members, `Enterprise Employee Group` and `Enterprise Manager Group`.

```
<policy-store>
     <applications>
         <application>
            <name>SummitADF</name>
            <app-roles>
               <app-role>
                  <name>Application Employee Role</name>

<class>oracle.security.jps.service.policystore.ApplicationRole</class>
                  <display-name>Application Employee Role</display-name>
                  <members>
                     <member>
                        <class>oracle.security.jps.internal.core.principals.

JpsXmlEnterpriseRoleImpl</class>
                        <name>Enterprise Employee Group</name>
                     </member>
                     <member>
                        <class>oracle.security.jps.internal.core.principals.

JpsXmlEnterpriseRoleImpl</class>
                        <name>Enterprise Manager Group</name>
                     </member>
                     ...
                  </members>
               </app-role>
               ...
            </app-roles>
            <jazn-policy>
              ...
            </jazn-policy>
         </application>
    </applictions>
</policy-store>
```

Creating a Login Page

Both implicit and explicit authentication are supported by ADF Security. You can create a login link, a login page, a welcome page and, perform various other actions.

ADF Security allows for implicit and explicit authentication:

- In an **implicit authentication** scenario, if a user who is not yet authenticated tries to access a web page associated with ADF security-aware resources that are not granted to `anonymous-role`, then authentication is triggered dynamically. After the user successfully logs in, another check will be done to verify whether the authenticated user has view access granted on the requested page's ADF security-aware resource.
- In an **explicit authentication** scenario, your application has a public page that displays a login link, which, when clicked, triggers an authentication challenge to log in the user. The login link may optionally specify some other target page that should be displayed (assuming the authenticated user has access) after the successful authentication.

The implicit and explicit authentication scenarios are handled for you by default when you run the Configure ADF Security wizard, as described in What You May Need to Know About ADF Authentication. However, when you customize the default, generated login page (or supply your own page) to use ADF Faces components, you will need to configure the container-managed deployment descriptor (`web.xml` file).

To explicitly handle user authentication:

1. Create a login link component and add it to the public home web page for your application.
2. Create a managed bean using API specific to Servlet 3.0 to handle the login attempts by the user.
3. Create a JSF login page using ADF Faces components.
4. Ensure that the login page's resources are accessible.

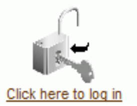
For more information about implicit and explicit authentication, see What Happens at Runtime: How ADF Security Handles Authentication.

How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication

You can create a standard login link component that can be added to any page in your application to enable users to authenticate or subsequently log off. This component keeps track of the authenticated state of the user and returns the appropriate login or logout URLs and icons. The login link component will redirect users back to a specific page once they are authenticated. Hence, using this login link component provides you with a single, consistent object.

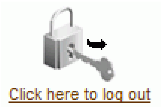
To the unauthenticated user, the login link component will look similar to Figure 47-16.

Figure 47-16 Component Before User Logs In



Then when the user clicks the login link and logs in as a user with the appropriate credentials, the component will look similar to Figure 47-17.

Figure 47-17 Component After User Logs In



Before you begin:

It may be helpful to have an understanding of ADF authentication. For more information, see Creating a Login Page.

You will need to complete this task:

> Copy your login and logout image files (GIF, JPG, or PNG files) to the `public_html` directory of your project.

> **Note:**
>
> The images used should reference the appropriate skin image if your application uses skins. For more information about skins, see the Customizing the Appearance Using Styles and Skins chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

To create the login link component and add it to a page:

1. In the Applications window, double-click the web page that will display the component.
2. In the ADF Faces page of the Components window, from the Common Components panel, drag a **Link** and drop it on the page.
3. In the Structure window, right-click **af:link** and choose **Go to Properties**.
4. In the Property window, to specify the label for the Link component, enter an Expression Language (EL) expression in the **Text** field.

   For example, you can enter an EL expression similar to this to conditionally render the link text:

   ```
   #{securityContext.authenticated ? &quot;Click to log out&quot; :
                                     &quot;Click to log in&quot;}
   ```

The `authenticated` property of the `securityContext` bean will evaluate to true and render the log out option if the current user is authenticated. Otherwise, the link is rendered with the login option.

5. In the Property window, to specify the URL for the Link component, enter an EL expression in the **Destination** field.

   For example, this EL expression conditionally renders a URL to forward the user depending on whether or not they are authenticated:

```
#{securityContext.authenticated ? \"Logout\" : \"Login\"}" id="gl2"
destination="#{securityContext.authenticated ?
                                              \"/adfAuthentication?
logout=true\" : \"/adfAuthentication?login=true\"}
```

   When the user clicks the link, the destination will be determined by the `success_url` and `end_url` settings on the ADF authentication servlet `init-param`. Note that these settings should specify the view activity name instead of the web page name to ensure control flow rules are enforced for page navigation after login. The `authenticated` property of the `securityContext` bean will evaluate to true and forward to the page defined by `success_url` if the current user is authenticated. When the user is not authenticated, there is no need to forward to the login page because the ADF authentication servlet triggers log in, which is handled by the container-managed security configuration. Note that log out is handled by the ADF authentication servlet which invalidates the session.

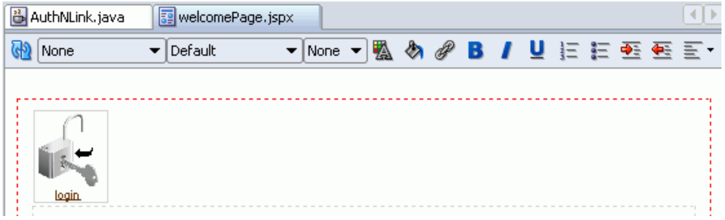
6. In the Property window, to specify the link component image for the Link component, enter an EL expression in the **Icon** field.

   For example, this EL expression conditionally renders the link component image as the lock GIF if the user is not authenticated; otherwise, renders the image with the key GIF:

```
#{securityContext.authenticated ? '/images/lock.gif' : '/images/key.gif'}
```

   Figure 47-18 shows how the login link component appears when added to the global menu facet of the page.

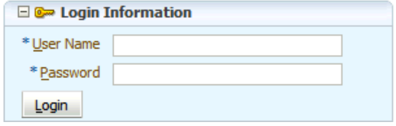
Figure 47-18 Login Link Component on the Page



How to Create a Login Page Specifically for Explicit Authentication

The default login form that is generated for you when you run the Configure ADF Security wizard is provided as a convenience for testing your application within JDeveloper. The default form does not allow you to customize the page using ADF Faces components to match the user interface of the application. You can replace the default form with an ADF Faces-based login page that enables you to include customizable components, as shown in Figure 47-19.

Figure 47-19 Login Page



However, if designing a login page with ADF Faces components is not a requirement, then a simple JSP or HTML login page can be also used. For details about generating a simple login page when running the Configure ADF Security wizard, see How to Enable ADF Security.

Creating Login Code for the Backing Bean

Before you create the login page as an ADF Faces page, you need to create a managed bean to handle login attempts. In this login bean sample, authentication is handled programmatically using Servlet 3.0-specific API. The login bean handles the login action initiated from a login link with the `doLogin()` method. Upon successful login, this method invokes the servlet API to redirect to a landing page. You will add this bean to the `adfc-config.xml` file and register it with `request` scope.

> **Note:**
>
> This backing bean example described in this section does not authenticate with Oracle Single Sign-On (Oracle SSO). The backing bean handles authentication using login and logout methods provided by Servlet 3.0, which provides generic support for programmatic login on application servers that support Java EE 6 or later.

Before you begin:

It may be helpful to have an understanding of the login page. For more information, see How to Create a Login Page Specifically for Explicit Authentication.

You will need to complete this task:

Run the Configure ADF Security wizard to enable ADF Authentication and Authorization.

To create and register a backing bean for login:

1. In the Applications window, right-click the project in which you want to create the backing bean and choose **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, select **Java** and then **Class**, and click **OK**.
3. In the Create Java Class dialog, enter the name for the login page backing bean class file and disable the default options **Constructors from Superclass** and **Implement Abstract Methods**, and click **OK**.

   For convenience, you might name the backing bean based on the name of your login page, for example, ***LoginPageName*.java**.
4. In the Applications window, expand **Application Sources** and double-click the new ***LoginPageName*.java** backing bean.

5. In the source editor, create two private fields by adding the following in the declaration section of the *LoginPageName*`.java` file:

```
private String _username;
private String _password;
```

6. Generate or create public accessors for both fields.

   You can right-click in the source editor and choose **Generate Accessors** to add the following public accessors to the file:

```
public void setUsername(String _username) {
    this._username = _username;
}

public String getUsername() {
    return _username;
}

public void setPassword(String _password) {
    this._password = _password;
}

public String getPassword() {
    return _password;
}
```

7. Import the following classes:

```
javax.faces.application.FacesMessage
javax.faces.context.ExternalContext
javax.faces.context.FacesContext

javax.servlet.ServletException
javax.servlet.http.HttpServletRequest
javax.servlet.http.HttpSession
```

8. Add a `doLogin()` method to this Java class to handle user attempts to log in:

```
public String doLogin() {
  FacesContext ctx = FacesContext.getCurrentInstance();

  if (_username == null || _password == null) {
     showError("Invalid credentials",
                 "An incorrect username or password was specified.", null);
  } else {
      ExternalContext ectx = ctx.getExternalContext();
      HttpServletRequest request = (HttpServletRequest)
                                   ctx.getExternalContext().getRequest();
      try {
          request.login(_username, _password); // Servlet 3.0 login
          _username = null;
          _password = null;
          HttpSession session = request.getSession();
          session.setAttribute("success_url", "/faces" +
ctx.getViewRoot().getViewId());
          redirect(ectx.getRequestContextPath() + "/adfAuthentication");
      } catch (ServletException fle) {
          showError("ServletException", "Login failed.
             Please verify the username and password and try again.",
null);
      }
22   }
23   return null;
24 }
```

The `doLogin()` method performs the following tasks:

Line 2 and **Lines 6-9** get an object encapsulating the HTTP request from the `ExternalContext`.

Lines 3-5 handle an error when credentials have not been provided. The `showError()` method is a method which you will implement to deal with miscellaneous problems with the login process.

Lines 11-13 attempt to log in the user issuing the request using the Servlet 3.0 API `login()` method. In this programmatic login example, which relies on the Servlet API, Oracle Single Sign-On (Oracle SSO) is not supported.

Lines 14-16 create an HTTP session and set the ADF authentication servlet parameters `success_url` as an attribute of the session. Setting `success_url` on the session ensures the destination page URL is not passed as a request parameter that would be subject to malicious redirects. In this example, the destination page is the current page obtained from the Faces context.

Note: If you run the ADF Security wizard and use the wizard to create a login form, upon successful login, you would want the session to redirect to the target protected page instead of returning to the login page. In this case, `session.setAttribute` in lines 15 and 16 should take `success_url` and the full path of the destination page as attribute, for example: `/faces/protectedPage`.

Line 17 calls a method, `redirect()` which you will implement later in this section to forward the user to the URL that the ADF authentication servlet gets from the HTTP session, as set in Line 15.

Lines 18-21 handle a `ServletException`, which can be thrown by many different problems with a login. For example, exceptions can result from incorrect credentials or attempts to log into a locked account or uses of an expired password. The `showError()` method is a method which you will implement to deal with miscellaneous problems with the login process.

Line 23 returns null so that ADF Controller will not attempt to follow a control flow case.

9. Create stubs for the methods `redirect()` and `showError()`.

10. Add a `redirect()` method with its actions:

```
1  private void redirect(String forwardUrl) {
2    FacesContext ctx = FacesContext.getCurrentInstance();
3    ExternalContext ectx = ctx.getExternalContext();
4    try {
5      ectx.redirect(forwardUrl);
6    } catch (IOException ie) {
7        showError("IOException", "An error occurred during redirecting.
8                        Please consult logs for more information.", ie);
9    }
10 }
```

The `redirect()` method performs the following tasks:

Line 2 gets the ADF Faces `ctx`, which forwards a response to a particular URI.

Lines 3-5 use the `ctx` to redirect the current HTTP response to the URL.

Lines 6-8 handle an `IOException`, which is thrown when the request cannot be read or the response cannot be written to.

11. Implement a `showError()` method:

```
private void showError(String errType, String message, Exception e){
  FacesMessage msg =
        new FacesMessage(FacesMessage.SEVERITY_ERROR, errType, message);
  FacesContext.getCurrentInstance().addMessage("d2:it35", msg);
  if (e != null) {
      e.printStackTrace();
  }
}
```

    This `showError()` method adds a summary error message to the `FacesContext`, and then prints the full stack trace of the exception to the console.

12. Optionally, when you want to trigger logout programmatically from a task flow method call activity, create a stub for a `logoff()` method and implement it as:

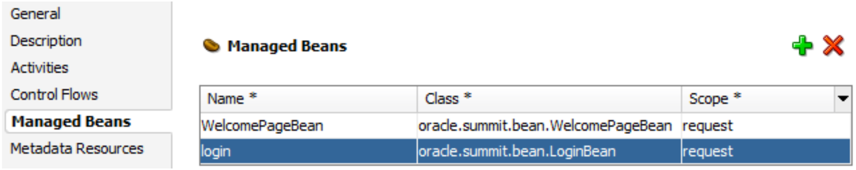
```
public String logoff() {
  FacesContext ctx = FacesContext.getCurrentInstance();
  ExternalContext ectx = ctx.getExternalContext();
  HttpServletRequest httpRequest = (HttpServletRequest) ectx.getRequest();
  try {
      httpRequest.logout(); // Servlet 3.0 logout
      HttpSession session = httpRequest.getSession(false);
      if (session != null) {
          session.invalidate();
      }
      String logoutUrl = ectx.getRequestContextPath() + "/faces" +
                            ctx.getViewRoot().getViewId();
      redirect(logoutUrl);
  } catch (ServletException e) {
      showError("ServletException", "An error occurred during logout.
                  Please consult logs for more information.", e);
  }
  return null;
}
```

    This `logoff()` method uses the `logout()` method of Servlet 3.0 API to process a logoff action.

13. Save the Java file.
14. In the Applications window, expand **WEB-INF** and double-click **adfc-config.xml**.
15. In the editor window, click the **Overview** tab.
16. In the overview editor, click the **Managed Beans** navigation tab.
17. In the Managed Beans page, in the **Managed Beans** section, click the **Add** icon and enter a name for the bean, enter the fully qualified class name, and select scope **request**.

    For example, the class name might look like `oracle.summit.bean.LoginBean`, as shown in Figure 47-20.

Figure 47-20 Login Bean Registered in adfc-config.xml File



Name *	Class *	Scope *
WelcomePageBean	oracle.summit.bean.WelcomePageBean	request
login	oracle.summit.bean.LoginBean	request

18. Save all.

Creating an ADF Faces-Based Login Page Specifically for Explicit Authentication

A simple login page that utilizes ADF Faces layout components and ADF Faces user interface components includes two input fields and a button. You must bind the properties of these UI components to the login handler methods that you defined in the managed bean for the login page.

Note that the page that you can create with this procedure does not support implicit authentication. When you choose to implement implicit authentication, you can customize the default, wizard-generated login form which supports container-managed authentication. The Java EE container expects a form that relies on the `j_security_check` mechanism to handle user-submitted `j_username`, and `j_password` input. In the explicit authentication scenario documented here, Java EE container-managed authentication is not used.

Before you begin:

It may be helpful to have an understanding of explicit authentication. For more information, see How to Create a Login Page Specifically for Explicit Authentication.

You will need to complete this task:

Create the managed bean to handle the user's login attempts, as described in Creating Login Code for the Backing Bean.

To create the ADF Faces-based login page for explicit authentication:

1. In the Applications window, right-click the project in which you want to create the login page and choose **New** and then **New Gallery**.
2. In the New Gallery, expand **Web Tier**, select **JSF** and then **Page**, and click **OK**.
3. In the Create JSF Page dialog, select **JSP XML**.
4. In the **File Name** field, specify a name for your login page. For example, enter `LoginPage.jspx`.

   Select no other options and do not select the option to expose UI components in a managed bean. You will manually bind the components to the managed bean you created for the login page.
5. Click **OK**.
6. Save the page.
7. In the ADF Faces page of the Components window, from the Layout panel, drag a **Panel Box** and drop it on the Structure window below the **af:form** node.
8. In the Property window, enter values for the **Text**, **Horizontal**, **Width**, and **Height** fields.

For example, to create a basic login page, you can enter:

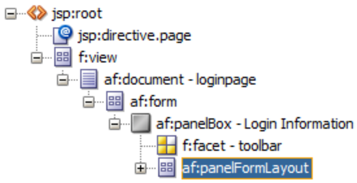
Text set to `Login Information`

Icon set to `/images/key_ena.png`

Width/**Height** set to `300`/`200` pixels

9. From the Components window, drag a **Panel Form Layout** and drop it below the **af:panelBox** node in the Structure window, as shown in Figure 47-21.

Figure 47-21 Login Page Structure with Panel Form Layout



```
jsp:root
    jsp:directive.page
    f:view
        af:document - loginpage
            af:form
                af:panelBox - Login Information
                    f:facet - toolbar
                    af:panelFormLayout
```

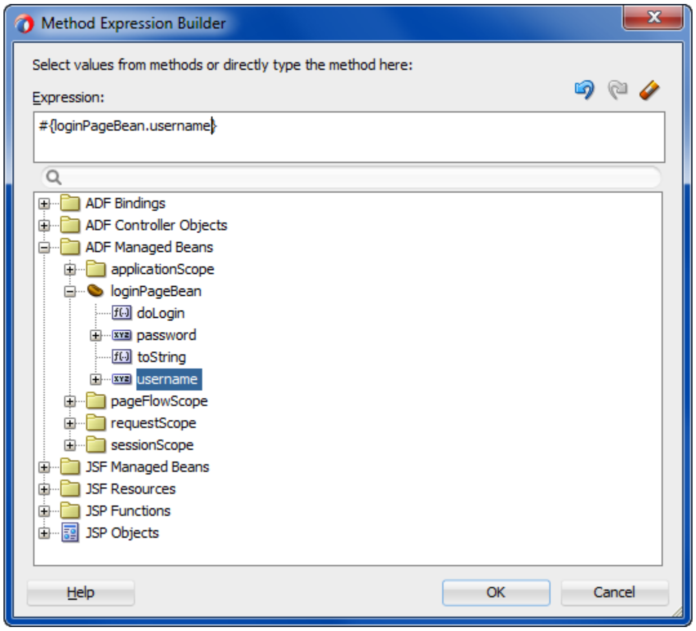
10. From the Common Components panel, drag an **Input Text** and drop it on the **Panel Form Layout** node for the **username** field and another **Input Text** for the password field.
11. In the Property window for the input fields, enter `Username` and `Password` in the **Label** fields and expand the **Behavior** section and select **true** from both fields' **Required** dropdown list.
12. In the Property window, for the password field, expand the **Appearance** section select **true** from the **Secret** dropdown list.
13. To handle processing of the values for the two input fields, perform these steps for each field:

    a. In the Structure window, select one of the input fields (for example, select the **af:inputText - Username** node), and then in the Property window click the **Property Menu** dropdown menu next to the **Value** field and choose **Expression Builder**.

    b. In the Expression Builder, expand **ADF Managed Beans** and expand your login bean, and then select the expression value corresponding to your bean's handler method.

       For example, if you selected the **username** input field in the Structure window, then you would select **username** from the Expression Builder dialog, as shown in Figure 47-22.

Figure 47-22 username Selection in Expression Builder Dialog



Method Expression Builder

Select values from methods or directly type the method here:

Expression:

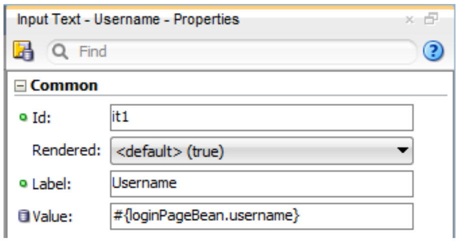
#{loginPageBean.username}

- ADF Bindings
- ADF Controller Objects
- ADF Managed Beans
  - applicationScope
  - loginPageBean
    - doLogin
    - password
    - toString
    - username
  - pageFlowScope
  - requestScope
  - sessionScope
- JSF Managed Beans
- JSF Resources
- JSP Functions
- JSP Objects

c. Click **OK**.

The expression shown in the Property window binds the field to the managed bean you created for the login page. For example, for the username input field, the expression is similar to `#{loginPageBean.username}` as shown in Figure 47-23.

Figure 47-23 username Value in Property Window



Input Text - Username - Properties

Common

Id: it1

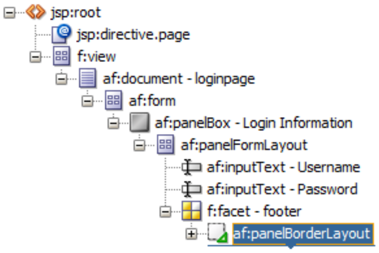
Rendered: <default> (true)

Label: Username

Value: #{loginPageBean.username}

14. From the Components window, from the Layout panel, drag a **Panel Border Layout** and drop it inside the **footer** node of the **af:panelBox** node, as shown in Figure 47-24.

Figure 47-24 Login Page Structure with Panel Border Layout



- jsp:root
  - jsp:directive.page
  - f:view
    - af:document - loginpage
      - af:form
        - af:panelBox - Login Information
          - af:panelFormLayout
            - af:inputText - Username
            - af:inputText - Password
            - f:facet - footer
              - af:panelBorderLayout

15. In the JSP/HTML visual editor, delete the panel border layout facets labeled **End**, **Top**, and **Bottom**. Leave only the **Start** facet.

16. In the Structure window, expand **Panel Border Layout facets** and select the **start** node, and then from the Components window drag and drop a **Button**.

17. In the Property window, enter `Login` in the button component's **Text** field.

18. To handle processing of the login button action, perform these steps.

    a. In the Structure window, select **af:button** under the **start** node, and then in the Property window, click the **Property Menu** dropdown menu next to the **Action** field and choose **Expression Builder**.

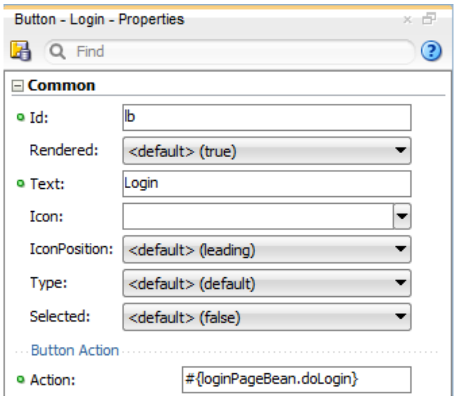
    b. In the Expression Builder, expand **ADF Managed Beans** and expand your login bean, and then select the expression value corresponding to your login method.

       For example, if you created a method in the login bean named `doLogin()`, then you would select **doLogin** in the Expression Builder dialog.

    c. Click **OK**.

       The expression shown in the Property window binds the button to the managed bean you created for the login page. For example, for the login button, the expression is similar to `#{loginPageBean.doLogin}` as shown in Figure 47-25.

Figure 47-25 login Action in Property Window



Button - Login - Properties

Common

Id: lb

Rendered: <default> (true)

Text: Login

Icon:

IconPosition: <default> (leading)

Type: <default> (default)

Selected: <default> (false)

Button Action

Action: #{loginPageBean.doLogin}

19. Save the page.

Ensuring That the Login Page Is Public

Because the application is secured by ADF Security, all web pages defined within bounded task flows and any web page defined by an ADF page definition will be inaccessible by default. Since all users must be allowed to log on, the login page should remain publicly accessible, and thus you should add no databound components to the page. As long as the login page uses no databound components, then it will be accessible by default.

No further steps are required to ensure that the container will always redirect to the defined authentication point before allowing access to the page (which in this case is the authentication page).

How to Ensure That the Custom Login Page's Resources Are Accessible for Explicit Authentication

When you run the ADF Security wizard and choose the **ADF Authentication** option (because you do not want to enable ADF authorization) and your application uses a custom login page or a custom error page, you may need to edit the default Java EE security constraint added to the `web.xml` file by ADF Security. As shown in the following example, the default URL pattern (`/*`) defined in the `allPages` security constraint covers everything under the Java EE application root, meaning that the resource files (such as images, style sheets, or JavaScript library) used by the login page are also included.

```
<security-constraint>
   <web-resource-collection>
      <web-resource-name>allPages</web-resource-name>
      <url-pattern>/*</url-pattern>
   </web-resource-collection>
   <auth-constraint>
      <role-name>valid-users</role-name>
   </auth-constraint>
</security-constraint>
```

If the pages you create use resources, such as images, CSS files, or JavaScript libraries, the default `allPages` security constraint in the `web.xml` file will prevent those resources from loading at runtime. To allow your application to display those resources, you should save the resources in a folder of their own and then edit the `allPages` security constraint so that the resources folder is not contained in the URL pattern.

Note that this resource issue does not apply when you run the ADF Security wizard and choose the **ADF Authentication and Authorization** option (the default). Specifically, in that case, the default generated constraint is on the ADF Authentication servlet and the constraint (`/adfAuthentication`) excludes any resource files.

How to Create a Public Welcome Page

Because web applications are generally secured, there is always a need for a starting point or home page for unauthenticated users. To create this public welcome page, you create an ADF Faces page to act as the entry point for the application, which contains links to other pages within the application. However, only links to public pages should be rendered to unauthenticated users and, conversely, links to secured pages should be rendered only after the user has logged in and has the appropriate privileges to view the target page.

Best Practice:

When the user presses Ctrl-N or Ctrl-T to open a new browser window or tab and no welcome page is defined in the application's `web.xml` file, the browser will display a 403 or 404 error. To prevent this error, you must specify a welcome page definition in the application's `web.xml` file. You can create this definition when you run the Configure ADF Security wizard. For details about running the wizard, see How to Enable ADF Security.

Ensuring That the Welcome Page Is Public

After you have created a regular ADF Faces page, the page will, by default, be public and accessible by unauthenticated users. If, however, you have associated the welcome page with an ADF resource, for example, by dropping databound ADF Faces components into the welcome page using the Data Controls panel, then ADF Security will secure the page by default. You can make any ADF resource publicly accessible using the overview editor for security policies to grant a view privilege on the resource to the provided `anonymous-role`. For details about the `anonymous-role` see, What Happens When You Make an ADF Resource Public.

Adding Login and Logout Links

You can add login and logout links to your public welcome page so that users can explicitly log in and out while they are in the application. While Java EE container-managed security supports the concept of authentication when accessing a secured resource, there is no standard way to log out and stay within a secured application. However, it is a common practice in web applications to allow the user to stay on the same page if that page is public or to return the user to the welcome page if that page is secured. While adding the login and logout links to each page would let the user end their login session anywhere within the application (and return to the welcome page), having these links on the welcome page enables users to explicitly authenticate on entering the application.

For example, you can create an ADF Faces panel group with three components, including an output text area, an image, and login/logout links. To render the appropriate login or logout link, you can use an EL expression that evaluates the user’s authentication status. Specifically, you can use `securityContext.authenticated` to access the ADF security context, as shown in the following example. The expression evaluates to `true` or `false` and, in this example, the result determines which login/logout image and link to display. As the following example shows, the link triggers the `logon` and `logoff` methods of the security bean.

```
<af:panelGroupLayout inlineStyle="width:100%; height:15px;" id="ptpgl3">
     <af:spacer width="7" height="10" id="pts2"/>
     <af:outputText value="Welcome #{securityContext.userName}!"
                           inlineStyle="font-weight:bold; width:100px" id="ptot2"
                           rendered="#{securityContext.authenticated}"/>
     <af:image source="#{securityContext.authenticated ? '/images/lock.gif' : '/
images/key.gif'}"
               id="pti2" inlineStyle="width:16px; height:16px;"
shortDesc="switchable icon"/>
     <af:link text="Logon" id="l1" action="#{securityBean.logon}"
                rendered="#{!securityContext.authenticated}"/>
     <af:link text="Logoff" id="l2" action="#{securityBean.logoff}"
```

```
                rendered="#{securityContext.authenticated}"/>
     <f:facet name="separator">
         <af:spacer width="5" height="10" id="pts1"/>
     </f:facet>
</af:panelGroupLayout>
```

The security bean that implements the logon and logoff methods may use the ADF AuthenticationService API to protect the application from malicious redirects. This achieves the same level of protection as invoking the ADF authentication servlet with null success_url and end_url parameters that the web.xml file whitelists, but is considered a best practice alternative to handling navigation with task flows. For more details about redirects, see How to Redirect a User After Authentication.

As an alternative to rendering the link directly within a page, you can create a login link component with the login and logout links that you can add to a page template, as described in How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication.

Hiding Links to Secured Pages

Since an anonymous user should not have access to any secured pages, any navigation component on the welcome page that points to a secured page should be hidden from view based on the following two criteria:

- Is the user authenticated with a known user identity?
- Does the specified user identity have permission to view the target?

If either of these criteria has not been met, the rendered attribute of any navigation component on a public page that points to a secured resource must have its rendered attribute set to false, thus hiding it from the anonymous user. To enforce these rules within your welcome page, see Using Expression Language (EL) with ADF Security.

How to Redirect a User After Authentication

When you have chosen to implement implicit authentication, after the user accesses a secured web page and logs in, the ADF authentication servlet will redirect back to the original page that initiated the login request. With ADF Security authentication enabled, the ADF automatically passes on the session map the original page as the ADF authentication success_url parameter. Typically, this is the desired behavior.

Additionally, when you have chosen to implement implicit authentication, you can protect the Fusion web application from malicious redirects by specifying the success_url parameter as an init-param element within the web.xml file. However, because the ADF authentication servlet automatically passes the original page as the success_url parameter, which supersedes any web.xml setting, in practice the only scenario in which an init-param setting in web.xml takes effect is when the user explicitly types the adfAuthentication URL into the browser.

However, when you choose to implement explicit authentication and display an explicit login link in your page, the ADF Security framework is not able to determine the originating page. In this case, your login link ensures the ADF Authentication servlet redirects to the desired page after authentication by passing the view activity name of the web page as the servlet success_url parameter, as shown in the following example.

```
<af:link text="Login" destination="/adfAuthentication?success_url=/faces/
viewactivityname"/>
```

> **Best Practice:**
>
> For explicit authentication, to ensure that the Fusion web application handles the ADF authentication redirect as an ADF Controller navigation event, specify the redirect target by its view activity name. Specifically, without specifying a view activity as the redirect target, command components, such as the `af:button` component, will always return to the original page after login. Passing the view activity name as the redirect target of the ADF authentication servlet `success_url` and `end_url` parameters ensures the application handles navigation using control flow rules in all cases.

In the case of explicit authentication, following the best practice of defining the `success_url` with a task flow view activity name protects the Fusion web application from malicious redirects by ensuring the ADF authentication servlet ignores any `adfAuthentication` URL that a user may attempt to type into the browser. Alternatively, when a task flow activity is not convenient, your application can use the `AuthenticationService` API to implement login and logout methods that handle the redirect in a secure way. For more information about using the API in a security bean, see What You May Need to Know About Redirecting to a Different Host Server.

In cases where the user is authenticated but not authorized to view a web page, you can redirect the ADF authentication servlet to an error page in your application. Error handling in Fusion web applications is under the control of the ADF Controller exception handler unless you have created an application that does not use a task flow in its design. For example, in an unbounded task flow, where you have defined an unbounded task flow with a top-level welcome page and a browse page (secured through its ADF page definition), you would see an error page from the application, named `authorizationErrorPage.jspx`, specified in the `adfc-config.xml` file, as shown in the following example.

```
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <exception-handler>authorizationErrorPage</exception-handler>
  <view id="welcomePage">
    <page>/welcomePage.jspx</page>
  </view>
  <view id="browse">
    <page>/browse.jspx</page>
  </view>
  <view id="authorizationErrorPage">
    <page>/authorizationErrorPage.jspx</page>
  </view>
  <control-flow-rule>
    <from-activity-id>welcomePage</from-activity-id>
    <control-flow-case>
      <from-outcome>goToSecuredPage</from-outcome>
      <to-activity-id>browse</to-activity-id>
    </control-flow-case>
  </control-flow-rule>
</adfc-config>
```

For details about how to specify an error page as a view activity for the ADF Controller exception handler, see Handling Exceptions in Task Flows.

In cases where the user is not authenticated and an authorization failure occurs, the framework redirects to the ADF authentication servlet, which in turn triggers a Java EE constraint that prompts for login. In this case, container-managed security relies on the login page and error page that you specify in the `<login-config>` element of the `web.xml` file.

If you create a Fusion web application without utilizing task flows, then you can specify an `<init-param>` setting in `web.xml` for the **ADF binding filter**, as shown in the following example. In this case, when no task flow is present in the application, page authorization checking is handled by the ADF binding filter, and the `unauthorizedErrorPage` parameter will be passed to the ADF binding request handler.

> **Note:**
>
> The `unauthorizedErrorPage` parameter feature is provided for compatibility with previous releases where ADF Controller was not available. In Fusion web applications, when you need to redirect users to an error page, you use the task flow exception handler to specify the error page, as shown in the previous example.

```
<filter>
    <filter-name>adfBindings</filter-name>
    <filter-class>oracle.adf.model.servlet.ADFBindingFilter</filter-class>
    <init-param>
        <param-name>unauthorizedErrorPage</param-name>
        <param-value>faces/authorizationErrorPage.jspx</param-value>
    </init-param>
</filter>
```

How to Trigger a Custom Login Page Specifically for Implicit Authentication

When you have chosen to implement implicit authentication to allow users to access protected resources (which may be by direct URL access or by navigating to an ADF Security protected resource), the ADF Security authentication servlet initiates the Java EE container to display the login form configured in the `web.xml` file. For implicit authentication, when you have customized the default, wizard-generated login form to use ADF Faces components, you must modify the URL pattern for the servlet mapping to reference the ADF Faces servlet.

You can accomplish this in the Authentication Type page of the Configure ADF Security wizard when you configure ADF Security, or in the `web.xml` file directly. If you have already run the Configure ADF Security wizard, you can use the following procedure to confirm that the `web.xml` file has been updated as described.

When you have chosen to implement explicit authentication and have created a public page to allow users to login to access protected resources, the login form you create will not be triggered by ADF Security. In the explicit authentication scenario, you do need to configure the `web.xml` file.

> **Note:**
>
> Configuring the `web.xml` file with the login page application path when your application implements explicit authentication programmatically, as described in Creating an ADF Faces-Based Login Page Specifically for Explicit Authentication, may produce unpredictable results and login may fail. Only modify the `web.xml` file when you are implementing implicit authentication and you have created a form that relies on the `j_security_check` action, as does the default, wizard-generated login form.

Before you begin:

It may be helpful to have an understanding of the login page. For more information, see How to Create a Login Page Specifically for Explicit Authentication.

To reference an ADF Faces login page for implicit authentication:

1. In the Applications window, expand **WEB-INF** and double-click **web.xml**.
2. In the overview editor for the `web.xml` file, click the **Security** navigation tab.
3. In the Security page, expand the **Login Authentication** section, and set the login page to include a reference to the ADF Faces servlet such that the login page can be part of the ADF Faces lifecycle `/faces/ADFlogin.jspx` page.

   When you add a page using the file browser, the path entered in the `web.xml` file will not specify `/faces`. Modify the entry so that the path references the servlet mapping path for the ADF Faces servlet. For example, if the URL pattern specified by the mapping is `/faces/*`, then your path should look like `/faces/`*`yourpage`*`.jspx`, as shown in Figure 47-26.

   Figure 47-26 Adding a Reference to the Faces Servlet in the Login Configuration

   
   ● Form-Based Authentication
   Login Page: /faces/facesLogin.jspx
   Error Page: /faces/facesError.jspx

How to Ensure That the Redirect Destination Page is Available

When the ADF authentication servlet directs the user to login, it puts the redirect destination defined by the `success_url` on the Session map. However, in the case where the session times out before the user has authenticated, the Session map looses the value of `success_url` and the application looses the ability to navigate to the destination page.

To ensure the login redirect destination is always available to the application, you can define the `success_url` parameter as a task flow navigation outcome rule or you can define it statically when you run the Configure ADF Security wizard as a single whitelisted page that will appear in the `web.xml` file.

Because the `web.xml` file must be defined prior to deployment, the Fusion web application supports an alternative, dynamic approach to configuring the redirect URL `success_url` parameter that involves defining connection reference values. These values may also be configured in `connections.xml` file directly.

To use the `connections.xml` file as a persistence store for the ADF authentication servlet redirect destination:

1. In the `web.xml` file, add the `init-param` named `oracle.adf.share.security.authentication.connections` to the ADF authentication servlet definition and specify the `param_value` as the connection reference name that appears in the `connections.xml` file, located in the `adf/META-INF` folder, as the following example shows.

```
<servlet>
  <servlet-name>adfAuthentication</servlet-name>
    <servlet-class>
      oracle.adf.share.security.authentication.AuthenticationServlet
    </servlet-class>
    <init-param>
      <param-name>
        oracle.adf.share.security.authentication.connections
      </param-name>
      <param-value>my_connection_name</param-value>
    </init-param>
   ...
</servlet>
```

2. In the `connections.xml` file, define the `success_url` and, optionally, `end_url` in the named connection reference, as the following example shows.

```
<References xmlns="http://xmlns.oracle.com/adf/jndi">
  <Reference name="my_connection_name"
             className=

"oracle.adf.share.security.authentication.AuthenticationConnection"
             xmlns="">
    <Factory className=

"oracle.adf.share.security.authentication.AuthenticationConnection"/>
    <RefAddresses>
      <StringRefAddr addrType="success_url">
        <Contents>
           http://localhost:port/context_root/faces/welcomePage</Contents>
      </StringRefAddr>
      <!-- end_url for logout -->
      <StringRefAddr addrType="end_url">
        <Contents>
           http://localhost:port/context_root/faces/publicPage</Contents>
      </StringRefAddr>
    </RefAddresses>
  </Reference>
</References>
```

Note that the destination URL may omit the host name, port number, and context root, when redirecting the application to the current request host, port, and context root. In this case, the URL is specified as `/faces/pagename`, where `/faces` loads the page in the context of ADF Faces and supports pages designed with ADF Faces components.

At runtime, if the redirect URL is not on Session map, the ADF authentication servlet gets the connection name from `init-param` named `oracle.adf.share.security.authentication.connections` to lookup the connection from `connections.xml` file. If no connection is named or if `success_url` (login) or end_url (logout) are not in connections.xml, then the ADF authentication servlet will check if success_url or end_url is defined in the web.xml.

What You May Need to Know About Redirecting to a Different Host Server

During logout it may be necessary to redirect the user to an arbitrary web page or host server that differs from the originating server of the Fusion web application. In this scenario, the application should be protected from a malicious redirect by ensuring the destination page URL is not placed by the application on the Request and will instead use the Session map. To accomplish this, a best practice is to block passing ADF redirect parameters on the browser URL by adding the servlet init-param element disable_url_param set to true to the ADF authentication servlet definition in the web.xml file as this example shows.

```
<servlet>
   <servlet-name>adfAuthentication</servlet-name>
   <servlet-class>
        oracle.adf.share.security.authentication.AuthenticationServlet
   </servlet-class>
   <init-param>
      <param-name>success_url</param-name>
      <param-value>faces/welcome</param-value>
   </init-param>
   <init-param>
      <param-name>end_url</param-name>
      <param-value>faces/welcome</param-value>
   </init-param>
   <init-param>
      <param-name>disable_url_param</param-name>
      <param-value>true</param-value>
   </init-param>
   <load-on-startup>1</load-on-startup>
</servlet>
...
```

Legacy applications that were built before ADF enforced passing the redirect parameters on the Session map that would otherwise expose the parameters on the browser URL Request should not set the disable_url_param to true and should instead consider implementing a security bean using the ADF interface oracle.adf.share.security.AuthenticationService to handles ADF-specific login and logout methods by placing the target destination on the Session map.

The following example illustrates how to use the logout() method of the AuthenticationService interface. This method will internally put the passed in URL on the Session map and will ignore the end_url parameter that might explicitly be set on the URL by a user. Similarly, the login() method places the login URL destination on the Session map. When you need logout to redirect to a web page on a different server, your method implementation may pass the URL of the desired web page and still be protected from a malicious redirect.

```
import javax.faces.context.ExternalContext;
import javax.faces.context.FacesContext;

import javax.servlet.http.HttpServletRequest;
import javax.servlet.http.HttpServletResponse;
import oracle.adf.share.security.AuthenticationService;
import oracle.adf.share.security.authentication.AuthenticationServiceUtil;

public class SecurityBean {
    public SecurityBean() {
        super();
    }

    public boolean isAuthenticated() {
        ExternalContext ectx =
                          FacesContext.getCurrentInstance().getExternalContext();
        return ectx.getUserPrincipal() != null;
    }

    public void logon() {
        if (!isAuthenticated())
        {
            FacesContext ctx = FacesContext.getCurrentInstance();
            AuthenticationServiceUtil.getAuthenticationService().login("/faces" +
                                        ctx.getViewRoot().getViewId(), null,
null);
        }
    }

    public void logoff() {
        if (isAuthenticated())
        {
            AuthenticationServiceUtil.getAuthenticationService().
                                                  logout("/faces/index", null);
        }
    }
}
```

An alternative to the programmatic approach handles placing the destination URL on the Session map by invoking the ADF authentication servlet in an explicit link with null value success_url and end_url parameters. In this case, the ADF authentication servlet will try to obtain the redirect values from the web.xml file (or the connections.xml file) and will ignore any values that a user might attempt to enter on the URL. This approach requires configuring the ADF authentication servlet definition in the web.xml by specifying an init-param element for the success_url and end_url parameters. In effect, this is a declarative approach that results in a whitelist with a single destination for login and logout redirects.

What You May Need to Know About Fusion Web Application Logout and Browser Caching

When basic type authentication is in effect as specified in the Fusion web application's web.xml file, the browser caches authentication credentials. This is a known issue with basic authentication that re-authenticates users after the logout redirect is performed by the ADF authentication servlet. In this scenario, in order to complete the logout session and prevent users from accessing resources, it is necessary to close the browser and restart a new browser session.

To ensure the ADF application completes logout and prevents a user from being able to access resources after logout, use form-based authentication instead of basic authentication. You can select form-based authentication when you run the Configure ADF Security wizard, as described in How to Enable ADF Security.

What You May Need to Know About Displaying Error Pages in Internet Explorer

When you enable ADF Security to display a custom error page, any HTTP errors that the application generates in response to a request to view a page, should result in the error page being displayed. However, in certain versions of Internet Explorer, the browser will display either the custom error page or an error message built into Internet Explorer. If Internet Explorer displays only an error message you can disable the option to display error message numbers in the Advanced settings of the Internet Options dialog. In Internet Explorer 10, this option is enabled by default. You should disable **Show friendly HTTP error messages** when you want to display a custom error page that you enabled with the Configure ADF Security wizard.

To ensure custom error pages display in Internet Explorer 10:

1. In Internet Explorer toolbar, click the **Tools** button.
2. In the Internet Options dialog, click the **Advanced** tab.
3. In the Advanced tab, scroll and locate **Show friendly HTTP error messages**.
4. Click the option to disable it and click **OK**.

Testing Security in JDeveloper

For testing ADF Security, JDeveloper lets you run the application using Integrated WebLogic Server and decides whether to migrate security objects defined in your application.

Integrated WebLogic Server enables you to run the application directly within JDeveloper and determine whether or not to migrate security objects, including the application policies, users, and credentials that your application defines. By default, all security objects are migrated to Integrated WebLogic Server each time you run the application.

How to Configure, Deploy, and Run a Secure Application in JDeveloper

JDeveloper is configured by default to deploy the security objects from your application repositories to Integrated WebLogic Server each time you run the application. You can change this behavior by selecting security deployment options in the Application Properties dialog to:

- Decide whether to overwrite the domain-level policies with those from the application `jazn-data.xml` file
- Decide whether to overwrite the system credentials from the application's `cwallet.sso` file

  The `cwallet.sso` file (located in JDeveloper in the Application Resources panel of the Applications window under the **Descriptors-META-INF** node) stores credentials as securely kept objects that are presented to the authentication provider to be matched against identities. The file is encrypted and cannot be browsed or edited within JDeveloper. At design-time, different components make use of `cwallet.sso` file and are responsible for creating the necessary credentials in it.

- Decide whether to migrate the identity store portion of the `jazn-data.xml` file to the domain-level identity store

If you make no changes to the deployment settings, each time you run the application, JDeveloper will overwrite the domain-level security policies and system credentials. Additionally, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. However, if you prefer to run the application without updating the existing security objects in Integrated WebLogic Server, you have this option.

Before you begin:

It may be helpful to have an understanding of using Integrated WebLogic Server. For more information, see Testing Security in JDeveloper.

To configure security deployment and run the application in JDeveloper:

1. In the main menu, choose **Application** and then **Secure > Configure Security Deployment**.
2. In the Application Properties dialog, in the Deployment page, in the **Security Deployment Options** section, select the security objects that you want to deploy to Integrated WebLogic Server.

   By default, each time you run the application, JDeveloper will overwrite the application policies and system credentials at the domain level with those from the application. If you prefer not to overwrite either of these repositories, deselect **Application Policies** or **Credentials**. When deselected, JDeveloper will merge only new polices or credentials into the domain-level stores.

   By default, each time you run the application, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. You can disable migration of the application identity store by deselecting **Users and Groups**.
3. Click **OK**.
4. In the Applications window, right-click the user interface project that contains the secured web pages and choose **Run**.

   When you choose **Run** on the user interface project, JDeveloper will run the application using the default run target you configured for the project. For example, you can configure a task flow activity as the run target to start your application. To configure the default run target, see Testing Task Flows.

   The Create Default Domain dialog appears the first time you run the application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

What Happens When You Configure Security Deployment Options

When you run the application using Integrated WebLogic Server, JDeveloper migrates the security policies and credentials to the domain level based on security deployment configuration settings specified in the Application Properties dialog. During the deployment process, JDeveloper updates the weblogic-application.xml file that it adds to the deployment archive file with the Application Properties settings, as shown in the following example. Note that these settings are not added to the weblogic-application.xml file in the application source directory and thus are not visible.

```
<application-param>
    <param-name>jps.credstore.migration</param-name>
    <param-value>OVERWRITE</param-value>
</application-param>
<application-param>
    <param-name>jps.policystore.migration</param-name>
    <param-value>OVERWRITE</param-value>
</application-param>
```

The OVERWRITE value allows you to modify the security policies and credentials in your application and redeploy either to Oracle WebLogic Server running in development mode or to Integrated WebLogic Server (set up to run in development mode by default).

> **Note:**
>
> When you eventually deploy to a production environment, the migration settings in the weblogic-application.xml file are ignored; it would be considered a security vulnerability to allow existing policies and credentials to be overwritten. For information about deploying to a production environment, see Preparing the Secure Application for Deployment.

JDeveloper also updates the weblogic-application.xml file with OPSS lifecycle listeners, as shown in the following example. To initiate the migration process before the application runs, the lifecycle listeners observe the migration settings for policies and credentials and overwrite the security objects at the domain level.

```
<listener>
    <listener-class>
        oracle.security.jps.wls.listeners.JpsApplicationLifecycleListener
    </listener-class>
</listener>
<listener>
    <listener-class>
        oracle.security.jps.wls.listeners.JpsAppVersionLifecycleListener
    </listener-class>
</listener>
```

During the migration process, JDeveloper maps the Oracle Platform Security Services (OPSS) application role member classes to the Integrated WebLogic Server member classes and migrates the users to WebLogic Server identity store users and migrates the roles to WebLogic Server identity store groups. In Oracle WebLogic Server, users is an implicit group equivalent to OPSS authenticated-role.

Identity store migration is not controlled by the application lifecycle listener settings in the weblogic-application.xml file. Instead, an Oracle WebLogic Mbean handles migrating the identities when running in Integrated WebLogic Server or when deploying from JDeveloper. If the user already exists, the Mbean will not migrate the entire user definition. Only the user password will be updated.

How to Use the Built-In test-all Application Role

When you run the Configure ADF Security wizard, you can enable the option to add the `test-all` application role to the policy store in the `jazn-data.xml` file. When you enable this option, you also specify the scope of grants to the application role for your application:

- Select **Grant to Existing Objects Only** when you want JDeveloper to grant view rights to the `test-all` application role and you want this policy to apply to all the ADF task flows and web pages that appear in your user interface project at the time you run the wizard.
- Select **Grant to All Objects** when you want JDeveloper to grant view rights to the `test-all` application role and you want this policy to apply to all existing and future ADF task flows and web pages that developers will create in the user interface project. Note that the wizard displays the option **Grant to New Objects** after you run the wizard the first time with the **Grant to All Objects** option selected.

After you run the wizard, the `test-all` role appears in the `jazn-data.xml` file and is visible in the overview editor for security policies. You will not need to populate the `test-all` role with test users since the wizard assigns the built-in application role `anonymous-role` to the `test-all` role. In this case, all users will automatically have the `anonymous-role` principal and will be permitted to access the application.

> **Note:**
>
> Before you deploy the application, you must remove all occurrences of the `test-all` role from the policy store, as described in How to Remove the test-all Role from the Application Policy Store. This will prevent unauthorized users from accessing the web pages of your application.

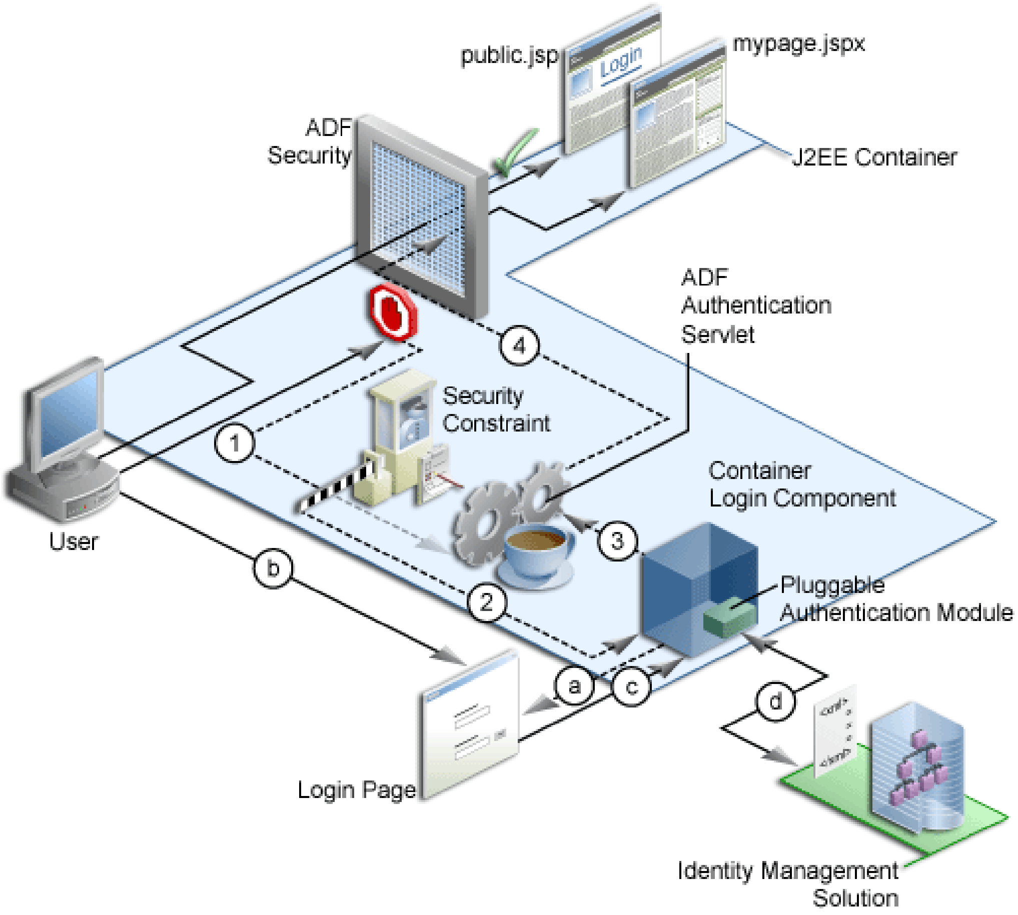
You can rerun the wizard and disable automatic grants at any time. Once disabled, new ADF task flows and web pages that you create will not utilize the `test-all` role and will therefore require that you define explicit grants, as described in Defining ADF Security Policies.

What Happens at Runtime: How ADF Security Handles Authentication

When you test the application in JDeveloper using Integrated WebLogic Server, the identity store is migrated to the embedded LDAP server, with information stored in Oracle Internet Directory.

Figure 47-27 illustrates the authentication process when users attempt to access an ADF bounded task flow or any web page containing ADF bindings (such as `mypage.jspx`) without first logging in. Authentication is initiated implicitly because the user does not begin login by clicking a login link on a public page. In the case of the secured page, no grants have been made to the anonymous user.

Figure 47-27 ADF Security Implicit Authentication



In Figure 47-27, the implicit authentication process assumes that the resource does not have a grant to `anonymous-role`, that the user is not already authenticated, and that the authentication method is Form-based authentication. In this case, the process is as follows:

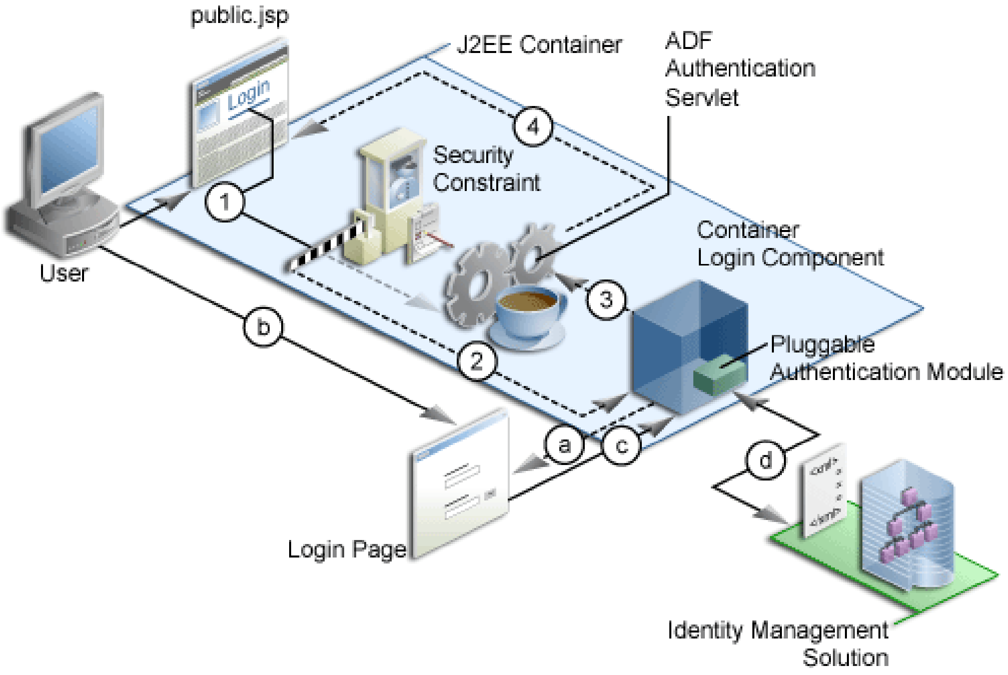
1. When the bounded task flow or web page (with ADF bindings) is requested, the ADF bindings servlet filter redirects the request to the ADF authentication servlet (in the figure, Step 1), storing the logical operation that triggered the login.
2. The ADF authentication servlet has a Java EE security constraint set on it, which results in the Java EE container invoking the configured login mechanism (in the figure, Step 2). Based on the container's login configuration, the user is prompted to authenticate:
   a. The appropriate login form is displayed for form-based authentication (in the figure, Step 2a).
   b. The user enters their credentials in the displayed login form (in the figure, Step 2b).
   c. The user posts the form back to the container's `j_security_check()` method (in the figure, Step 2c).
   d. The Java EE container authenticates the user, using the configured pluggable authentication module (in the figure, Step 2d).

3. Upon successful authentication, the container redirects the user back to the servlet that initiated the authentication challenge, in this case, the ADF authentication servlet (in the figure, Step 3).
4. On returning to the ADF authentication servlet, the servlet subsequently redirects to the originally requested resource (in the figure, Step 4).

   Whether or not the resource is displayed will depend on the user's access rights and on whether authorization for ADF Security is enforced, as explained in What Happens at Runtime: How ADF Security Handles Authorization.

Figure 47-28 illustrates the explicit authentication process when the user becomes authenticated starting with the login link on a public page.

Figure 47-28 ADF Security Explicit Authentication



In an explicit authentication scenario, an unauthenticated user (with only the `anonymous` user principal and `anonymous-role` principal) clicks the **Login** link on a public page (in the figure, Step 1). The login link is a direct request to the ADF authentication servlet, which is secured through a Java EE security constraint in the `web.xml` file.

In this scenario, the current page is passed as a parameter to the ADF authentication servlet. As with the implicit case, the security constraint redirects the user to the login page (in the figure, Step 2). After the container authenticates the user, as described in Step a through Step d in the implicit authentication case, the request is returned to the ADF authentication servlet (in the figure, Step 3), which subsequently returns the user to the public page, but now with new user and role principals in place.

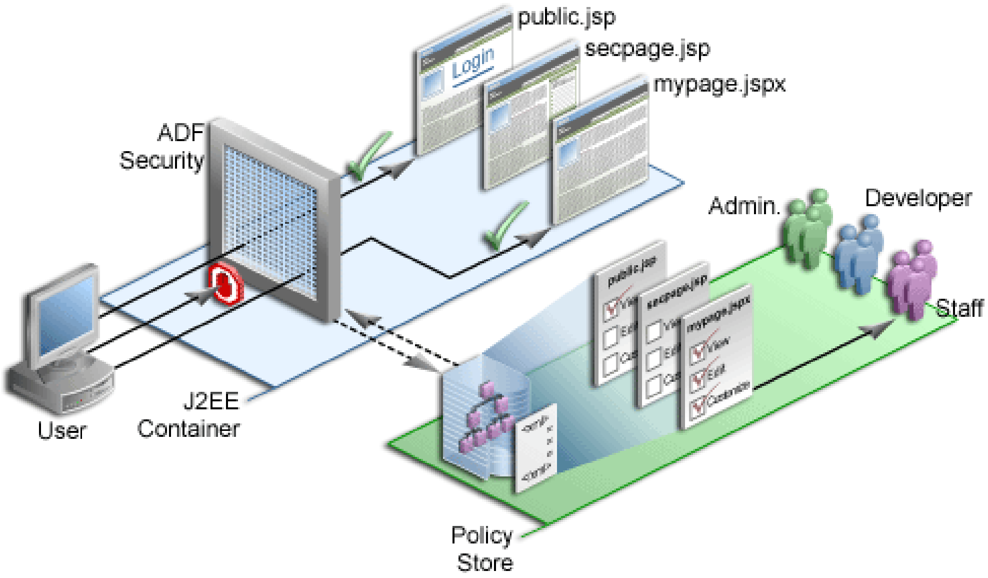
What Happens at Runtime: How ADF Security Handles Authorization

When ADF authorization is enabled, the ADF bounded task flows and web pages outside of a task flow that have an ADF page definition will be secure by default.

When a user attempts to access these web pages, ADF Security checks to determine whether the user has been granted access in the policy store. If the user is not yet authenticated, and the page is not granted to the `anonymous-role`, then the application displays the login page or form. If the user has been authenticated, but does not have permission, a security error is displayed. If you do not configure the policy store with appropriate grants, the pages will remain protected and therefore stay unavailable to the authenticated user.

Figure 47-29 illustrates the authorization process.

Figure 47-29 ADF Security Authorization



The user is a member of the application role *staff* defined in the policy store. Because the user has not yet logged in, the security context does not have a subject (a container object that represents the user). Instead, Oracle Platform Security Services provides ADF Security with a subject with the `anonymous` user principal (a unique definition of the user) and the `anonymous-role` principal.

With the `anonymous-role` principal, typically the user would be able to access only pages not defined by ADF resources, such as the `public.jsp` page, whereas all pages that are defined either by an ADF task flow or outside of a task flow using an ADF page definition file are secure by default and unavailable to the user. An exception to this security policy would be if you were to grant `anonymous-role` access to ADF resources in the policy store. In this case, the user would not be allowed immediate access to the page defined by an ADF resource.

When the user tries to access a web page defined by an ADF resource, such as `mypage.jspx` (which is specified by an ADF page definition, for example), the ADF Security enforcement logic intercepts the request and because all ADF resources are secured by default, the user is automatically challenged to authenticate (assuming that the `anonymous-role` is not granted access to the ADF resource).

After successful authentication, the user will have a specific subject. The security enforcement logic now checks the policy store to determine which role is allowed to view `mypage.jspx` and whether the user is a member of that role. In this example for mypage.jspx, the view privilege has been granted to the staff role and because the user is a member of this role, they are allowed to navigate to mypage.jspx.

Similarly, when the user tries to access secpage.jsp, another page defined by ADF resources, for which the user does not have the necessary view privilege, access is denied.

Users and roles are those already defined in the identity store of the resource provider. Application roles are defined in the policy store of the jazn-data.xml file.

Preparing the Secure Application for Deployment

Oracle ADF applications should be deployed to a target application server after testing. You can run an application in the Integrated WebLogic Server as well as deploy it to a standalone Oracle WebLogic Server

After testing in JDeveloper using Integrated WebLogic Server, you will eventually want to deploy the application to a standalone server. Initially, the server you target will be your staging environment where you can continue development testing using that server's identity store before deploying to the production environment. Thus, you will typically not migrate the test users you created to run with Integrated WebLogic Server. The steps you perform to migrate credentials (in the cwallet.sso file) and security policies (in the jazn-data.xml file) to standalone Oracle WebLogic Server will depend on the configured mode of the target server and whether you deploy using JDeveloper or a tool outside of JDeveloper.

> **Note:**
>
> For details about deploying from JDeveloper to a development environment, see Deploying Fusion Web Applications.

When the target server is configured for **development mode**, you can deploy directly from JDeveloper. In this case, JDeveloper automatically handles the migration of the policy store, system credentials, and identity store (users and groups) as part of the deployment process. Application security deployment properties are configured by default to allow the deployment process to overwrite the domain-level policy store and the system credentials. Additionally, the identity store deployment property is configured by default to migrate the identity store consisting of your test users. You can change this default deployment behavior in the Application Properties dialog, as described in How to Configure, Deploy, and Run a Secure Application in JDeveloper.

> **Note:**
>
> Note that migration of system credentials to Oracle WebLogic Server running in development mode will be performed only if the target server is configured to permit credential overwrite. For details about configuring Oracle WebLogic Server to support overwriting of system credentials, see the Configuring the OPSS Security Store chapter in *Securing Applications with Oracle Platform Security Services*.

When the target server is configured for **production mode**, you typically handle the migration task outside of JDeveloper using tools like Oracle Enterprise Manager. For details about using tools outside of JDeveloper to migrate the policy store to the domain-level in a production environment, see the Configuring the OPSS Security Store chapter in *Securing Applications with Oracle Platform Security Services*. Note that Oracle WebLogic Server running in production mode does not support the overwriting of system credentials under any circumstances.

Before you deploy the application, you will want to remove the `test-all` application role if you enabled the automatic grants feature in the Configure ADF Security wizard. Because the `test-all` role makes all ADF resources public, its presence increases the risk that your application may leave some resources unprotected. You must therefore remove the role before you migrate application-level policy store.

Additionally, when you prepare to deploy the application to Oracle WebLogic Server, you will want to remove the test identities that you created in the `jazn-data.xml` file. This will ensure that users you created to test security policies are not migrated to the domain-level identity store.

> **Best Practice:**
>
> If you deploy your application to the standalone environment, you must not migrate users and enterprise roles in your local identity store that are already configured for Oracle WebLogic Server. For example, if you were to deploy the identity store with the user `weblogic` and enterprise role `Administrators`, you would overwrite the default administration configuration on the target server. To ensure you avoid all possible conflicts, you can disable migration of the identity store, as described in How to Remove Test Users from the Application Identity Store.

How to Remove the test-all Role from the Application Policy Store

The overview editor for security policies provides the facility to display all resources with view grants made to ADF Security's built-in `test-all` role. You can use this feature in the overview editor to delete the `test-all` role grant and replace it with a grant to the roles that your application defines.

Alternatively, you could delete the `test-all` role using the overview editor for the `jazn-data.xml` file, by selecting the `test-all` role in the Application Roles page of the editor and clicking the **Delete Application Role** button. However, when you remove the `test-all` role this way, you will still need to create a grant to replace the ones that you delete. Because the overview editor lets you combine both of these tasks, the following procedure describes its usage.

Before you begin:

It may be helpful to have an understanding of the Oracle WebLogic Server. For more information, see Preparing the Secure Application for Deployment.

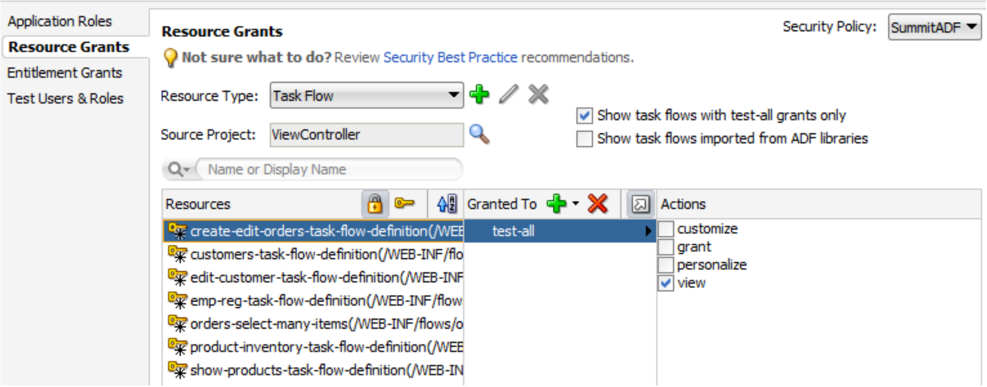
To remove the test-all application role and substitute custom application roles:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.

2. In the Resource Grants page of the overview editor for security policies, select **Task Flow** from the **Resource Type** dropdown list and then select the **Show task flows with test-all grants only** checkbox to view the list of task flows with grants to this built-in role.

   If no grant exists for the `test-all` role, then the **Resources** list in the overview editor will appear empty. The `test-all` role is defined only when enabled in the Configure ADF Security wizard. If it is enabled, you will see those task flows with `test-all` grants listed, as shown in Figure 47-30.

Figure 47-30 Showing Task Flows with test-all Grants in the Overview Editor



Application Roles
Resource Grants
Entitlement Grants
Test Users & Roles

Resource Grants

Security Policy: SummitADF

Not sure what to do? Review Security Best Practice recommendations.

Resource Type: Task Flow

Source Project: ViewController

☑ Show task flows with test-all grants only
☐ Show task flows imported from ADF libraries

Name or Display Name

Resources	Granted To	Actions
create-edit-orders-task-flow-definition(/WEB	test-all	☐ customize ☐ grant ☐ personalize ☑ view
customers-task-flow-definition(/WEB-INF/flo		
edit-customer-task-flow-definition(/WEB-INF		
emp-reg-task-flow-definition(/WEB-INF/flow		
orders-select-many-items(/WEB-INF/flows/o		
product-inventory-task-flow-definition(/WEB		
show-products-task-flow-definition(/WEB-IN		

3. In the **Resources** column, select the first task flow in the list.
4. In the **Granted to** column, select **test-all** and click the **Remove Grantee** icon.
5. In the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role** and then use the Select Application Roles dialog to add the desired role.
6. Repeat these steps to remove the `test-all` role and substitute your own application role for all remaining task flows.
7. In the Resource Grants page of the overview editor, select **Web Page** from the **Resource Type** dropdown list and repeat these steps to remove the `test-all` role for all web pages and their ADF page definitions.
8. With the **Show task flows/web pages with test-all grants only** checkbox selected, verify that the overview editor displays no resources with `test-all` grants.

How to Remove Test Users from the Application Identity Store

The standalone Oracle WebLogic Server that you will deploy to will have its own identity stored already configured. To ensure that you do not migrate test users and enterprise role groups you created in JDeveloper to the domain level, you should remove the test user realm from the `jazn-data.xml` file.

Alternatively, if you are deploying from JDeveloper, you can disable the migration of users and groups by deselecting the **Users and Groups** option in the Application Properties dialog, as described in How to Configure, Deploy, and Run a Secure Application in JDeveloper.

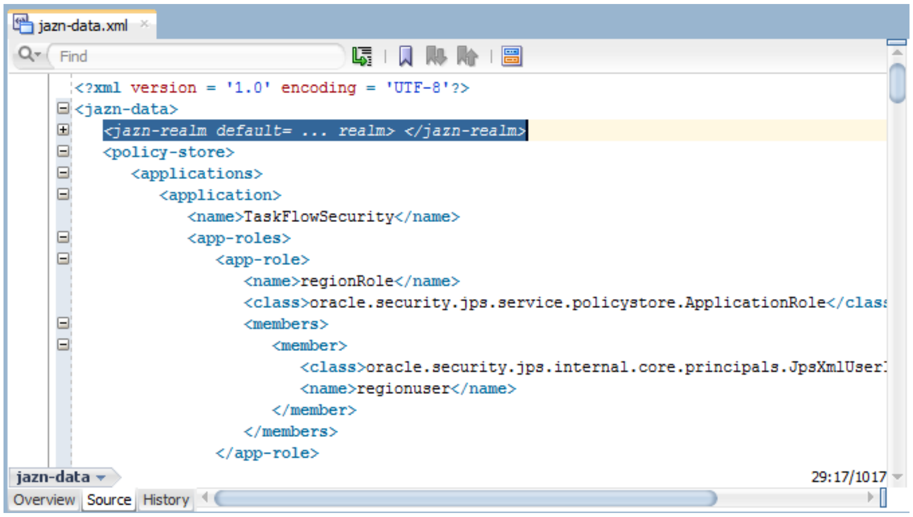
Before you begin:

It may be helpful to have an understanding of the Oracle WebLogic Server. For more information, see Preparing the Secure Application for Deployment.

To remove test users and enterprise role groups from the identity store:

1. In the main menu, choose **Application** and then **Secure > Users**.
2. In the editor window for the `jazn-data.xml` file, click the **Source** tab.
3. In the source for the `jazn-data.xml` file, click the **-** icon next to the **<jazn-realm>** element so the entire element appears collapsed as shown in Figure 47-31.

Figure 47-31 Selecting the <jazn-realm> Element in the XML Editor



```
<?xml version = '1.0' encoding = 'UTF-8'?>
<jazn-data>
    <jazn-realm default= ... realm> </jazn-realm>
    <policy-store>
        <applications>
            <application>
                <name>TaskFlowSecurity</name>
                <app-roles>
                    <app-role>
                        <name>regionRole</name>
                        <class>oracle.security.jps.service.policystore.ApplicationRole</class
                        <members>
                            <member>
                                <class>oracle.security.jps.internal.core.principals.JpsXmlUser]
                                <name>regionuser</name>
                            </member>
                        </members>
                    </app-role>
```

4. With the element selected, press **Delete** and save the file.

How to Secure Resource Files Using a URL Constraint

Resource files, including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the application. ADF Security does not secure these files. Although securing such files is not a requirement for securing the web pages of the application, in some cases it may be desirable to protect resource files to fully harden your application. Please note that JavaScript files are downloaded to the browser and, as such, can be read at that time.

To serve up resource files, the ADF Faces framework relies on `org.apache.myfaces.trinidad.webapp.ResourceServlet`, which delegates to a resource loader. The Fusion web application's `web.xml` file contains a servlet mapping that maps the resource servlet to URL patterns. By default, JDeveloper uses the patterns `/adf/*` for MyFaces Trinidad Core, and `/afr/*` for ADF Faces.

Because ADF Security does not protect the resource servlet, you can protect the Java EE access paths for the resource servlet with a security constraint. To implement your own security for the resource files in the `web.xml` file, define a security constraint for the `/adflib/*`, `/adf/*` and `/afr/*` paths and assign a specific security role to them. This security constraint will require all users to be authenticated before they can access the first page of the Fusion web application.

The following example shows the security role `resource_role` and the constraint with the URL patterns mapped to this role. After you define the security role, the administrator for the target server must map this role to an Oracle WebLogic Server enterprise role (user group) or create an enterprise role with the same name (in which case no mapping is required).

```
<security-role>
    <description>Java EE role to map to an enterprise role. All users who will
      be allowed to run Fusion web app must be members of that role.     </
description>
    <role-name>resource_role</role-name>
</security-role>

<security-constraint>

Disabling ADF Security

You can disable ADF Security but that does not delete the created permission. This option can be used to run a previously secured application unsecured.

JDeveloper allows you to disable ADF Security when you want to temporarily run the application without enforcing authorization checks against the application policy store. This will allow you to run the application and access all resources without the protection provided by existing security policies.

How to Disable ADF Security

To disable ADF Security at the level of your application, run the wizard and choose one of these options:

- **ADF Authentication** disables ADF authorization but leaves the ADF authentication servlet enabled. For example, you may want to run your application in JDeveloper with authorization checking against security policies temporarily disabled. This option will require the user to log in the first time a page in the application is accessed by mapping the Java EE application root "/" to the `allPages` Java EE security constraint that will trigger user authentication. ADF resources will not be security-aware because authorization checking is not enforced. Thus, once the user is logged in, all web pages containing ADF resources will be available to the user.
- **Remove ADF Security Configuration** disables the ADF authentication servlet and disables authorization checking on ADF resources. In this case, you can run the application with no user authentication and no security for ADF resources in place.

You may select either option with the intention of reenabling ADF Security at any time. The wizard specifically does not alter the application policy store that contains the security policies that application developers defined for ADF resources. This means that you can return to the wizard at any time, select the **ADF Authentication and**

Authorization option, and reenable ADF Security against your application's existing policy store and identity store.

Before you begin:

It may be helpful to have an understanding of disabling ADF Security. For more information, see Disabling ADF Security.

To disable ADF authorization checking:

1. In the main menu, choose **Application** and then **Secure > Configure ADF Security**.
2. In the ADF Security page, select either the **ADF Authentication** option or the **Disable ADF Security Configuration** option. Click **Next**.

   After you run the wizard with either of these options, the ADF resources of your user interface projects will no longer be security-aware.
3. Click **Finish**.

What Happens When You Disable ADF Security

If you run the Configure ADF Security wizard with the **Remove ADF Security Configuration** option selected, it removes the ADF-specific metadata in the `web.xml` file and `adf-config.xml` file, as described in Table 47-2.

Similarly, running the wizard with the **ADF Authentication** option selected to disable only authorization checking performs the following updates:

- Leaves the ADF-specific metadata in the `web.xml` file unchanged and adds the `allPages` security constraint.

  With the `allPages` security constraint present, users will be expected to authenticate when they first access the application.
- Sets the `authorizationEnforce` parameter in the `<JaasSecurityContext>` element of the `adf-config.xml` file to `false`, as shown in the following example.

```
<JaasSecurityContext

initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
  jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
                             authorizationEnforce="false"
                             authenticationRequire="true"/>
```

The `adf-config.xml` file is located in the `/.adf/META_INF` folder of your workspace. In JDeveloper, you can locate the file in the Application Resources panel of the Applications window by expanding the **Descriptors-ADF META-INF** node. Note that if you view the `adf-config.xml` file in an editor outside of JDeveloper, you must save the workspace to see the wizard-applied changes in the file.

Advanced Topics and Best Practices

There are additional security configurations that go beyond the default ADF Region and task flow authorization. Then there are best practices that will help you to secure the ADF application to allow users to access the web pages you intend.

After you have completed the process of enabling ADF Security, you may want to customize your application to work with ADF Security in the user interface. For example, you can use Expression Language (EL) to render UI components in the web page based on evaluation of custom permissions that you define just for a group of UI components. Additionally, you can define methods within a managed bean to expose information, such as the user name and role membership, in your application.

Using Expression Language (EL) with ADF Security

You can use Expression Language (EL) to evaluate the policy directly in the UI, while the use of Java enables you to evaluate the policy from within a managed bean. ADF Security implements several convenience methods for use in EL expressions to access ADF resources in the security context. For example, you can use the EL expression and ADF Security Context API methods to determine whether the user is allowed to access a particular task flow. Good security practice dictates that your application should hide resources and capabilities for which the user does not have access. And for this reason, if the user is not allowed access to a particular task flow, you would evaluate the user's permission grant to determine whether or not to render the navigation components that initiate the task flow.

> **Note:**
>
> The ability to evaluate a policy is limited to the current request. For this reason, it is important to understand where the policy evaluation occurs, because evaluating the policy at anything other than the request scope can lead to unexpected results.

How to Evaluate Policies Using EL

The use of EL within a UI component allows for the component's attribute values to be defined dynamically, resulting in modification of the UI component at runtime. In the case of securing resources, the UI component attribute of interest is the `rendered` attribute, which allows you to show and hide components based on available permissions. By default, the `rendered` attribute is set to `true`. By dynamically changing this value based on the permission, you can set the UI component to be shown or hidden. For example, if the user has the appropriate permission, the `rendered` attribute should be set to `true` so that the UI component is shown. If they do not have permission, the attribute should be set to `false` and the UI component hidden from view.

To evaluate a policy using EL, you must use the ADF Security methods in the `securityContext` EL namespace. These methods let you access information in the ADF security context for a particular user or ADF resource.

Table 47-11 shows the EL expression that is required to determine whether a user has the associated permission. If the user has the appropriate permission, the EL expression evaluates to `true`; otherwise, it returns `false`.

Table 47-11 EL Expression to Determine View Permissions on ADF Resources

Expression	Expression action

`#{securityContext.taskflowViewable['`*`MyTaskFlow`*`']}`
For example:
`#{securityContext.taskflowViewable ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}`
	Where *`MyTaskFlow`* is the WEB-INF node-qualified name of the task flow being accessed. Returns `true` if the user has access rights. Returns `false` if the user does not have sufficient access rights.

`#{securityContext.regionViewable['`*`MyPagePageDef`*`']}`	Where *`MyPagePageDef`* is the qualified name of the page definition file associated with the web page being accessed. Returns `true` if the user has access rights. Returns `false` if the user does not have sufficient access rights.

> **Note:**
>
> In the case of page permission, the value of the page definition can be specified dynamically by using late-binding EL within a managed bean, as described in What You May Need to Know About the valid-users Role.

Table 47-12 shows the EL expression that lets you get general information from the ADF security context not related to a particular ADF resource. For example, you can access the current user name when you want to display the user's name in the user interface. You can also check whether the current user is a member of certain roles or granted certain privileges. Your application may use this result to dynamically hide or show menus.

Table 47-12 EL Expression to Determine User Information in the ADF Security Context

Expression	Expression Action
`#{securityContext.userName}`	Returns the user name of the authenticated user.
`#{securityContext.authenticated}`	Returns `true` if the user is logged in. Returns `false` if the user is not logged in. This is useful for rendering a dynamic link for login/logout, or for rendering a "Welcome, *username*" message when the user has been authenticated. For an example that uses this expression, see Adding Login and Logout Links.
`#{securityContext.userInRole['`*`roleList`*`']}`	Where *`roleList`* is a comma-separated list of role names. Returns `true` if the user is in at least one of the roles. Returns `false` if the user is in none of the roles, or if the user is not currently authenticated.

Table 47-12 (Cont.) EL Expression to Determine User Information in the ADF Security Context

Expression	Expression Action
`#{securityContext.userInAllRoles['roleList']}`	Where *`roleList`* is a comma-separated list of role names. Returns `true` if the user is in all of the roles. Returns `false` if the user is not in all of the roles, or if the user is not currently authenticated.
`#{securityContext.userGrantedPermission['permission']}`	Where *`permission`* is a string containing a semicolon-separated concatenation of `permissionClass=<class>;target=<artifact_name>;action=<action>`. Returns `true` if the user has access rights. Returns `false` if the user does not have sufficient access rights. Note that the convenience methods `taskflowViewable` and `regionViewable` shown in Table 47-11 provide the same functionality.
`#{securityContext.userGrantedResource['resource']}`	Where *`resource`* is a string containing a semicolon-separated concatenation of `resourceName=<name>;resourceType=<type>;action=<action>`. Returns `true` if the user has access rights. Returns `false` if the user does not have sufficient access rights. You can use this expression to test the permission grant in the display property of a resource that is not contained in a task flow (like an ADF Faces panel or a menu item). You first create a custom resource type for the UI component that you want to protect. For more details, see How to Protect UI Components Using OPSS Resource Permissions and EL.

Before you begin:

It may be helpful to have an understanding of using EL. For more information, see Using Expression Language (EL) with ADF Security.

To associate the rendering of a navigation component with a user's granted permissions on a target task flow or page definition:

1. In the Applications window, double-click the page that contains the navigation component that you wish to conditionally render.
2. In the visual editor for the page, select the component that is used to navigate to the secured page.
3. In the Property window, click the **Property Menu** dropdown menu displayed menu next to the **Rendered** field and choose **Expression Builder**, as shown in Figure 47-32.

Figure 47-32 Binding the Rendered Property to Data

whether the component is rendered. When set to false, no output will be delivered for this component (the component will not in any way be rendered, and

4. In the Expression Builder, expand the **ADF Bindings - securityContext** node and select the appropriate EL value, and then in the **Expression** field, enter the qualified name of the ADF resource that the user will attempt to access.

   For example, as shown in Figure 47-33, to limit access to a task flow that your application displays, you would create an expression like:

   ```
   #{securityContext.taskflowViewable
        ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}
   ```

   In this example, the expression determines the user's access rights to view the target task flow `audit-expense-report`. If the user has the access rights, then the expression evaluates to `true` and the `rendered` attribute receives the value `true`.

> **Tip:**
>
> In the Expression Builder dialog, expand **Description** for additional information about any security EL method you select.

5. Click **OK**.

When you run the application, the component will be rendered or hidden based on the user's ability to view the target page.

What Happens When You Use the Expression Builder Dialog

When you use the Expression Builder to define an expression for the `rendered` attribute, JDeveloper updates the component definition in the open `.jspx` file. The component's `rendered` attribute appears with an expression that should evaluate to either `true` or `false`, as shown in the following example. In this example, the component is a navigation link with the link text `Checkout` defined by another expression. The page that contains the navigation link renders the component only when the user has sufficient rights to access the checkout task flow.

```
<af:commandNavigationItem
   text="#{res['global.nav.checkout']}"
   action="globalCheckout"
   id="cni3"
   rendered="#{securityContext.taskflowViewable
                    ['/WEB-INF/checkout-task-flow.xml#checkout-task-flow']}"
/>
```

What You May Need to Know About Delayed Evaluation of EL

The ability to evaluate a security permission is scoped to the request. If you want to evaluate permissions to access a target page from a managed bean that is scoped to a higher level than request (for example, a global menu that is backed by a managed bean), you must implement delayed EL evaluation (late-binding). By passing in the target page as a managed property of the bean, you ensure that the EL expression is evaluated only after the required binding information is available to the managed bean. Because EL is evaluated immediately when the page is executed, placing the EL expression directly in the properties of a UI component, backed by a managed bean, would result in an out-of-scope error.

The following example shows a property (`authorized`) of a managed bean that returns `true` or `false` based on a user's ability to view a named target page. In this case, the `_targetPageDef` variable is a managed property containing the name of the target page. Within the UI, the EL expression would reference the `authorized` property.

```
public boolean isAuthorized()
{
 if (_targetPageDef != null) {
  FacesContext fctx = FacesContext.getCurrentInstance();
  ADFContext adfCtx = ADFContext.getCurrent();
  SecurityContext secCtx = adfCtx.getSecurityContext();
  boolean hasPermission = secCtx.hasPermission(new RegionPermission
     (_targetPageDef, RegionPermission.VIEW_ACTION));
     if (hasPermission) {
        return hasPermission;
     }
```

```
          else {
             fctx.addMessage(null, new FacesMessage (
             FacesMessage.SEVERITY_WARN, "Access Permission not defined! " , null));
             return false;
          }
      }
```

How to Protect UI Components Using OPSS Resource Permissions and EL

Security expressions in the ADF Security EL namespace described in Table 47-12 let you check the user permission, authentication and role membership status before displaying UI components in your page. When you need fine-grained protection over UI components to secure functional parts of the application that are not part of task flow security or web page security, you use the EL value `userGrantedResource` and a resource grant that you define for a custom resource type. For instance, through a resource grant that you create for a menu item, the application may either enable or disable a Cancel Shipment menu item to limit who may perform customer order updates.

Resource grants for custom resources types rely on the `ResourcePermission` class, which is provided by Oracle Platform Security Services (OPSS) and packaged with the application.

You use the overview editor for security policies to create a security policy for the custom resource type. And, in your web page, you use the security expression to evaluate the user's access rights to the UI component projected by the resource grant.

> **Best Practice:**
>
> Custom resource types in combination with the `ResourcePermission` matcher class let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user's ability to view UI components without having to overload the built-in actions defined by the ADF resources' permission classes. Be aware that you do not need to create custom resource types to manage access to web pages. This level of access is provided by the default ADF Security view permission that you work with in the overview editor for security policies.

To grant resource policies for a custom resource type:

1. Create the custom resource type for the UI component you want to protect.
2. Create the resource grant for the custom resource.
3. Associate the rendering of a UI component with a role's granted resource permission.

Creating the Custom Resource Type

You use the Create Resource Type dialog to create a resource type for the UI component that you want to protect. JDeveloper will match your resource type definition to the OPSS permission class `oracle.security.jps.ResourcePermission`.

This class allows you to specify custom actions that you can grant to functional parts of your application that are not protected by task flow security or web page security. For example, you might want to create a resource type to protect sensitive parts of the application accessed by the user through a menu UI component.

The Create Resource Type dialog lets you identify the type of resource you wish to protect (for example, the name `MenuProtection` would identify the menu UI component), a display name visible in the security policy store (for example, `Menu Protection`), and a description of how the resource type will be used in the resource grant (for example, `Resource permission to grant menu item permissions`). The dialog also lets you enter one or more custom action names that you will use to grant permission. For example, you might name the action `process` for use in a security policy that grants access to a protected menu item.

Before you begin:

It may be helpful to have an understanding of the ADF Permission class. For more information, see How to Protect UI Components Using OPSS Resource Permissions and EL.

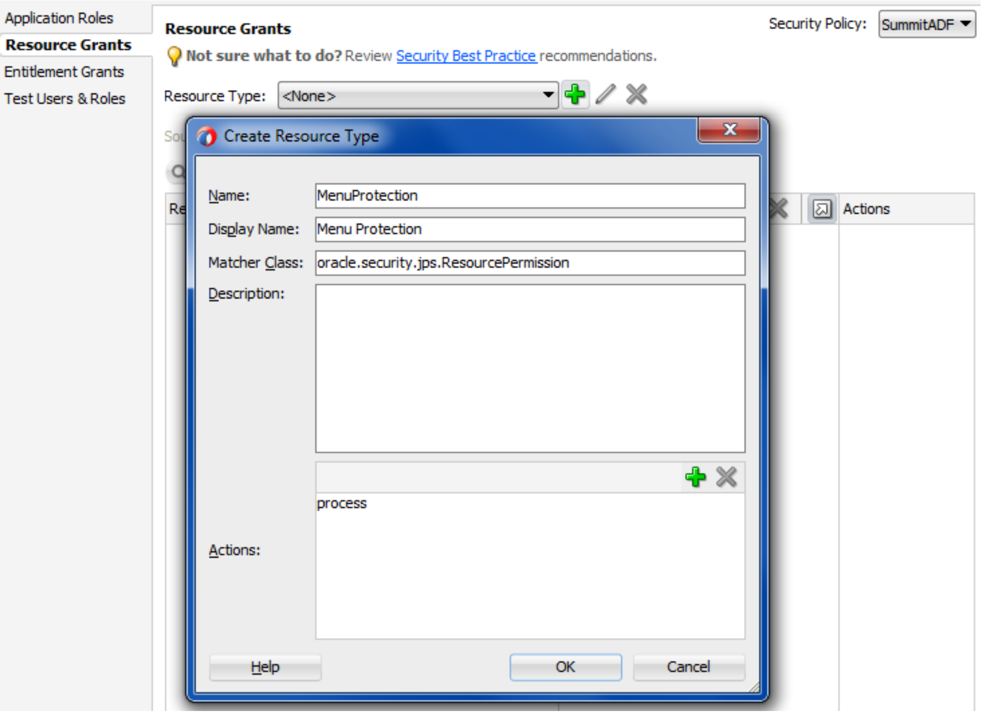
To create the custom resource type:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, click **New Resource Type**.
3. In the Create Resource Type dialog, enter the name and display name that describes the UI component.

   For example, to protect menu items, you might enter `MenuProtection` for the name and `Menu Protection` for the display name.
4. In the **Actions** list, click **Add** and enter the name of the actions that your permission will grant and click **OK**.

   For example, when protecting a menu item, you might enter `process` to signify that permission to process the menu selection is being granted. You can enter multiple action names when you intent to grant specific actions to individual users or roles. The overview editor displays the custom permission grant, as shown in Figure 47-34.

Figure 47-34 Creating a Custom Resource Type



Name: MenuProtection
Display Name: Menu Protection
Matcher Class: oracle.security.jps.ResourcePermission
Description:
Actions: process

Creating a Resource Grant for a Custom Resource Type

You use the overview editor for the `jazn-data.xml` file to create the ADF Security policy for a custom resource. The finished source should look similar to the permission grant defined in the policy store, as shown in the following example.

```
<grant>
  <grantee>
    <principals>
      <principal>
         <name>AccountManagersadmin</name>
         <class>oracle.security.jps.service.policystore.ApplicationRole</class>
      </principal>
     </principals>
  </grantee>
  <permissions>
     <permission>
       <class>oracle.security.jps.ResourcePermission</class>
       <name>resourceType=MenuProtection,resourceName=CancelShipment</name>
       <actions>process</actions>
     </permission>
   </permissions>
</grant>
```

The `<permission>` target name identifies the custom resource type and name that you assigned the resource. For example, a resource name that lets users cancel shipments from a menu selection in their account might be named `CancelShipment`.

The actions are those that your custom resource type defines. For example, in the Menu Protection resource type defines the single action `process` to grant permission to process the menu selection.

Before you begin:

It may be helpful to have an understanding of the `ResourcePermission` class. For more information, see How to Protect UI Components Using OPSS Resource Permissions and EL.

You will need to complete this task:

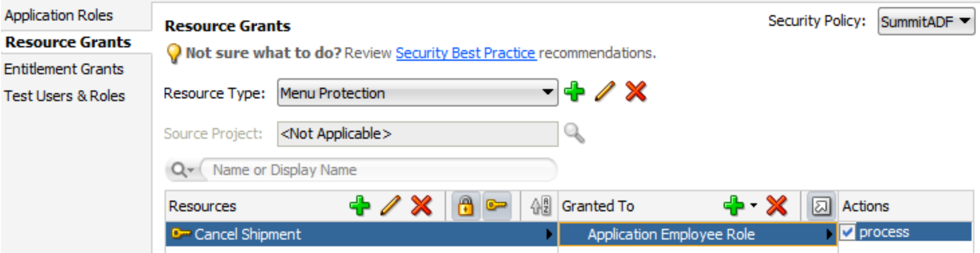
> Create the custom resource type, as described in Creating the Custom Resource Type.

To create the resource grant for a custom resource type:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select the custom resource from the **Resource Type** dropdown list.
3. In the **Resources** column, click the **Add Resource** icon.
4. In the Create Resource dialog, enter the name, display name, and description for the resource that the security policy will specifically protect and then click **OK**.
5. In Resource Grants page of the overview editor, in the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.
6. In the **Actions** column, select action that you defined for the custom resource type.

   The overview editor displays the resource grant, as shown in Figure 47-35.

Figure 47-35 Creating a Grant for a Custom Resource in the Overview Editor



Resource Grants

Security Policy: SummitADF

Not sure what to do? Review Security Best Practice recommendations.

Resource Type: Menu Protection

Source Project: <Not Applicable>

Resources	Granted To	Actions
Cancel Shipment	Application Employee Role	☑ process

Associating the Rendering of a UI Component with a Resource Grant

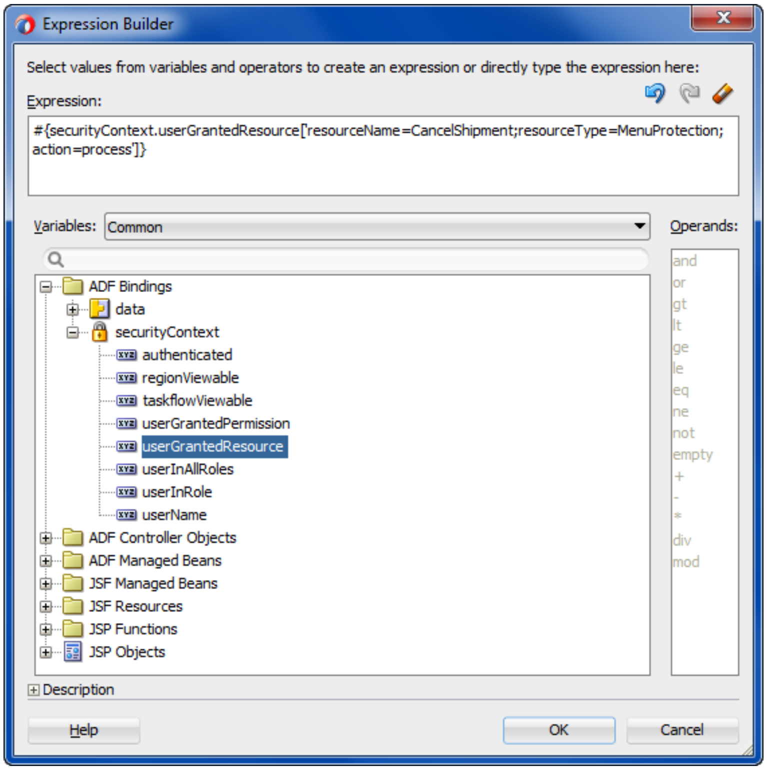
You use the Expression Builder dialog for the UI component display property to define an EL expression that controls rendering the component. For example, to protect a menu item in an application that allows authorized users to cancel shipments, the application specifies a `userGrantedResource` expression on the **disabled** property of the menu item defined by `af:commandMenuItem`. As the following example shows, the expression tests whether the user has been granted the resource type and then either displays the menu item or, when the user has not been granted the resource, disables the menu item.

```
#{!securityContext.userGrantedResource

['resourceName=CancelShipment;resourceType=MenuProtection;action=process']}
```

Figure 47-36 shows how the expression appears in the Expression Builder dialog.

Figure 47-36   Defining EL in the Expression Builder Dialog



Select values from variables and operators to create an expression or directly type the expression here:

Expression:

```
#{securityContext.userGrantedResource['resourceName=CancelShipment;resourceType=MenuProtection;
action=process']}
```

Variables: Common

Before you begin:

It may be helpful to have an understanding of the `ResourcePermission` class. For more information, see How to Protect UI Components Using OPSS Resource Permissions and EL.

You will need to complete these tasks:

1. Create the custom resource type, as described in Creating the Custom Resource Type.
2. Create the ADF security policy using the custom permission, as described in Creating a Resource Grant for a Custom Resource Type.

To associate the rendering of a UI component with a user's granted resource:

1. In the Applications window, double-click the page that contains the UI component that you wish to conditionally render.
2. In the visual editor for the page, select the component that is used to navigate to the secured page.
3. In the Property window, click the **Property Menu** dropdown menu displayed menu next to the **Rendered** field and choose **Expression Builder**.
4. In the Expression Builder, expand the **ADF Bindings - securityContext** node and select **userGrantedResource**, and then, in the **Expression** field, enter a concatenated string that defines the permission.

   Enter the permission string as a semicolon-separated concatenation of `resourceName=`*`theResourceInstanceName`*`;resourceType=`*`customResourceTypeNa`* *me*;action=*actionName*. For example, to protect a menu item in an application that allows authorized users to cancel shipments, you would enter an expression similar to the one shown in the following example, where the resource type for userGrantedResource identifies the resource type used in the custom resource grant.

```
#{!securityContext.userGrantedResource

['resourceName=CancelShipment;resourceType=MenuProtection;action=process']}
```

In this example, the expression evaluates the permission based on the custom resource type named MenuProtection that you added to the application policy store.

5. Click **OK**.

How to Perform Authorization Checks for Entity Object Operations

In the Fusion web application, you can enable security for the data collection when you secure the operations of the entity object. The user must have sufficient privileges to view, update, or delete the data for the entire row set.

The oracle.jbo.ViewCriteriaRow API allows you to perform authorization checks for the standard operations (read, update, removeCurrentRow) at the level of entity rows. The following example shows how to use the authorization checking API, getSecurityHints() and allowsOperation(), on the entity row, to test whether the user has permission to delete data.

```
if(row.getSecurityHints().allowsOperation("removeCurrentRow").hasPermission())
        // code for the data
else
        // display error message
```

Note that the allowsOperation() method expects as input the secured operation name rather than the name of the action that secures it. The operation name for deleting an entity row is removeCurrentRow (where delete is the action name).

When you want to perform authorization checks for the entity object that underlies data bound components in a JSF page of the Fusion web application, you can use EL expressions. For example, the following EL expression returns true if the user has been granted the permission to perform the operation specified. The <*operationName*> used in the expression must be the read, update, or removeCurrentRow operation that you enabled for the entity object.

```
#{row.hints.allows.<operationName>}
```

Authorization checking expressions are evaluated in the context of a row collection. When you want to check entity permissions outside of the context of the row collection, you must use the userGrantedResource method as shown in Table 47-12.

Getting Information from the ADF Security Context

The implementation of security in a Fusion web application is by definition an implementation of the security infrastructure of the ADF Security framework. As such, the security context of the framework allows access to information that is required as you define the policies and the overall security for your application.

How to Determine Whether Security Is Enabled

Because the enforcement of ADF Security can be turned on and off at the container level independent of the application, you should determine whether ADF Security is enabled prior to making authorization checks. You can achieve this by calling the `isAuthorizationEnabled()` method of the ADF Security Context, as shown in the following example.

```
if (ADFContext.getCurrent().getSecurityContext().isAuthorizationEnabled()){
  //Authorization checks are performed here.
}
```

How to Determine Whether the User Is Authenticated

As the user principal in a Fusion web application is never `null` (that is, it is either `anonymous` for unauthenticated users or the actual user name for authenticated users), it is not possible to simply check whether the user principal is `null` to determine if the user has logged on or not. As such, you must use a method to take into account that a user principal of `anonymous` indicates that the user has not authenticated. You can achieve this by calling the `isAuthenticated()` method of the ADF Security Context, as shown in the following example.

```
// ============ User's Authenticated Status =============
private boolean _authenticated;
public boolean isAuthenticated() {
  _authenticated =
ADFContext.getCurrent().getSecurityContext().isAuthenticated();
  return _authenticated;
}
```

How to Determine the Current User Name

Fusion web applications support the concept of public pages that, while secured, are available to all users. Furthermore, components on the web pages, such as portlets, require knowledge of the current user identity. As such, the user name in a Fusion web application will never be `null`. If an unauthenticated user accesses the page, the user name `anonymous` will be passed to page components.

You can determine the current user's name by evaluating the `getUserName()` method of the ADF security context, as shown in the following example. This method returns the string `anonymous` for all unauthenticated users and the actual authenticated user's name for authenticated users.

```
// ============ Current User's Name/PrincipalName =============
     public String getCurrentUser() {
      _currentUser = ADFContext.getCurrent().getSecurityContext().getUserName();
      return _currentUser;
     }
```

Because the traditional method for determining a user name in a Faces-based application (`FacesContext.getCurrentInstance().getExternalContext().getRemoteUser()`) returns `null` for unauthenticated users, you need to use additional logic to handle the public user case if you use that method.

How to Determine Membership of a Java EE Security Role

As Fusion web applications are JavaServer Faces-based applications, you can use the isUserInRole(roleName) method of the Faces external context, as shown in the following example, to determine whether a user is in a specified role. Because ADF Security is based around JAAS policies, you should not need to use Java EE security roles to secure pages associated with ADF security-aware resources based on role membership. However, you might use the method to check the role for a page that is not associated with an ADF security-aware resource.

In this example, a convenience method (checkIsUserInRole) is defined. The use of this method within a managed bean enables you to expose membership of a named role as an attribute, which can then be used in EL.

```
public boolean checkIsUserInRole(String roleName){
        return
(FacesContext.getCurrentInstance().getExternalContext().isUserInRole(roleName));
}

public boolean isCustomer() {
        return (checkIsUserInRole("Application Customer Role"));
 }
```

How to Determine Permission Using Java

To evaluate the security policies from within Java, you can use the hasPermission method of the ADF security context. This method takes a permission object (defined by the resource and action combination) and returns true if the user has the corresponding permission.

In the following example, a convenience function is defined to enable you to pass in the name of the page and the desired action, returning true or false based on the user's permissions. Because this convenience function is checking page permissions, the RegionPermission class is used to define the permission object that is passed to the hasPermission method.

```
private boolean TestPermission (String PageName, String Action)  {
  Permission p = new RegionPermission("view.pageDefs." + PageName + "PageDef",
                                       Action);
  if (p != null) {
     return ADFContext.getCurrent().getSecurityContext().hasPermission(p);
  }
  else {
     return (true);
}
```

As it is possible to determine the user's permission for a target page from within a backing bean, you can use this convenience method to dynamically alter the result of a Faces navigation action. In the following example, you can see that a single command button can point to different target pages depending on the user's permission. By checking the view permission from the most secured page (the manager page) to the least secured page (the public welcome page), the command button's backing bean will apply the appropriate action to direct the user to the page that corresponds to their permission level. The backing bean that returns the appropriate action uses a convenience method defined in the following example.

```
//Button Definition
<af:button text="Goto Your Group Home page"
  binding="#{backing_content.commandButton1}"
  id="commandButton1"
  action="#{backing_content.getSecureNavigationAction}"/>

//Backing Bean Code
    public String getSecureNavigationAction() {
      String ActionName;
      if (TestPermission("ManagerPage", "view"))
        ActionName = "goToManagerPage";
      else if (TestPermission("EmployeePage", "view"))
        ActionName = "goToEmployeePage";
      else
        ActionName = "goToWelcomePage";
      return (ActionName);
    }
```

Best Practices for Working with ADF Security

These best practices summarize the rules that govern enforcement of security by the ADF Security framework. Understanding these best practices will help you to secure the application to allow users to access the web pages you intend.

Do build your application with ADF Security enabled from the start.

When you enable security, you essentially lock down the application and you will be required to make explicit permission grants to specific ADF security-aware resources you create. Knowing about these resources and making grants on them as you build the application will enable you to iteratively test security to ensure that you structure your application in a way that achieves the desired result.

Do define permission grants for bounded task flows.

Pages that the user accesses within the process of executing a bounded task flow will not be individually permission-checked and will run under the permission grants of the task flow. This means that any page that you add to the task flow should not have its own page definition-level security defined. Upon requesting a flow, the user will be allowed either to view all the pages of the task flow or to view none of the pages, depending on their level of access.

Do not define permission grants for individual pages of a bounded task flow.

It is important to realize that task flows do not prevent users from accessing pages directly. Any web page that is located in a directory that is publicly accessible can be reached from a browser using a URL. To ensure that pages referenced by a bounded task flow cannot be accessed directly, remove all permission grants that exist for their associated page definition file. When pages require additional security within the context of a bounded task flow, wrap those pages in a sub-task flow with additional grants defined on the nested task flow.

Do use task flows to reduce the number of access points exposed to end users.

When you use task flows you can reduce the number of access points that you expose to end users. For example, configure an unbounded task flow to display one page that provides navigation to the remaining pages in your application. Use bounded task flows for the remaining pages in the application. By setting the URL Invoke property of these bounded task flows to `url-invoke-disallowed`, your application has one access point (the page on the unbounded task flow). For more information about the URL Invoke property, see How to Call a Bounded Task Flow Using a URL.

Do specify an alternative task flow for unauthorized users.

End users who attempt to invoke a bounded task flow in a region for which they do not have the necessary permission will see a region that renders as blank in place of the requested task flow. The region when left blank may confuse end users as it does not provide feedback as to why the requested task flow does not appear. Consider configuring an alternative task flow that does not require authorization when this scenario occurs. For more information configuring an alternative task flow, see Handling Access to Secured Task Flows by Unauthorized Users.

Do define permission grants for individual pages outside of a bounded task flow.

Page-level security is checked for pages that have an associated page definition binding file *only* if the page is directly accessed or if the page is accessed in an *unbounded* task flow. There is a one-to-one relationship between the page definition file and the web page it secures.

If you want to secure a page that uses no ADF bindings, you can create an empty page definition binding file for the page.

Do define custom permissions to render UI component based on the user's access rights.

Custom ADF permission classes let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user's ability to view UI components without having to overload the built-in actions defined by the ADF resources' permission classes.

Do define entity object attribute permissions to manage the user's access rights to row-level data displayed by UI components.

Entity objects and entity object attributes both define permission classes that let you define permissions for the read, update, and delete operations that the entity object initiates on its data source. In the case of these data model project components, you must explicitly grant permissions to an application role in order to opt into ADF Security authorization. However, once you enable authorization for an entity object, all rows of data defined by the entity object will be protected by the grant. At this level of granularity, your table component would render in the web page either with all data visible or with no data visible—depending on the user's access rights. As an alternative to securing the entire collection, you can secure individual columns of data. This level of granularity is supported by permissions you set on the individual attributes of entity objects. When entity objects are secured, users may see only portions of the data that the table component displays.

Do use task flow or page-level permission grants to avoid exposing row-level create/insert operations to users with view-only permission.

The correct way to control access to a page that should allow only certain users to update new rows in a table is to use task flow or page-level permission grants. However, as an alternative, it is possible to secure table buttons corresponding to particular operations by specifying an EL expression to test the user's access rights to view the button. When the custom permission is defined and the `userGrantedPermission` expression is set on the `Rendered` property of the button, only users with sufficient privileges will see the button. This may be useful in a case where the user interface displays a page that is not restricted and view-only permission for row-level data is defined for the entity object. In this case, when viewed by the user, the Delete button for the editable table associated with the entity object will appear disabled. However, in the case of an input table, the user interface does not disable the button for the `CreateInsert` operation even though the user may not have update permission.

Do not use JDeveloper as a user identity provisioning tool.

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, always rely on the system administrator to configure user identities through the tools provided by the domain-level identity management system. You should delete all users and groups that you create in the `jazn-data.xml` file before deploying the application.

Do not allow users to access a web page by its file name.

When you deploy the Fusion web application, you should always permit users to access the web page from a view activity defined in the ADF Controller configuration file. Do not allow users to access the JSPX file directly by its physical name (for example, similar to the file name `AllDepartments.jspx`.

Assuming the view activity is named `AllDepartments`, then there are two ways to call the page:

1. `localhost:7101/myapp/faces/AllDepartments`
2. `localhost:7101/myapp/faces/AllDepartments.jspx`

The difference is that the call 1) is in the context of the ADF Controller task flow, which means that navigation on the page will work and any managed beans that are referenced by the page will be properly instantiated. The call in 2) also serves the page, however, the page may not function fully. This may be considered a security breach.

To prevent direct JSPX file access, move the JSPX file under the `/public_html/WEB-INF` directory so that direct file access is no longer possible. To access a document, users will have to call its view activity name.

Note that this suggestion does not protect documents that are unprotected in ADF Security. It only helps to lock down access to the physical file itself.

Thus, the following security guidelines still apply:

1. Apply ADF Security permissions to all JSPX documents associated with view activities defined in the `adfc-config.xml` file.
2. Move all JSPX documents in the user interface project under the `/public_html/WEB-INF` directory to prevent direct file access.
3. Limit the pages in the `adfc-config.xml` to the absolute minimum and place all other pages into bounded task flows.
4. Make bounded task flows inaccessible from direct URL access (which is the default configuration setting for new task flows).
5. Apply ADF Security permissions to bounded task flows.

48

Testing and Debugging ADF Components

This chapter describes the tools for logging and testing an application that uses Oracle ADF. It contains debugging procedures for setting breakpoints using the ADF Declarative Debugger. Finally, it explains how to write and run regression tests for your ADF Business Components-based business services.
This chapter includes the following sections:

About ADF Debugging

ADF debugging is the process of identifying, separating, and fixing specific contributing factors leading to failures at runtime.

Like any debugging task, debugging the web application's interaction with **Oracle Application Development Framework** (Oracle ADF) is a process of isolating specific contributing factors. However, in the case of web applications, generally this process does not involve compiling Java source code. Your web pages contain no Java source code, as such, to compile. In fact, you may not realize that a problem exists until you run and attempt to use the application. For example, these failures are only visible at runtime:

- A page not found servlet error
- The page is found, but the components display without data
- The page fails to display data after executing a method call or built-in operation (like Next or Previous)
- The page displays, but a method call or built-in operation fails to execute at all
- The page displays, but unexpected validation errors occur

The failure to display data or to execute a method call arises from the interaction between the web page's components and the **ADF Model** layer. When a runtime failure is observed during ADF lifecycle processing, the sequence of preparing the model, updating the values, invoking the actions, and, finally, rendering the data failed to complete.

Fortunately, most failures in the web application's interaction with Oracle ADF result from simple and easy-to-fix errors in the declarative information that the application defines or in the EL expressions that access the runtime objects of the page's ADF **binding container**.

In your databound Fusion web application, you should examine the declarative information and EL expressions as likely contributing factors when runtime failures are observed. To understand editing the declarative files, see Correcting Simple Oracle ADF Compilation Errors, and Correcting Simple Oracle ADF Runtime Errors.

One of the most useful diagnostic tools is the ADF Logger. You use this logging mechanism in JDeveloper to capture runtime traces messages. With ADF logging enabled, JDeveloper displays the application trace in the Message Log window. The trace includes runtime messages that may help you to quickly identify the origin of an application error. Read Using the ADF Logger, to configure the ADF Logger to display detailed trace messages.

Supported Oracle ADF customers can request Oracle ADF source code from Oracle Worldwide Support. This can make debugging **ADF Business Components** framework code a lot easier. Read Using ADF Source Code with the Debugger, to understand how to configure JDeveloper to use the Oracle ADF source code.

If the error cannot be easily identified, you can utilize the ADF Declarative Debugger in JDeveloper to set breakpoints. When a breakpoint is reached, the execution of the application is paused and you can examine the data that the ADF binding container has to work with, and compare it to what you expect the data to be. Depending on the types of breakpoints, you may be able to use the step functions to move from one breakpoint to another. For more information about the debugger, read Using the ADF Declarative Debugger.

JDeveloper provides integration with JUnit for your Fusion web application through a wizard that generates regression test cases. Read Regression Testing with JUnit, to understand how to write test suites for your application.

Correcting Simple Oracle ADF Compilation Errors

Simple Oracle ADF compilation errors occur when you modify the Oracle declarative files and it does not conform to the XML schema defined by Oracle ADF.

When you create web pages and work with the ADF **data controls** to create the **ADF binding** definitions in JDeveloper, the Oracle ADF declarative files you edit must conform to the XML schema defined by Oracle ADF. When an XML syntax error occurs, the JDeveloper XML compiler immediately displays the error in the Structure window.

Although there is some syntax checking during design time, the JDeveloper compiler is currently limited by an inability to resolve EL expressions. EL expressions in your web pages interact directly with various runtime objects in the web environment, including the web page's ADF binding container. At present, errors in EL expressions can be observed only at runtime. Thus, the presence of a single typing error in an object-access expression will not be detected by the compiler, but will manifest at runtime as a failure to interact with the binding container and a failure to display data in the page. For information about debugging runtime errors, see Correcting Simple Oracle ADF Runtime Errors.

Tip:

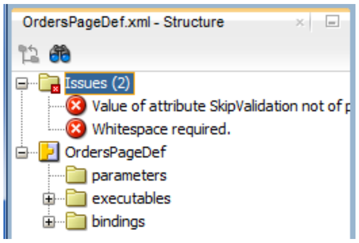
The Expression Builder is a dialog that helps you build EL expressions by providing lists of objects, managed beans, and properties. It is particularly useful when creating or editing ADF databound EL expressions because it provides a hierarchical list of ADF binding objects and their valid properties from which you can select. You should use the Expression Builder to avoid introducing typing errors. For details, see Creating ADF Data Binding EL Expressions.

The following example illustrates two simple compilation errors contained in a **page definition file**: `fals` instead of `false` and `ChangeEventPolicy="ppr"/` instead of `ChangeEventPolicy="ppr"/>` (that is, the attribute is missing a closing angle bracket).

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
                Package="oracle.summit.view.pageDefs"
                SkipValidation="fals">
  <parameters/>
  <executables>
    <iterator Binds="InventoryForOrderItem" RangeSize="-1"
DataControl="BackOfficeAppModuleDataControl" id="InventoryForOrderItemIterator"
              ChangeEventPolicy="ppr"/
  ...
</pageDefinition>
```

During compilation, the Structure window displays the XML errors in the page, as shown in Figure 48-1.

Figure 48-1 The Structure Window Displays XML Errors

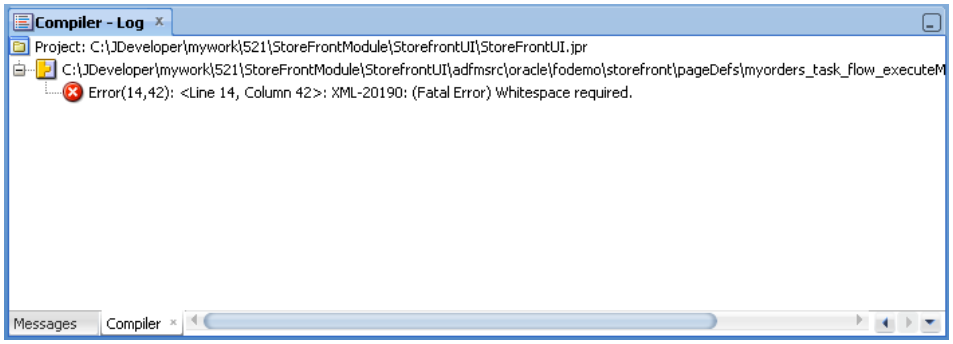


OrdersPageDef.xml - Structure

Issues (2)
Value of attribute SkipValidation not of p
Whitespace required.
OrdersPageDef
parameters
executables
bindings

The Compiler-Log window also displays the compilation errors in the page, as shown in Figure 48-2.

Figure 48-2   The Compiler Window Displays XML Compile Errors



```
Project: C:\JDeveloper\mywork\521\StoreFrontModule\StorefrontUI\StoreFrontUI.jpr
C:\JDeveloper\mywork\521\StoreFrontModule\StorefrontUI\adfmsrc\oracle\fodemo\storefront\pageDefs\myorders_task_flow_executeM
  Error(14,42): <Line 14, Column 42>: XML-20190: (Fatal Error) Whitespace required.
```

To view and correct schema validation errors:

1. In the main menu, choose **View** and then **Structure** to open the Structure window or choose **View** and then **Log** to open the Log Window.
2. In either window, double-click the error message.
3. In the XML editor, locate the highlighted lines.

   The highlighted lines will be lines with errors.
4. Correct any errors.

   After an error has been corrected, the corresponding error message will be automatically removed from the Structure window.
5. Optionally, you can recompile the project by choosing **Run > Make** and checking to see whether the compiler still produces the error message.

Correcting Simple Oracle ADF Runtime Errors

Simple Oracle ADF runtime errors occur when the failures of the ADF Model layer cannot be detected with the help of JDeveloper compiler.

Failures of the ADF Model layer cannot be detected by the JDeveloper compiler, in part because the page's data-display and method-execution behavior relies on the declarative ADF **page definition files**. The ADF Model layer utilizes those declarative files at runtime to create the objects of the ADF binding container.

To go beyond simple schema validation, you will want to routinely run and test your web pages to ensure that none of the following conditions exists:

- The project dependency between the data model project and the user interface project is disabled.

  By default, the dependency between projects is enabled whenever you create a web page that accesses a data control in the data model project. However, if the dependency is disabled and remains disabled when you attempt to run the application, an internal servlet error will be generated at runtime:

  ```
  oracle.jbo.NoDefException: JBO-25002: Definition
  model.DataControls.dcx of type null not found
  ```

To correct the error, double-click the user interface project, and select the **Dependencies** node in the dialog. Make sure that the ***ModelProjectName*.jpr** option appears selected in the panel.

- Page definition files have been renamed, but the `DataBindings.cpx` file still references the original page definition file names.

  While JDeveloper does not permit these files to be renamed within the IDE, if a page definition file is renamed outside of JDeveloper and the references in the `DataBindings.cpx` file are not also updated, an internal servlet error will be generated at runtime:

  ```
  oracle.jbo.NoDefException: JBO-25002: Definition
  oracle.<path>.pageDefs.<pagedefinitionName> of type Form Binding
  Definition not found
  ```

  To correct the error, open the `DataBindings.cpx` file and use the source editor to edit the page definition file names that appear in the `<pageMap>` and `<pageDefinitionUsages>` elements.

- The web page file (`.jsp` or `.jspx`) has been renamed, but the `DataBindings.cpx` file still references the original file name of the same web page.

  The page controller uses the page's URL to determine the correct page definition to use to create the ADF binding container for the web page. If the page's name from the URL does not match the `<pageMap>` element of the `DataBindings.cpx` file, an internal servlet error will be generated at runtime:

  ```
  javax.faces.el.PropertyNotFoundException: Error testing property
  <propertyname>
  ```

  To correct the error, open the `DataBindings.cpx` file and use the source editor to edit the web page file names that appear in the `<pageMap>` element.

- Bindings have been renamed in the web page EL expressions, but the page definition file still references the original binding object names.

  The web page may fail to display information that you expect to see. To correct the error, compare the binding names in the page definition file and the EL expression responsible for displaying the missing part of the page. Most likely the mismatch will occur on a **value binding**, with the consequence that the component will appear but without data. Should the mismatch occur on an **iterator binding** name, the error may be more subtle and may require deep debugging to isolate the source of the mismatch.

- Bindings in the page definition file have been renamed or deleted, and the EL expressions still reference the original binding object names.

  Because the default error-handling mechanism will catch some runtime errors from the ADF binding container, this type of error can be very easy to find. For example, if an iterator binding named `findUsersByNameIter` was renamed in the page definition file, yet the page still refers to the original name, this error will display in the web page:

  ```
  JBO-25005: Object name <iterator> for type Iterator Binding Definition
  is invalid
  ```

  To correct the error, right-click the name in the web page and choose **Go to Page Definition** to locate the correct binding name to use in the EL expression.

- EL expressions were written manually instead of using the expression picker dialog and invalid object names or property names were introduced.

This error may not be easy to find. Depending on which EL expression contains the error, you may or may not see a servlet error message. For example, if the error occurs in a binding property with no runtime consequence, such as displaying a label name, the page will function normally but the label will not be displayed. However, if the error occurs in a binding that executes a method, an internal servlet error `javax.faces.el.MethodNotFoundException: methodname` will display. Or, in the case of an incorrectly typed property name on the method expression, the servlet error `javax.faces.el.PropertyNotFoundException: propertyname` will display.

If this list of typical errors does not help you to find and fix a runtime error, you can initiate debugging within JDeveloper to find the contributing factor. For an Oracle ADF application, start setting ADF declarative breakpoints to find the problem. Using the ADF Declarative Debugger to set ADF declarative breakpoints is described in Using the ADF Declarative Debugger, and Setting ADF Declarative Breakpoints. This process involves pausing the execution of the application as it proceeds through the application and examining data. You can also use the ADF Declarative Debugger to set Java code breakpoints, as described in Setting Breakpoints in Java Code and Groovy Script.

Reloading Oracle ADF Metadata in Integrated WebLogic Server

Simply changing the ADF medatata files or class files will not have any effect on runtime after you have deployed the application to the Integrated WebLogic Server. You must recompile the project and refresh the web browser.

JDeveloper support for hot reloading of Oracle ADF metadata is an alternative to quitting the running application, editing your project's XML definition files, redeploying, and rerunning the application in Integrated WebLogic Server to view the latest changes.

Changes that you make to the Fusion web application projects will not be picked up automatically by an application that you have deployed to Integrated WebLogic Server. You can, however, reload metadata from the data model project and user interface project any time you want to synchronize the running application with changes you have made to your application's XML definition files.

To reload metadata so your changes are reflected in the deployed Fusion web application, you must recompile the project and refresh the web browser.

Metadata that JDeveloper will hot reload in Integrated WebLogic Server, include:

- In the data model project, changes to the definition files of business components.
- In the user interface project, changes to the binding definitions in the page definition files and changes to task flows in the task flow definition files.

This support makes it possible to make incremental changes and test them.

Validating ADF Controller Metadata

ADF Controller recovers metadata and then validation is performed. For example, in an application, the grammar in ADF Controller metadata is validated by enabling the enable-grammar-validationsetting in the adf-config.xml file.

Basic validation is performed when **ADF Controller** retrieves metadata. The most serious errors, for example, a task flow that is missing a default activity, result in parsing exceptions.

The `enable-grammar-validation` setting in `adf-config.xml` allows you to validate the grammar in ADF Controller metadata before deploying an application. When `enable-grammar-validation` is set to `true`, ADF Controller metadata is validated against ADF Controller XSDs. For example, invalid characters in ADF Controller metadata, such as a slash (/) in a **view activity** ID, are flagged as exceptions.

By default, `enable-grammar-validation` is set to `false`. For performance reasons, it should be set to `true` only during application development or when troubleshooting an application.

Using the ADF Logger

Logging is important in debugging and tracing errrors. In the ADF framework, you can use the ADF logger to identify and investigate application errors.

If you are not able to easily find the error in either your web page or its corresponding page definition file, you can use the JDeveloper debugging tools to investigate where your application failure occurs.

You configure the logging session by editing the `logging.xml` configuration file using the editor for Oracle Diagnostic Logging Configuration. Logging configuration can be set at any time, even while the application is running in JDeveloper.

Unlike many files in JDeveloper, you cannot directly open the `logging.xml` file. Instead you use menu commands at these locations to open the Oracle Diagnostic Logging Configuration editor:

- Right-click an active server instance in the Application Servers window.
- Click the Actions dropdown menu displayed in the Log window's debugger process panel, after you have started the application in debug mode.

You use the Oracle Diagnostic Logging Configuration editor to set the desired logging level to control the level and number of messages that are displayed. You can set the logging level for both persistent and transient loggers and declare handlers for each logger.

JDeveloper creates diagnostic log files in the Oracle Diagnostic Logging (ODL) format, used by Oracle Fusion Middleware components. Log file naming and the format of the contents of log files conform to an Oracle standard. By default, the diagnostic messages are in text format. For information about the ODL format, see Understanding ODL Messages and ODL Log Files in *Administering Oracle Fusion Middleware*.

In the editor, as an alternative to the default ODL format, you can configure the Java Logger to display Java diagnostic messages.

After you have created a log, you can view and filter the log messages with Oracle Diagnostic Log Analyzer. This tool allows you to set filters for different log levels, define message time frames, and search on message text.

You can then use the ADF Declarative Debugger to set breakpoints and examine the application. For additional information, see Setting ADF Declarative Breakpoints, and Setting Breakpoints in Java Code and Groovy Script.

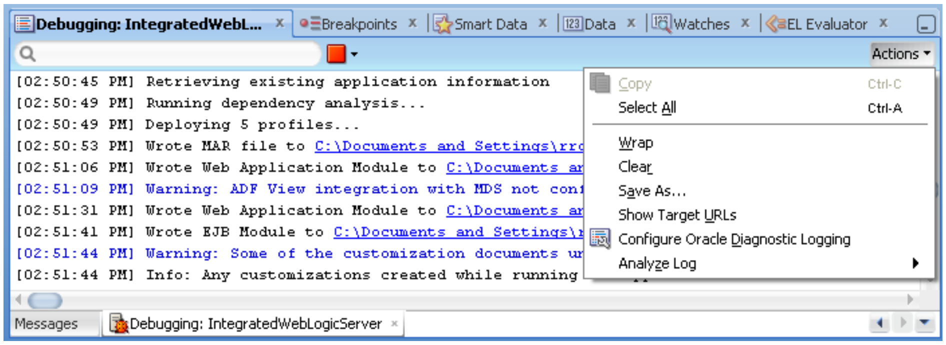
How to Set ADF Logging Levels

You can use the Oracle Diagnostic Logging Configuration editor to configure the logging levels specified in the `logging.xml` configuration file. The file can be configured before and while the application is running in Integrated WebLogic Server. The changes will apply without the need to restart the server.

When Integrated WebLogic Server is running, you can define both persistent and transient loggers. When Integrated WebLogic Server is not running, you can only define persistent loggers. The transient loggers will last only for the session and will not be entered in the `logging.xml` configuration file. If the server is not running, you must explicitly save the configuration changes to the `logging.xml` file for the updates to take effect in the next server run.

You can access the Oracle Diagnostic Logging Configuration editor from the Application Servers window or from the Log window, which is shown in Figure 48-3.

Figure 48-3   Log Window with Toolbar



```

Handler Declarations: "oracle.adfdiagnostics" Logger

Declare handlers to be used by this logger. Use the Source view to add and edit the handler definitions.

☑ Use Parent Handlers

Handlers:

No handlers declared for this logger

You can only use JDeveloper menu commands to open the `logging.xml` configuration file and launch the editor for Oracle Diagnostic Logging Configuration. However, you may find the following information about the location of the configuration file useful.

> **Note:**
>
> You can declare and add log handler definitions by clicking the **Source** tab and entering them in the XML editor.

If you are using Integrated WebLogic Server in JDeveloper on the Windows platform, you can find the `logging.xml` configuration file in a location similar to:

```
C:\Users\username\AppData\Roaming\JDeveloper\<your_JDev_system_folder>\Def
aultDomain\config\fmwconfig\servers\DefaultServer
```

The log files for Integrated WebLogic Server are in a location similar to:

```
C:\Users\username\AppData\Roaming\JDeveloper\<your_JDev_system_folder>\Def
aultDomain\servers\DefaultServer\logs
```

The log files for a standalone WebLogic Server instance are in a location similar to:

`$domain_home/servers/<your_servername>/logs`

You can configure logging levels before a test run from the Application Servers window, or, while the application is running, from the Log window's run panel toolbar, or, during a debug session, from the Log window's debug process toolbar.

To configure the log levels:

1. In the main menu, choose **Window** and then **Application Servers**.
2. In the Application Servers window, expand **Application Servers**, and right-click **IntegratedWebLogicServer** and choose **Configure Oracle Diagnostic Logging for "IntegratedWebLogicServer"**.

   Or, after you start the application, from the Log window's Running: IntegratedWebLogicServer panel, choose **Actions - Configure Oracle Diagnostic Logging.** The Running Log window is only visible while you run the application.

   Or, while you debug the application, from the Log window's debug process panel, choose **Actions - Configure Oracle Diagnostic Logging.** The debug process panel is only visible in the Log window after you have started the application in debug mode.
3. In the editor for Oracle Diagnostics Logging Configuration, select **ODL Log Levels** or **Java Log Levels** for the logger type you want to view.
4. If you want to see persistent loggers only, select **Hide Transient Loggers**.
5. To add a logger:
   a. If the server is running, click the **Add** icon dropdown menu and choose **Add Persistent Logger** or **Add Transient Logger**. If the server is not running, click **Add** to add a persistent logger. You cannot add a transient logger.
   b. In the Add Logger dialog, enter a logger name.
   c. Select the logging level.
   d. Click **OK**.
6. For any logger, including a newly created logger, you can specify its handlers by selecting from a list of available handlers by clicking the **Add** icon for the **Handler Declarations** section.

   Or, you can select **Use Parent Handlers** to assign its parent's handler to the logger. By default, a logger uses its parent's handler.

> **Note:**
>
> You can declare and add log handler definitions by clicking the **Source** tab and entering them in the XML editor.

How to Create an Oracle ADF Debugging Configuration

Oracle ADF leverages the Java Logging API (`java.util.logging.Logger`) to provide logging functionality when you run a debugging session. Java Logging is a standard

API that is available in the Java platform at http://docs.oracle.com/javase/7/docs/api/java/util/logging/package-summary.html.

To log a complete hierarchy tree of ADF event messages, you must configure a Java log level that is not more restrictive than `CONFIG` (or an ODL log level that is not more restrictive than `Notification:16`) for the single package:

- `oracle.adfdiagnostics` will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, ADF Desktop Integration, and Oracle ADF internal classes.

Figure 48-5 shows specific the logger configured to enable the most detailed Oracle ADF log messages. Note that the `oracle.adfdiagnostics` package is set to CONFIG and not to a higher, more restrictive log level (where SEVERE, WARNING, and INFO are Java log levels higher than CONFIG and FINE, FINER, and FINEST are lower levels than CONFIG). Enabling a logger for the `oracle.adfdiagnostics` package ensures that the logger records a complete hierarchy of ADF events.

Figure 48-5 Configuring a Logger for Oracle ADF Debugging

oracle.bali		
oracle.clickhistory		

For backward compatibility, the Java system property `jbo.debugoutput` set to the value `console` or `ADFLogger` (to route diagnostics through the standard Logger implementation, which can be controlled in a standard way through the `logging.xml` file) is supported. The easiest way to set this system property while running your application inside JDeveloper is to edit your project properties and in the Run/Debug page, select a run configuration and click **Edit**. Then add the string `-Djbo.debugoutput=console` to the **Java Options** field.

To create an ADF Model debugging configuration:

1. In the main menu, choose **Window** and then **Application Servers**.
2. In the Application Servers window, expand **Application Servers**, and right-click **IntegratedWebLogicServer** and choose **Configure Oracle Diagnostic Logging**.

   Or, after you start the application, from the Log window's Running: IntegratedWebLogicServer panel, choose **Actions - Configure Oracle Diagnostic Logging.** The Running Log window is only visible while you run the application.

Or, while you debug the application, from the Log window's debug process panel, choose **Actions - Configure Oracle Diagnostic Logging.** The debug process panel is only visible in the Log window after you have started the application in debug mode.

3. In the editor for Oracle Diagnostics Logging Configuration, select **ODL Log Levels** or **Java Log Levels** for the logger type you want to view.
4. Expand the **oracle** node and select a log level that are not more restrictive than `CONFIG` (for Java Log) or that are not more restrictive than `Notification` (for ODL Log) for the following package:
   - **oracle.adfdiagnostics** will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

     Enabling a logger for this package ensures that the logger records a complete hierarchy of ADF events.
5. Select the Java log level **FINEST** for other desired Oracle ADF loggers.

To create an ADF view Javascript logging configuration:

1. In the Applications window, double-click the application or project **web.xml** file.
2. In the source editor, add the following elements to the file:

```
<context-param>
  <param-name>
     oracle.adf.view.rich.LOGGER_LEVEL
  </param-name>
  <param-value>
      FINE
  </param-value>
</context-param>
```

How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers

For non-Oracle ADF loggers, before you use the actual debugger, running the application with Java log level set to FINE, FINER, or FINEST will enable framework diagnostics logging. The debug diagnostic messages can be helpful to see what happens when the problem occurs. To enable debug diagnostic messages, use the Oracle Diagnostics Logging Configuration Editor to configure the desired loggers with a Java log level set to FINEST. If you have configured diagnostic logging for the supported loggers, JDeveloper will direct debug diagnostics messages to the JDeveloper Log window.

Currently, Oracle ADF does not support logging with Java log level FINE, FINER, or FINEST. For more details about Oracle ADF loggers, see How to Create an Oracle ADF Debugging Configuration.

How to Use the Log Analyzer to View Log Messages

You can use Oracle Diagnostic Log Analyzer to view the log entries of a log file. The log analyzer allows you to filter the entries by log level, entry type, log time, and entry content (using one or more search criteria). You can also order the messages and show and hide columns for better viewing.

Figure 48-6 shows Oracle Diagnostic Log Analyzer set to view Java Log levels.

Figure 48-6 Oracle Diagnostic Log Analyzer Displays Java Log Messages

You can also use the log analyzer on log files created in other test runs. For instance, you can analyze the log sent to you by another developer for another application.

Viewing Diagnostic Messages in the Log Analyzer

You can configure logging levels before a test run from the Application Servers window or during a debug session from the Log window toolbar. The level you specify will determine the type and quantity of log messages.

In the case of ADF events, all messages are generated for the ODL log at the level `Notification` or for the Java log at the level `Info`. Fewer ADF messages will be generated at the `Incident Error/Severe` and `Error/Warning` levels.

After you select the log level for the messages you wish to view, you can use the Search panel of the By Log Message page to filter the messages to display from the log file.

> **Note:**
>
> For further details about search criteria that you can specify to search on ADF-specific messages, see Sorting Diagnostic Messages By ADF Events.

You can start the log analyzer before a test run from the **Tools** menu or during a debug session from the log window toolbar.

Before you begin:

It may be helpful to have an understanding of logging. For more information, see Using the ADF Logger.

You will need to complete these tasks:

1. Set logging levels, as described in How to Set ADF Logging Levels.
2. Enable logging, as described in How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers.
3. Create a log file, either from your test run or from another source.

To start the log analyzer:

1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.

   Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).
2. In the editor for Oracle Diagnostic Log Analyzer, select **By Log Message**.
3. In the By Log Message page, in the **Log** field, enter the path and name of the log file or click **Browse Log Files** to navigate to the log file.

   > **Tip:**
   >
   > The Choose Log File dialog helps you to navigate to the directory that contains the log files generated by JDeveloper. Click the **Browse Log Files** icon next to the **Log** text field, and then click the **Server Logs** icon from the scroll list. From the list of log files, you can select more than one log file to analyze at a time.
4. From the dropdown list, select either **ODL Log Level** or **Java Log Level**.
5. Select the corresponding checkbox for each type of log entry you want to view. You must select at least one type.

   The available ODL log level types are:

   - INCIDENT ERROR
   - ERROR
   - WARNING
   - NOTIFICATION - corresponds to ADF event messages
   - TRACE
   - UNKNOWN.

   The available Java log level types are:

   - SEVERE
   - WARNING
   - INFO
   - CONFIG - corresponds to ADF event messages
   - FINE
   - FINER
   - FINEST
   - UNKNOWN

6. Specify a time period for the entries you want to view. You can select the most recent *period* or a range.
7. To filter the results, use the Search panel to query the log for a text pattern. For additional search criteria, click **Add**. The supported search criteria include:
   - **Enterprise Name:** Filters the log by the name of the enterprise.
   - **Detail:** Filters text in statements from the stack where the method was invoked.
   - **EnterpriseID:** Filters the log by the ID of the enterprise.
   - **Message:** Filters text in the logged messages.
   - **ADF Message Data:** Filters the log for data related to ADF lifecycle phase names, **view object** names, view object query statements, data control names, binding container names, and iterator binding names logged during the execution of ADF events.
   - **Source Method:** Filters the log by the method where the message is logged. For example, you can filter on the method `execute` to view all messages logged for view object query execution or ADF lifecycle phase execution.
   - **Application:** Filters the log by the application name where the message is logged. This is useful when the application is running in a composite application and you want to view messages for a specific application.
   - **Source Class:** Filters the log by the fully qualified class name of the method where the message is logged. To see more messages, enter a partial package name. For example, you can enter the partial package name `oracle.adf` or the full package name `oracle.jbo` to filter for all classes related to Oracle ADF.
   - **Module:** Filters the log by the fully qualified package name of the class where the message is logged. This is same package as the source class.
   - **Message Id:** Filters the log by the ID of the logged messages. Many messages share the same ID. For example, message ID `ADFC-52008` might have four `INFO` messages and one `Warning` message. You can select **Group by Id** in the log analyzer Results panel to group messages by their common ID.
8. To initiate the filters and display the log messages, click **Search**.
9. To order the results by the message ID, select the **Group by Id** checkbox.
10. To group the messages by time period or by request, in the **Related** column, select either **Related by Time** or **Related by Request**.

    When you select **Related by** option, the log analyzer groups the messages in the Results Messages panel according to the selected criteria (time, HTTP request, or enterprise name).
11. To open the ADF request (if any) that the message is a part of, in the **Related** column, select **Related by ADF Request**.

    When you select **Related by ADF Request**, the log analyzer displays the related request in the By ADF Request page.
12. To show or hide columns in the **Results** section, click the dropdown list to the right of the column headers and select among the list of displayed columns to change the visibility of a column.

Using the Log Analyzer to Analyze the ADF Request

Because Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases, you can use the log analyzer to investigate the details of the active (or previous) page request in your running application. Specifically, the By ADF Request page of the log analyzer lets you view ADF event messages in a hierarchical list, organized by the sequence of their execution. It also provides a graphical representation of the duration of each event. When you run your application and start the log analyzer with ADF logging configured, you can use this page to quickly identify whether a component of your application is contributing to a performance bottleneck due to unusually long execution times.

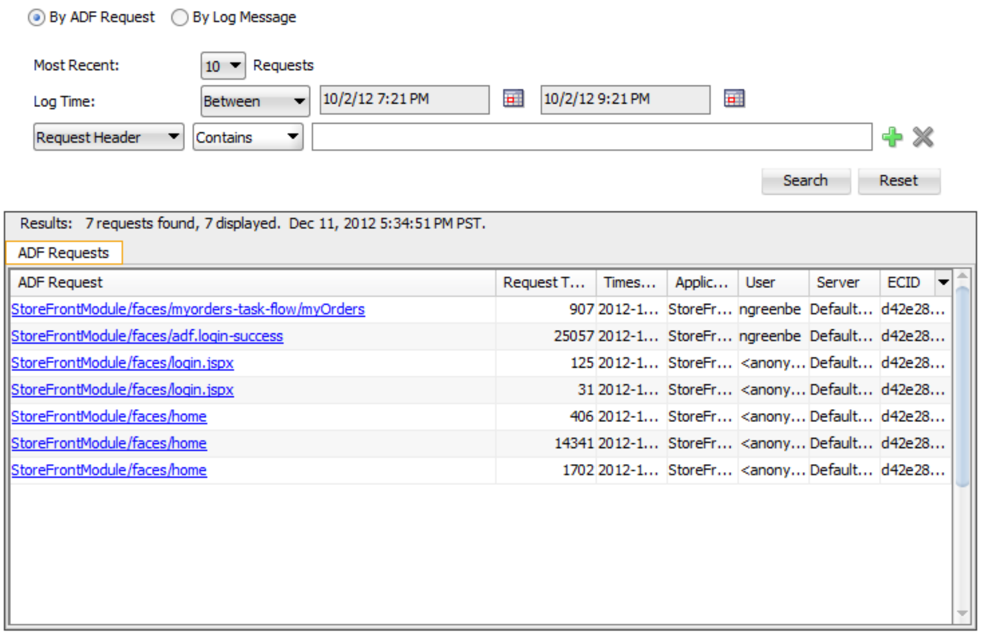
> **Note:**
>
> In contrast to the By Log Message page, the By ADF Request page of the log analyzer displays a hierarchical view of ADF event messages. The difference between these two pages is that the By ADF Request page focuses only on ADF page requests made when a page or **region** is submitted. For details about the ADF page lifecycle, see Understanding the Fusion Page Lifecycle .

You can enter search criteria in the By ADF Request page to display one or more specific requests from the log file. You can combine any of the following search criteria to filter the log file:

- The number of requests to display
- The timestamp for the request recorded in the log
- The logged-in user name, enterprise name, request header (to specify a search based on the page or region name), message, source class, module, server, detail, enterprise ID, ADF message data, application name in a composite application, source method, message ID, or ECID (a globally unique ID associate with every top-level task; sub-tasks invoked by that top-level task operate with an execution context that shares the same ECID)

After the request is completed, the log analyzer displays a summary of the ADF requests in a single table. Figure 48-7 shows the summary table that displays the list of ADF web requests.

Figure 48-7 Oracle Diagnostic Log Analyzer Displays Summary of ADF Web Requests



● By ADF Request ○ By Log Message

Most Recent: 10 Requests

Log Time: Between 10/2/12 7:21 PM 10/2/12 9:21 PM

Request Header Contains

Results: 7 requests found, 7 displayed. Dec 11, 2012 5:34:51 PM PST.

ADF Request	Request T...	Times...	Applic...	User	Server	ECID

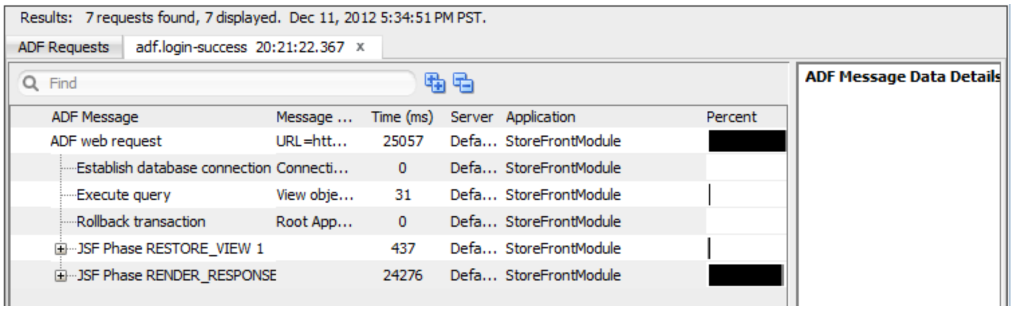
StoreFrontModule/faces/home	1702	2012-1...	StoreFr...	<anony...	Default...	d42e28...

For each ADF request displayed in the summary table, you can click the request link to view details about the request event hierarchy. Figure 48-8 shows the ADF Requests panel with the JSF lifecycle Restore View and Render Response phases displayed and their duration in milliseconds. The bar graph for the root node of the request event hierarchy (**ADF web request**) displays the total execution time.

Figure 48-8 Oracle Diagnostic Log Analyzer Displays ADF Web Request Event Hierarchy



Results: 7 requests found, 7 displayed. Dec 11, 2012 5:34:51 PM PST.

ADF Message	Message ...	Time (ms)	Server	Application	Percent
ADF web request	URL=htt...	25057	Defa...	StoreFrontModule	█
Establish database connection	Connecti...	0	Defa...	StoreFrontModule	
Execute query	View obje...	31	Defa...	StoreFrontModule	|
Rollback transaction	Root App...	0	Defa...	StoreFrontModule	
⊞ JSF Phase RESTORE_VIEW 1		437	Defa...	StoreFrontModule	|
⊞ JSF Phase RENDER_RESPONSE		24276	Defa...	StoreFrontModule	█

> **Note:**
>
> The **Percentage Request Time** bar graphs (black and gray) indicate which portion of the request's execution time resulted from ADF source code that was instrumented to generate ADF event messages (shown in black) and which portion resulted from ADF source code that is uninstrumented and therefore cannot generate ADF event messages (shown in gray). Additionally, note that the individual phases of the request do not sum to equal the total request time. This is due to the fact that only those phases of the lifecycle that are useful are represented in the log analyzer.

To examine the request in more detail, you can expand the tree for any ADF lifecycle node to further investigate where in the application the performance bottleneck occurred. Drilling down and then selecting the ADF event node in the request message panel gives you details about the component associated with each ADF event. For instance, expanding the **JSF Phase RENDER_RESPONSE** node displays all ADF events generated during that phase. Figure 48-9 shows the **JSF Phase RENDER_RESPONSE** node expanded with a long request duration bar graph for the **Get LOV list** node and the **Execute query** node. The **Execute query** node has been selected to reveal detailed ADF data in the ADF Message Data Details panel, including the view object's name and query statement. By drilling down and selecting the ADF event with the long execution time as indicated by the bar graph, you can obtain, for example, the name of the view object in the data model project that should be tuned for improved performance.

Figure 48-9 Oracle Diagnostic Log Analyzer Displays ADF Event Messages with ADF Data

Before you begin:

It may be helpful to have an understanding of logging. For more information, see Using the ADF Logger.

You will need to complete these tasks:

1. Set logging levels, as described in How to Set ADF Logging Levels.

   To log a complete hierarchy tree of ADF event messages, you must configure an ODL log level that is not more restrictive than `NOTIFICATION:16` or a Java log level that is not more restrictive than `CONFIG` for the following single package:

   - `oracle.adfdiagnostics` will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

   > **Tip:**
   >
   > The default log level for the Root Logger displayed by the editor for Oracle Diagnostics Logging Configuration ensures that ADF event messages are logged.

2. Enable logging, as described in How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers.
3. Create a log file, either from your test run or from another source.

To display ADF request messages in the log analyzer:

1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.

   Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, click the **By ADF Request** tab.
3. In the By ADF Request page, specify how many of the most recent request you want to display.

   The default displays only the most recent request.

4. Specify a time period for the entries you want to view. You can select the most recent *period* or a range.
5. To filter the request to display, use the search fields to query the log for a text pattern. For additional search fields, click the **Add Row** icon.
6. To initiate the filters and display matching ADF requests, click **Search**.
7. In the ADF Requests panel, click the desired request link to view the event hierarchy and look for ADF events that display long execution times as indicated by the **Time (ms)** bar graphs.
8. Select the desired ADF event and examine the ADF Message Data Details panel for details about the ADF component associated with the ADF event.
9. Examine the component in your application and determine whether optimization is possible.

Sorting Diagnostic Messages By ADF Events

Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases and during operations executed in the ADF Model data binding layer, ADF Controller source, and ADF Business Components source. Combined, the log analyzer refers to these messages as ADF events. You can use the log analyzer to investigate ADF events in your running application. The By Log Message page of the log analyzer lets you view ADF event messages in a flat list, organized by time of execution, with the option to switch to the By ADF Request page to view the ADF events in a hierarchical list, organized by the sequence of their execution.

ADF event messages contain useful information that helps you identify which ADF components in your application generated the event. For example, you can search the log for ADF event messages to identify the components related to displaying data in the page, executing queries, or initiating actions:

- Executing iterator binding: Displays the names of the iterators executed to manage displaying data in the page. This can be useful for diagnosing slow query updates.
- Execute query: Displays the name of the view object associated with the executed query. This can be useful when you want to view the query statement, bind parameters, and name of the view object.
- Executing method binding: Displays the names of the Java methods executed on the bound data source. This can be useful for diagnosing slow method execution.

After you display an ADF event message in the log analyzer, you can organize the event in the context of other logged messages. You can select options from the **Related** column to display:

- All messages leading up to the ADF event (related by time)
- All messages in the same web request as the ADF event (related by request)
- Only ADF event messages in the same web request (related by ADF request)

> **Tip:**
>
> The **Related by ADF Request** option displays detailed ADF data for the ADF event messages. This is the view to use, for example, when you want to display the query statement associated with the `Execute query` message.

Figure 48-10 shows the log analyzer search result for the ADF event message `Create Application Module`. The Results panel displays all messages that match the search criteria and the bottom panel displays detailed information about the component.

Figure 48-10 Oracle Diagnostic Log Analyzer Displays ADF Event Messages

When you select **Related by ADF Request** in the **Related** column of the Results panel, the log analyzer switches to display the By ADF Request page with the ADF event messages arranged hierarchically to show their execution dependencies. The By ADF Request page of the log analyzer is the preferred way to diagnose performance issues. For details about the By ADF Request page, see Using the Log Analyzer to Analyze the ADF Request. In the By Log Message page, the elapsed time is information that you can leave visible or hide from the Results panel.

Before you begin:

It may be helpful to have an understanding of logging. For more information, see Using the ADF Logger.

You will need to complete these tasks:

1. Set logging levels, as described in How to Set ADF Logging Levels.

   To log ADF event messages, do not configure an ODL log level that is more restrictive than `NOTIFICATION:16` or a Java log level that is more restrictive than `CONFIG` for the following package:

   - `oracle.adfdiagnostics` will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

   > **Tip:**
   >
   > The default log level for the Root Logger displayed by the editor for Oracle Diagnostics Logging Configuration ensures ADF event messages are logged.

2. Enable logging, as described in How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers.

3. Create a log file, either from your test run or from another source.

To display messages related by ADF events:

1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.

   Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, click the **By Log Message** tab.

3. In the By Log Message page, select the desired logger type, log levels, and log time.

   To search the log for ADF event messages, you must minimally select log level **Notification** (for ODL log level) or **Info** (for Java log level).

4. In the search dropdowns, choose the search criteria **Message** and **Contains**, and then enter any of the following ADF event messages and click **Search**.

   - `Executing iterator binding` - this can be useful for diagnosing slow query updates.
   - `Executing method binding` - this can be useful for diagnosing slow method execution.
   - `Execute query` - this can be useful when you want to view the query statement, bind parameters, and name of the view object.

   You can also filter the log on these additional ADF event messages:

   - `Refreshing binding container`
   - `Attaching an iterator binding to a datasource`
   - `Converting rows into hierarchical nodes`
   - `Estimated row count`
   - `Get LOV list`
   - `Filter LOV list`
   - `Validate Entity`
   - `Lock Entity's Parent`
   - `Lock Entity`
   - `Before posting the entity's changes`
   - `Posting the entity's changes`
   - `Posting in batches`
   - `Before committing the entity's changes`
   - `After committing the entity's changes`
   - `Before rolling back the entity's changes`
   - `After rolling back the entity's changes`
   - `Entity notifying an event`
   - `Entity notification name`
   - `Removing Entity`

- `Updating audit columns`
- `Applying Effective Date change`
- `Entity DML`
- `Entity read all attributes`
- `Create Application Module`
- `Create nested Application Module`
- `Passivating Application Module`
- `Activating Application Module`
- `Establish database connection`
- `Commit transaction`
- `Rollback transaction`
- `Validate transaction`
- `Validate value`

Examine the data portion of the Results panel for the ADF event information.

5. To view a hierarchical sequence of ADF events, with the desired ADF event message selected in the Results panel, in the **Related** column, click the icon for the desired event row and choose **Related By ADF Request** from the dropdown menu.

   The editor for Oracle Diagnostic Log Analyzer displays the By ADF Request page for the selected ADF event. Examine the bottom portion of the Results panel for additional ADF data for the ADF event. For example, you can see the query statement associated with the `Execute query` message in the ADF Data area of the Results panel.

What You May Need to Know About ADF Loggers and Log Levels

By default, the level is set to `WARNING` for all Oracle loggers. For Oracle ADF packages set `level="FINE"` for detailed logging diagnostics.

For the ADF view layer packages `oracle.adf.view.faces` and `oracle.adfinternal.view.faces`, edit these elements:

```
<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.adfinternal" level="FINE"/>
```

For the ADF Model layer packages, edit these elements:

```
<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.jbo" level="FINE"/>
```

For the **ADF Controller** layer packages, edit these elements:

```
<logger name="oracle.adf.controller" level="FINE"/>
<logger name="oracle.adfinternal.controller" level="FINE"/>
```

Alternatively, you can create a debug configuration in JDeveloper that you can choose when you start a debugging session.

The following example shows the portion of the `logging.xml` file where you can change the granularity of the log messages. Note in the example that the log for `oracle.adf.faces` has been changed to `FINE` to display more messages.

```
</logging_configuration>
...
  <loggers>
      <logger name="oracle.adf" level="INFO"/>
      <logger name="oracle.adf.faces" level="FINE"/>
      <logger name="oracle.adf.controller" level="INFO"/>
      <logger name="oracle.bc4j" level="INFO"/>
      <logger name="oracle.adf.portal" level="INFO"/>
      <logger name="oracle.vcr" level="INFO"/>
      <logger name="oracle.portlet" level="INFO"/>
      <logger name="oracle.adfinternal" level="INFO"/>
      <logger name="oracle.adfdt" level="INFO"/>
      <logger name="oracle.adfdtinternal" level="INFO"/>
   </loggers>
</logging_configuration>
```

For the latest information about the different levels of the Java Logging system, go to `http://www.oracle.com/technetwork/java/index.html`. Normally, the Java logging system supports the following log levels:

- SEVERE (most restrictive, highest log level)
- WARNING
- INFO
- CONFIG (the highest low level supported for Oracle ADF)
- FINE
- FINER
- FINEST (least restrictive, lowest log level)

What You May Need to Know About ADF Logging and Log Output

By default, loggers are hierarchical, so a logger that is a child of another logger will inherit the log level of its parent and may generate an unexpectedly large log output. As a result, when you enable loggers in the editor for Oracle Diagnostic Logging Configuration, you may want to set one log level for the parent logger and another log level for child loggers. This is especially important when you use settings `FINE`, `FINER`, `FINEST` that can be useful to diagnosis certain conditions like memory leaks, where detailed log messages are beneficial.

For example, when debugging memory leaks, you might set the `oracle.adf.share.ADFContext` logger to `FINEST`. This setting will automatically trigger the child `oracle.adf.share.ADFContext.allocationLogger` logger and may result in an allocation buffer exceeded condition for the log output file. Therefore, the solution to enable the messages needed to fix memory leaks is to make the parent level `FINEST`, while turning down the child logger to `INFO`.

```
<logger name="oracle.adf.share.ADFContext" level="FINE"/>
<logger name="oracle.adf.share.ADFContext.allocationLogger" level="INFO"/>
```

What You May Need to Know About ADF Logging and Oracle WebLogic Server

After you have deployed the Fusion web application to Oracle WebLogic Server, the operations performed by the application are logged directly to the Managed Server where the application is running:

`DOMAIN_HOME/servers/`*`server_name`*`/logs/`*`server_name`*`-diagnostic.log`

The log files for the different Managed Servers are also available from the Oracle WebLogic Server Administration Console. To verify the logs, access the Oracle WebLogic Server Administration Console `http://<admin_server_host>:<port>/console` and click **Diagnostics-Log Files**.

This log's granularity and logging properties can be changed using Oracle Enterprise Manager Fusion Middleware Control (Fusion Middleware Control). Fusion Middleware Control is a web browser-based, graphical user interface that you can use to monitor and administer a farm.

When the Fusion web application is deployed to a high availability environment, you can receive warning diagnostic messages specific to high availability by setting the level to `FINE`.

For details about using Fusion Middleware Control to change the log settings of Managed Servers and Oracle ADF, see Understanding ODL Messages and ODL Log Files in *Administering Oracle Fusion Middleware*.

Using the Oracle ADF Model Tester for Testing and Debugging

You can use the Oracle ADF Model Tester to test and validate your ADF Business Components even before you have started to build any custom user interface.

The Oracle ADF Model Tester (also referred to as the tester) is a Java application that you launch from JDeveloper when you want to interact with the business objects of the ADF Business Components data model project. The Oracle ADF Model Tester runs outside of JDeveloper and provides a full UI for testing and examining the data model project. You can run the tester to examine the view instances of the ADF **application module**, navigate the hierarchical relationship of view links, and execute custom methods from the application module's client interface, view object interface, and view row interface. The tester also interacts with the ADF Declarative Debugger to allow you to set breakpoints on the custom methods of these interfaces.

Additionally, the tester simulates many features that the user interface might expose by allowing you to view, insert, and update the contents of business objects in the database specified by the application module's configuration file (`bc4j.xcfg`). Specifically, you can use the tester to verify many aspects of the data model design, including a **master-detail relationship** between view instances, view instances and their attributes, view instance query result sets, search forms using **view criteria**, validation rules defined for attribute values, and dropdown lists on LOV-defined attributes (list of values). For more information about ways to interact with the tester to test your business objects, see Testing View Object Instances Using the Oracle ADF Model Tester. Additional information about testing with the Oracle ADF Model Tester also appears in sections specific to each business object throughout the chapters in the Building Your Business Services part of this book.

How to Run in Debug Mode and Test with the Oracle ADF Model Tester

Often you will find it useful to analyze and debug custom code in the service methods of your client interface implementation classes. When you use the Oracle ADF Model Tester, you can do this without needing to run the application with the user interface. You can use the Oracle ADF Model Tester as a testing tool to complement your debugging process.

> **Note:**
>
> The Oracle ADF Model Tester that you run in debug mode will not inherit your JDeveloper IDE Java options. To ensure that specific run/debug Java options are used with the tester, you must edit the run configuration for the data model project. You can modify the default run confirmation in the Run/ Debug page of the Project Properties dialog.

Before you begin:

It may be helpful to have an understanding of the using the runtime testing tools. For more information, see Using the Oracle ADF Model Tester for Testing and Debugging.

You will need to complete these tasks:

1. Set the desired Java options for your preferred run configuration, as described in the Running and Debugging Java Projects chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
2. Set breakpoints in the custom methods of your client interface, as described in Setting ADF Declarative Breakpoints.

To launch the Oracle ADF Model Tester and go into debug mode:

1. In the Applications window, right-click the desired application module and choose **Debug**.
2. In the Oracle ADF Model Tester, open the method testing panel for the desired client interface, as described in How to Test Custom Service Methods Using the Oracle ADF Model Tester.
3. In the method panel, select the desired method from the dropdown list, enter values to pass as method parameters, and click **Execute**.

   Return to JDeveloper to step through your code using the ADF Declarative Debugger. When you complete method execution, the method panel displays the return value (if any) and test result. The result displayed in the Oracle ADF Model Tester will indicate whether or not the method executed successfully.

How to Run the Oracle ADF Model Tester and Test with a Specific Application Module Configuration

When you right-click the application module in the Applications window and choose **Run** or **Debug**, JDeveloper will run the Oracle ADF Model Tester using the default configuration defined for the application module. If you want to test your business components with a different application module configuration (which can specify a different data source and its own set of runtime parameters), you can do so from the overview editor for the `bc4j.xcfg` file. The file is not visible in the Applications window and is only accessible from the Configurations page of the overview editor for the application module.

To run the Oracle ADF Model Tester with a specific application module configuration:

1. In the Applications window, double-click the application module that you want to test.
2. In the overview editor, click the **Configurations** navigation tab and then click the **bc4j.xcfg** configuration file link.
3. In the overview editor, select the configuration from the **Configurations** list.
4. Right-click the selected configuration and choose **Run** or **Debug** to launch the Oracle ADF Model Tester.

What Happens When You Run the Oracle ADF Model Tester in Debug Mode

The Oracle ADF Model Tester behaves as any other Java program. Specifically, it does not inherit Java options that you may have specified for the JDeveloper IDE. The tester instead uses the run configuration that you have specified for the data model project and any Java options that you may have set in that configuration.

JDeveloper lets you run the Oracle ADF Model Tester in two modes: either in debug mode or non-debug mode. When run in debug mode, the tester interacts with the ADF Declarative Debugger so that you execute custom methods using breakpoints you insert in custom Java code and Groovy script of the client interfaces. For instance, if you set a breakpoint on a method in the client interface and execute that method in the tester, then in debug mode, you can step through the code before the tester returns a success/fail result. In non-debug mode, the tester will immediately return a result to indicate whether the method executed successfully. Additionally, in either debug or non-debug mode, the tester can display runtime artifacts from the system catalog created at runtime for the application module.

How to Verify Runtime Artifacts in the Oracle ADF Model Tester

When you want to run the Oracle ADF Model Tester, but do not require the use of the ADF Declarative Debugger you can display information about the runtime artifacts from the application module's system catalog. The system catalog displays business object metadata and other information that you may find useful when you need to compare business objects.

To launch the Oracle ADF Model Tester without debugging:

1. In the Applications window, right-click the desired application module and choose **Run**.
2. In the Oracle ADF Model Tester, choose **Create - Create SysCat AM**.
3. In the data model tree, expand the **SysCatAMDefs**, right-click **ViewDefs**, and choose **Show Table**.
4. In the data viewer, scroll vertically to locate the desired view instance in the **SCName** (system catalog name) field.

   Exposing the system catalog in the tester allows access to metadata and other information specific to the runtime objects without running the debugger. For example, you can check whether a view instance has a custom Java implementation class or not.

How to Refresh the Oracle ADF Model Tester with Application Changes

The Oracle ADF Model Tester is a highly interactive tool. When you run the tester and determine a change is needed in the data model project, you can return to JDeveloper to edit the desired **application module instance** and refresh the Oracle ADF Model Tester data model to display the changes. This way you can verify your changes without needing to rerun the tester.

To reload application metadata in the Oracle ADF Model Tester:

1. In the data model project, edit your business objects and save the changes in the JDeveloper.
2. Recompile the data model project.

   For example, you can right-click the data model project in the Applications window and choose **Make** to complete the recompile step.

   Although the metadata changes that you make are not involved in compiling the project, the compile step is necessary to copy the metadata to the class path and to allow the Oracle ADF Model Tester to reload it.
3. In the Oracle ADF Model Tester, in the toolbar, click **Reload application metadata**.

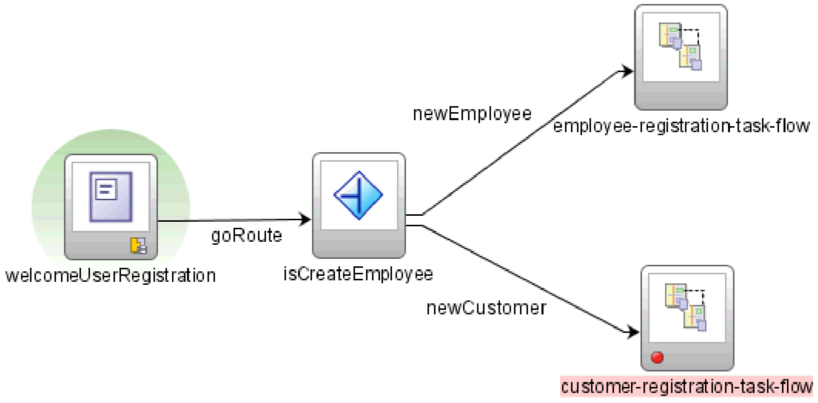
   Alternatively, you can choose **Reload Application** from the **File** menu of the Oracle ADF Model Tester.

Using the ADF Declarative Debugger

ADF Declarative Debugger allows you to place breakpoints on task flow activities, page definition bindings, page definition executables, and of course Java source code, too. When paused at a breakpoint during debugging runtime, several targeted new windows provide the ADF application developer a detailed and intuitive understanding of the application based on ADF runtime objects.

The ADF Declarative Debugger provides declarative breakpoints that you can set at the ADF object level (such as task flows, page definition executables, method and action bindings, ADF lifecycle phases), as well as standard breakpoints in custom Java code and Groovy script. ADF declarative breakpoints provide a high-level object view for debugging ADF applications. For example, you can break before a task flow activity to see what parameters would be passed to the task flow, as shown in Figure 48-11. To perform the same function using only Java breakpoints would require you to know which class or method to place the breakpoint in. ADF declarative breakpoints should be the first choice for ADF applications.

Figure 48-11 ADF Declarative Breakpoint on a Task Flow Activity



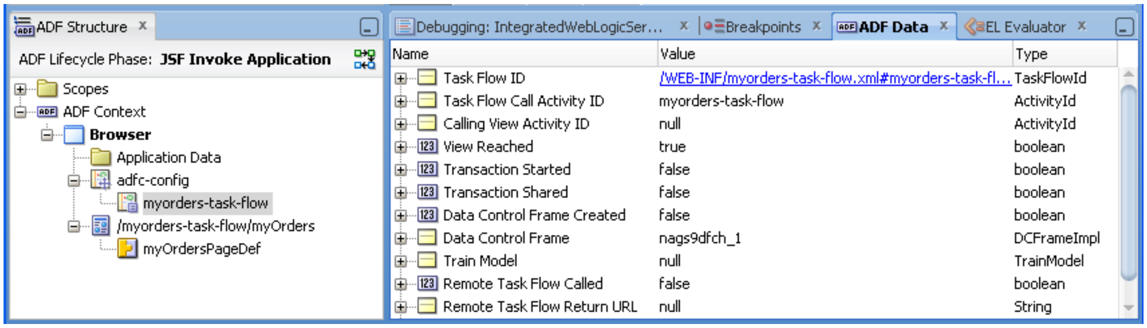
The ADF Declarative Debugger also supports standard Java code breakpoints. You can set Java code breakpoints in any ADF application. You may be able to use Java code breakpoints when an ADF declarative breakpoint does not break in the place you want.

The ADF Declarative Debugger is built on top of the Java debugger, so it has the features and behaviors of the Java debugger. But instead of needing to know the Java class or method, you can set ADF declarative breakpoints in visual editors.

The ADF Declarative Debugger provides standard debugging features such as the ability to examine variable and stack data. When an application pauses at any breakpoint (ADF Declarative or Java code breakpoint), you can examine the application status using a variety of windows. You can check where the break occurs in the Breakpoints window. You can check the call stack for the current thread using the Stack window. When you select a line in the Stack window, information in the Data window, Watches window, and all Inspector windows is updated to show relevant data. You can use the Data window to display information about arguments, local variables, and static fields in your application.

The ADF Structure window displays the runtime structure of the project. The ADF Data window automatically changes its display information based on the selection in the ADF Structure window. For example, if a task flow node is selected, the ADF Data window displays the relevant debugging information for task flows, as shown in Figure 48-12.

Figure 48-12 ADF Structure Window and ADF Data Window for a Task Flow Selection



ADF Lifecycle Phase: **JSF Invoke Application**

- Scopes
- ADF Context
  - **Browser**
    - Application Data
    - adfc-config
      - myorders-task-flow
    - /myorders-task-flow/myOrders
      - myOrdersPageDef

Name	Value	Type
Task Flow ID	/WEB-INF/myorders-task-flow.xml#myorders-task-fl...	TaskFlowId
Task Flow Call Activity ID	myorders-task-flow	ActivityId
Calling View Activity ID	null	ActivityId
View Reached	true	boolean
Transaction Started	false	boolean
Transaction Shared	false	boolean
Data Control Frame Created	false	boolean
Data Control Frame	nags9dfch_1	DCFrameImpl
Train Model	null	TrainModel
Remote Task Flow Called	false	boolean
Remote Task Flow Return URL	null	String

You can mix ADF declarative breakpoints with standard Java and Groovy breakpoints as needed in your debugging session. Although you can use step functions to advance the application from Java code breakpoint to Java code breakpoint, the step functions for ADF declarative breakpoints have more constraints and limitations. For information about using step functions on ADF declarative breakpoints, see Table 48-3.

For information on how to use ADF declarative breakpoints, see Setting ADF Declarative Breakpoints.

For information on how to use Java breakpoints on classes and methods, see Setting Breakpoints in Java Code and Groovy Script.

In a JSF application (including Fusion web applications), when a breakpoint breaks, you can use the EL Evaluator to examine the value of an EL expression. The EL Evaluator has the browse function that helps you select the correct expression to evaluate. See How to Use the EL Expression Evaluator.

Whether you plan to use ADF declarative breakpoints or standard Java and Groovy breakpoints, you can use the ADF Declarative Debugger with Oracle ADF source code. You can obtain Oracle ADF source code with Debug libraries. For information about loading source code. see Using ADF Source Code with the Debugger.

Using ADF Source Code with the Debugger

If you have valid Oracle ADF support, you can obtain complete source code for Oracle ADF by opening a service request with Oracle Worldwide Support. You can request a specific version of the Oracle ADF source code. You may be given download and password information to decrypt the source code ZIP file. Contact Oracle Worldwide Support for more information.

Adding Oracle ADF source code access to your application debugging session will:

- Provide access to the JDeveloper Quick Javadoc feature in the source editor. Without the source code, you will have only standard Javadoc.
- Enhance the use of Java code breakpoints by displaying the Oracle source code that's being executed when the breakpoint is encountered. You can also set breakpoints easier by clicking on the margin in the source code line you want to break on. Without the source code, you will have to know the class, method, or line number in order to set a breakpoint within Oracle code.
- For Java code breakpoints set within the source code, you will be able to see the values of all local variables and member fields in the debugger.

The ADF source code ZIP file may be delivered within an encrypted "outer" ZIP file to protect its contents during delivery. The "outer" ZIP name is sometimes a variant of the service request number.

After you have received or downloaded the "outer" ZIP archive file, unzip it with the provided password to access the actual source code ZIP file. The ADF source code ZIP name should be a variant of the Oracle ADF version number and build number. For example, the Oracle ADF source ZIP file may have a format similar to `adf_vvvv_nnnn_source.zip`, where *vvvv* is the version number and *nnnn* is the build number.

After you have access to the Oracle ADF source code ZIP file, extract its contents to a working directory.

How to Set Up the ADF Source User Library

You create a name for the source user library and then associate that name with the source ZIP file.

To add the ADF source zip file to the user library

1. In the main menu, choose **Tools** and then **Manage Libraries**.
2. In the Manage Libraries dialog, with the **Libraries** tab selected, click **New**.
3. In the Create Library window, enter a library name for the source that identifies the type of library.
4. Select the **Source Path** node in the tree structure. Click **Add Entry**.

> **Note:**
>
> Do not enter a value for the class path. You need to provide a value only for the source path.

5. In the Select Path Entry window, browse to the directory where the file was extracted and select the source ZIP file. Click **Select**.
6. In the Create Library window, verify that the source path entry has the correct path to the source ZIP file, and deselect **Deployed by Default**. Click **OK**.
7. Click **OK**.

How to Add the ADF Source Library to a Project

After the source library has been added to the list of available user libraries, add it to the project you want to debug.

To add the ADF source zip file to the project:

1. In the Applications window, double-click the project to which you want to add the ADF library or right-click the project and choose **Project Properties**.
2. In the Project Properties dialog, select **Libraries and Classpaths**.
3. Click **Add Library**.

4. In the Add Library dialog, under the **Users** node, select the source library you want to add and click **OK**.

   The source library should appear in the **Classpath Entries** section in the Project Properties dialog.

5. Click **OK**.

How to Use the EL Expression Evaluator

When the application is paused at a breakpoint, you can use the EL expression evaluator to enter an EL expression for evaluation. You can enter arbitrary EL expressions for evaluation within the current context. If the EL expression no longer applies within the current context, the value will be evaluated to `null`.

The EL Evaluator is different from the Watches window in that EL evaluation occurs only when stopped at a breakpoint, not when stopped at subsequent debugging steps.

The EL Evaluator is available for debugging any JSF application.

> ⚠ **Caution:**
>
> Be wary when you are evaluating EL expressions that you do not indirectly change application data and therefore the behavior of the application. For example, if you evaluate `#{foo.bar}`, the corresponding `getBar()` method modifies application data.

Before you begin:

It may be helpful to have an understanding of the ADF Declarative Debugger. For more information, see Using the ADF Declarative Debugger.

You will need to complete this task:

Set the desired breakpoints in the application, as described in Setting ADF Declarative Breakpoints. The application must be a JSF application. It does not need to be an ADF application.

To use the EL Evaluator:

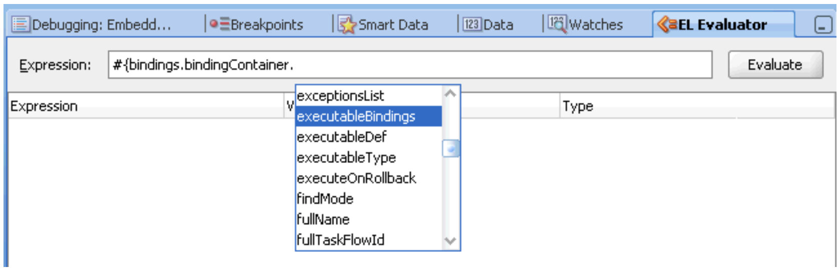
1. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug *<project_name>***.
   - From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
2. When the breakpoint is reached, the EL Evaluator should appear as a tab in the debugger window area. Click the **EL Evaluator** tab to bring it forward. If it does not appear, in the main menu, choose **Window** and then **Debugger > EL Evaluator**.

> **Note:**
>
> Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the object breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

3. Enter an EL expression in the **Expression** input field.

   When you click in the field after entering #{ or after a period, a discovery function provides a selectable list of expression items, as shown in Figure 48-13. Auto-completion will be provided for easy entry. You can evaluate several EL expressions at the same time by separating them with semicolons.

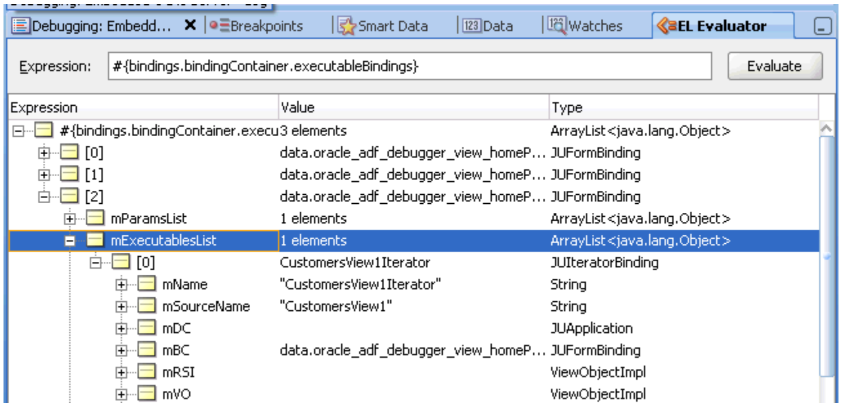
Figure 48-13 Using the Discovery Function of the EL Evaluator



Expression: #{bindings.bindingContainer.

4. When you finish entering the EL expression, click **Evaluate** and the expression is evaluated, as shown in Figure 48-14.

Figure 48-14 EL Expression Evaluated



Expression: #{bindings.bindingContainer.executableBindings}

Expression	Value	Type

mVO		ViewObjectImpl

How to View and Export Stack Trace Information

If you are unable to determine what the problem is and you cannot resolve it yourself, typically your next step is to ask someone else for assistance. Whether you post a question in the OTN JDeveloper Discussion Forum or open a service request on Metalink, including the stack trace information in your posting is extremely useful to anyone who will need to assist you further to understand exactly where the problem is occurring.

JDeveloper's Stack window makes communicating this information easy. Whenever the debugger is paused, you can view the Stack window to see the program flow as a stack of method calls that got you to the current line. You can use the Preferences dialog to set the Stack window preference to include the line number information, as well as the class and method name that will be there by default. Finally, the Stack window context menu option **Export** lets you save the current stack information to an external text file whose contents you can then post or send to whomever might need to help you diagnose the problem.

Before you begin:

It may be helpful to have an understanding of the ADF Declarative Debugger. For more information, see Using the ADF Declarative Debugger.

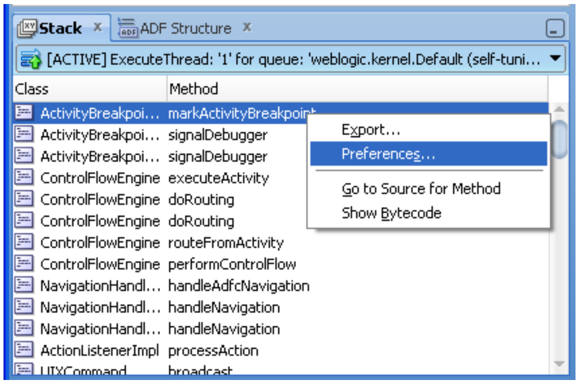
You will need to complete this task:

> Set the desired breakpoints in the application, as described in Setting ADF Declarative Breakpoints. The application must be a JSF application. It does not need to be an ADF application.

To save stack information to a text file:

1. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug *<project_name>***.
   - From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
2. When the breakpoint is reached and the debugger is paused, the Stack window should appear as a window to the side of the debugger window area. Click the **Stack** tab to bring it forward. If the Stack window does not appear, in the main menu, choose **Window** and then **Debugger > Stack**.
3. When you want to change the Stack window preference for example to include the line number information in the export file, right-click the Stack window background and choose **Preferences**, as shown in Figure 48-15.

Figure 48-15 Stack Window Context Menu



[ACTIVE] ExecuteThread: '1' for queue: 'weblogic.kernel.Default (self-tuni...

Class	Method
ActivityBreakpoi...	markActivityBreakpoint
ActivityBreakpoi...	signalDebugger
ActivityBreakpoi...	signalDebugger
ControlFlowEngine	executeActivity
ControlFlowEngine	doRouting
ControlFlowEngine	doRouting
ControlFlowEngine	routeFromActivity
ControlFlowEngine	performControlFlow
NavigationHandl...	handleAdfcNavigation
NavigationHandl...	handleNavigation
NavigationHandl...	handleNavigation
ActionListenerImpl	processAction
UIXCommand	broadcast

4. Right-click the Stack window background and choose **Export**.
5. In the Export Stack dialog, name the file and choose the location where you want to save the file. Click **OK**.

Setting ADF Declarative Breakpoints

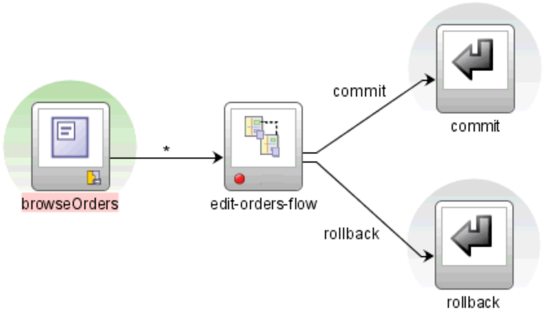
You can declaratively set breakpoints on task flow activities, page definition bindings, page definition executables, Java source code, and so forth using the ADF Declarative Debugger features.

You use the ADF Declarative Debugger features in JDeveloper to declaratively set breakpoints on **ADF task flow** activities, page definition executables, method, action, and value bindings, ADF Lifecycle phases, and contextual events. Instead of needing to know all the internal constructs of the ADF code, such as method names and class names, you can set breakpoints at the highest level of object abstraction.

You can add breakpoints to task flow activities in the task flow diagrammer or you can launch the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window. In the task flow diagrammer, you can select a task flow activity and use the context menu to toggle or disable breakpoints on that activity, or press the F5 button. After the application pauses at the breakpoint, you can view the runtime structure of the objects in the ADF Structure window as a tree structure. The ADF Data window displays a list of data for a given object selected in the ADF Structure window.

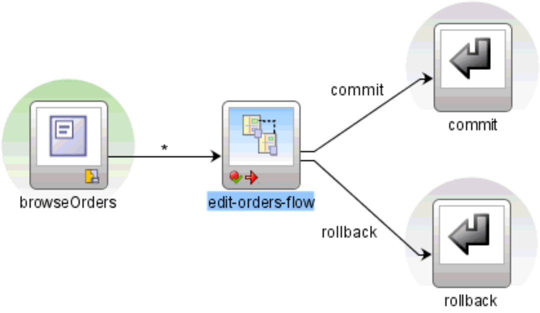
For example, when you set a breakpoint on a **task flow call activity** in the Browse Orders task flow, a red dot icon appears in the call activity, as shown in Figure 48-16.

Figure 48-16 ADF Declarative Breakpoint on a Task Flow Activity



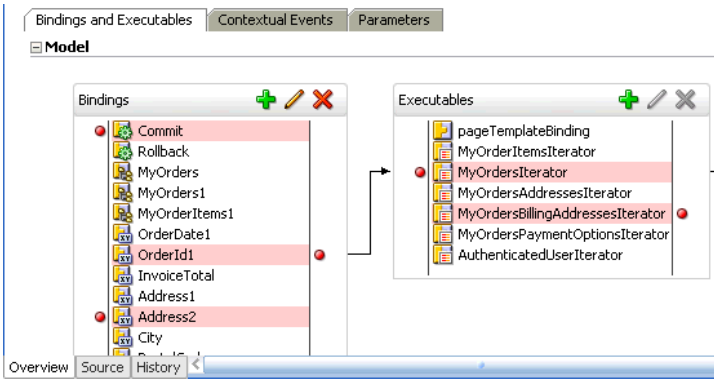
When the breakpoint is reached, the application is paused and the icon changes, as shown in Figure 48-17.

Figure 48-17 Application Paused at an ADF Declarative Breakpoint



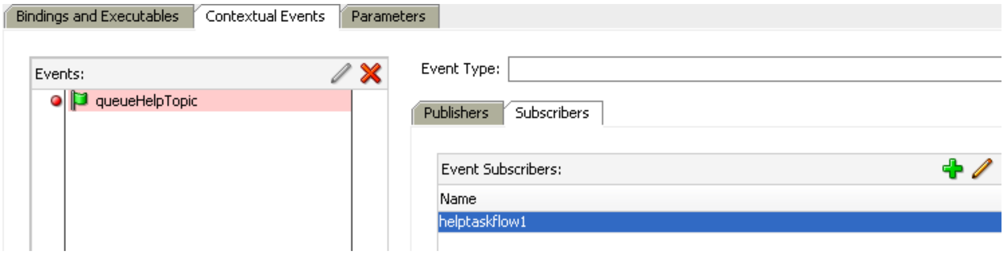
Similarly, you can set Before and After breakpoints in the page definition file. You set breakpoints for supported value bindings (see Table 48-1 for the list of supported value binding) and for executables by clicking on the left or right margin next to the item or by selecting from the context menu. Clicking on the left margin adds a **Before page definition** breakpoint, and clicking on the right margin adds an **After page definition** breakpoint. Again, a red dot icon that indicates the breakpoint is set, as shown in Figure 48-18.

Figure 48-18 ADF Declarative Breakpoints on ADF Bindings in the Page Definition File



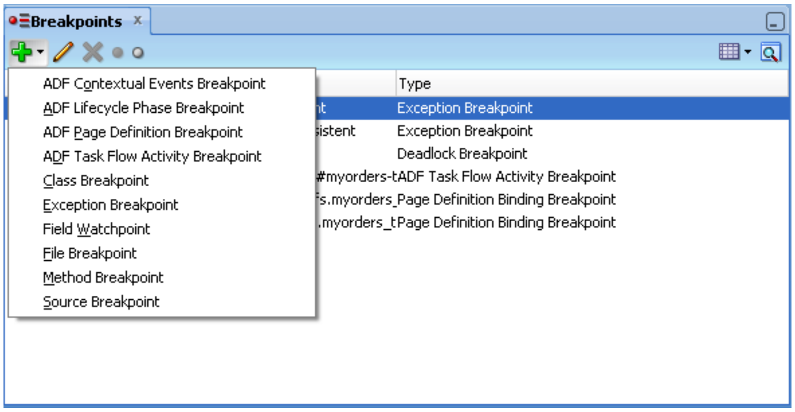
The page definition file also lets you set breakpoints on contextual events that your page or region within a page raises at runtime, as shown in Figure 48-19.

Figure 48-19 ADF Declarative Breakpoint on a Contextual Event in the Page Definition File



You can also set Before and After breakpoints on all the ADF lifecycle phases. You can launch the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window, as shown in Figure 48-20.

Figure 48-20 Breakpoints Window Add Breakpoint Icon Dropdown Menu



Breakpoints
ADF Contextual Events Breakpoint
ADF Lifecycle Phase Breakpoint
ADF Page Definition Breakpoint
ADF Task Flow Activity Breakpoint
Class Breakpoint
Exception Breakpoint

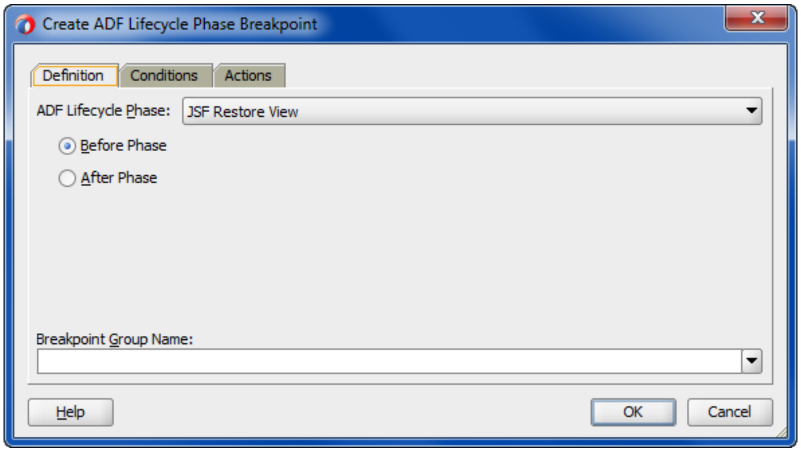
File Breakpoint
Method Breakpoint
Source Breakpoint

	Type
nt	Exception Breakpoint
sistent	Exception Breakpoint
	Deadlock Breakpoint
#myorders-t	ADF Task Flow Activity Breakpoint
s.myorders_	Page Definition Binding Breakpoint
.myorders_t	Page Definition Binding Breakpoint

The Create ADF Lifecycle Phase Breakpoint dialog allows you to select different lifecycle breakpoint options, as shown in Figure 48-21.

Figure 48-21 Create ADF Lifecycle Phase Breakpoint Dialog



ADF Lifecycle Phase: JSF Restore View

● Before Phase

○ After Phase

Breakpoint Group Name:

Alternatively, you can use the ADF Lifecycle Breakpoints dialog from the ADF Structure window or the task flow diagrammer to set ADF lifecycle phase breakpoints. For more information about ADF lifecycle phases, see Understanding the Fusion Page Lifecycle .

You can define both ADF declarative breakpoints and standard Java code breakpoints when using the ADF Declarative Debugger. Depending on your debugging scenario, you may only need to use the declarative breakpoints to debug the application. Or you may find it necessary to add additional breakpoints in Java code that are not available declaratively. For information on Java code breakpoints, see How to Set Java Breakpoints on Classes and Methods. Table 48-1 lists the available ADF Declarative Debugger breakpoint locations.

Table 48-1 ADF Declarative Debugger Breakpoints

ADF Area	Breakpoint Type	Where Inserted	JDeveloper Context Menu Command	Description
ADF lifecycle phase	Before ADF lifecycle phase Break after ADF lifecycle phase	ADF Structure window **ADF Lifecycle Breakpoints** toolbar button Task flow diagrammer Breakpoints window **Add** button		A Before breakpoint pauses debugging before the ADF lifecycle phase. An After breakpoint pauses debugging after the ADF lifecycle phase. The ADF lifecycle JSF Render Response and Prepare Render phase Before and After breakpoints are executed in the following order: • Before `jsfRenderResponse`. • Before `prepareRender`. (`prepareRender` phase executes). • After `prepareRender`. (`jsfRenderResponse` phase executes). • After `jsfRenderResponse`.
ADF page definition - bindings and executables	Break before/Break after executable: • Iterator • Region instantiation	Page definition overview editor **Bindings and Executables** tab, Executables section Breakpoints window **Add** button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses debugging before or after executable is refreshed. For task flow bindings, this represents two times per lifecycle: first, during `prepareModel` (initial region creation), and then again during `prepareRender` (where dynamic regions swap their corresponding task flow ID).
	Break before/Break after action binding: • `methodAction` • Built-in operations	Page definition overview editor **Bindings and Executables** tab, Bindings section Breakpoints window **Add** button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses debugging before or after binding is executed.
	Break before/Break after attribute value binding	Page definition overview editor **Bindings and Executables** tab, Bindings section Breakpoints window **Add** button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses debugging before or after the attribute's `setInputValue()` ADF source code method is executed. New values will be the parameters to `setInputValue()`.
	Break before/Break after **table binding**	Page definition overview editor **Bindings and Executables** tab, Bindings section Breakpoints window **Add** button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses debugging before or after the ADF hierarchical binding's `updateValuesFromRows()` source code method is executed. New values will be the parameters to `updateValuesFromRows()`.

Table 48-1 (Cont.) ADF Declarative Debugger Breakpoints

ADF Area	Breakpoint Type	Where Inserted	JDeveloper Context Menu Command	Description
	Break before/Break after tree binding	Page definition overview editor **Bindings and Executables** tab, Bindings section Breakpoints window **Add** button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses in either of these two cases: 1. When making a node selection in the tree, pauses debugging before or after the ADF hierarchical binding's `updateValuesFromRows()` source code method is executed. New values will be the parameters to `updateValuesFromRows()`. 2. When expanding the tree, pauses debugging before or after the ADF tree collection model's `modifyExpanded()` source code method is executed.
ADF page definition - contextual events	Break before/Break after contextual events	Page Definition overview editor **Contextual Events** tab, Events section Breakpoints window **Add** button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses debugging either before the event is dispatched or after the event, just before the event is consumed by a subscriber to the event.
ADF task flow	Break before activity	Task flow diagrammer Breakpoints window **Add** button	Toggle Breakpoint or F5 Disable Breakpoint	Pauses debugging before the activity executes within the JSF Invoke Application phase. The activity where the declarative breakpoint is defined has not yet been executed. An exception are view activities; they pause within the JSF Render Response phase after the view activity is executed, but before the new page is rendered. By pausing at that point, the view activity values can be inspected using the ADF Structure and ADF Data windows.

The ADF Declarative Debugger uses the standard debugger icons and notations for setting, toggling, and indicating the status of ADF declarative breakpoints.

When an ADF declarative breakpoint is set, it appears as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window, as shown in Figure 48-22, Figure 48-23, Figure 48-24, and Figure 48-25.

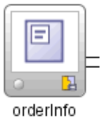
java.lang.Exception (uncaught), PersistenExce
java.lang.AssertionError (uncaught), PersExce

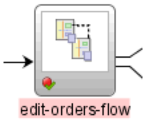
When an ADF task flow or page definition declarative breakpoint is disabled, the red icon becomes a gray icon, as shown in Figure 48-26.

Figure 48-26 ADF Declarative Breakpoint Disabled



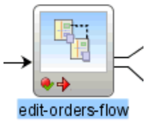
When an ADF task flow declarative breakpoint is active, the red dot icon has a green checkmark, as shown in Figure 48-27.

Figure 48-27 ADF Declarative Breakpoint Active



When the application is paused at an ADF declarative breakpoint, an **Execution Point** icon appears, as shown in Figure 48-28.

Figure 48-28 Application Paused at an Execution Point on a Task Flow



When the application is paused at an ADF lifecycle declarative breakpoint, an **Execution Point** icon appears next to the lifecycle phase in the ADF Lifecycle Breakpoints window, as shown in Figure 48-29. The name of the current ADF lifecycle phase is also displayed in the ADF Structure window.

Figure 48-29 Application Paused at an Execution Point on an ADF Lifecycle Phase

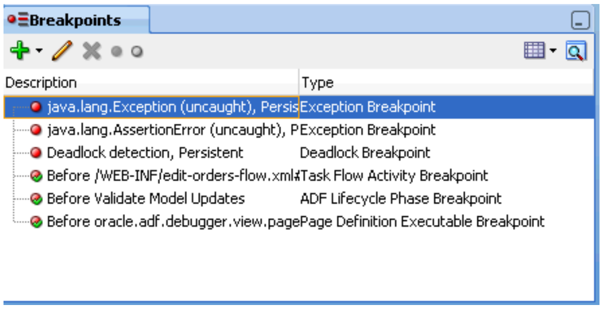
The Breakpoints window list all breakpoints, including ADF declarative breakpoints, as shown in Figure 48-30.

Figure 48-30 Breakpoints Window Showing ADF Declarative and Java Code Breakpoints



Breakpoints

Description	Type
java.lang.Exception (uncaught), Persis	Exception Breakpoint
java.lang.AssertionError (uncaught), P	Exception Breakpoint
Deadlock detection, Persistent	Deadlock Breakpoint
Before /WEB-INF/edit-orders-flow.xml#	Task Flow Activity Breakpoint
Before Validate Model Updates	ADF Lifecycle Phase Breakpoint
Before oracle.adf.debugger.view.page	Page Definition Executable Breakpoint

The Breakpoints window has a toolbar that includes buttons to add, edit, delete, enable, and disable breakpoints, as shown in Figure 48-30. The **Add Breakpoint** icon dropdown menu includes functions to create and manage ADF contextual events breakpoints, ADF lifecycle phase breakpoints, ADF page definition breakpoints (for ADF bindings and executables), ADF task flow activity breakpoints, and standard Java code breakpoints.

You can use the Breakpoints window to view the location of the ADF declarative breakpoint in its corresponding source file:

- Double-click a contextual event breakpoint to open the overview editor for the corresponding page definition file. You can then click the Contextual Events tab to view the location of the breakpoint.
- Double-click an ADF lifecycle phase breakpoint to open the ADF Lifecycle Breakpoints window which displays all ADF lifecycle execution points.
- Double-click a task flow activity breakpoint to open the task flow diagrammer for the corresponding task flow.
- Double-click an ADF binding breakpoint to open the overview editor for the corresponding page definition file.

To manage how the debugger handles a breakpoint, you can open the Edit ADF Breakpoint dialog for individual breakpoints that appear in the Breakpoints window. Or, you can select multiple ADF declarative breakpoints and customize the behavior of their common fields.

Table 48-2 lists how an ADF declarative breakpoint will appear in the Breakpoints window under the Description and Type columns.

Table 48-2 Breakpoints Window Display of ADF Declarative Breakpoints

Declarative Breakpoint Type	Description Column	Type Column
Before/After contextual event	Before *page definition@event name* After *page definition@event name*	Contextual events breakpoint
Before ADF lifecycle phase	Before *adf lifecycle phase*	ADF lifecycle phase breakpoint
After ADF lifecycle phase	After *adf lifecycle phase*	ADF lifecycle phase breakpoint
Before/After page definition executable: • Iterator	Before *page definition@executable id* After *page definition@executable id*	Page definition executable breakpoint
Before/After page definition action binding: • `methodAction` • Built-in Operations	Before *page definition@binding id* After *page definition@binding id*	Page definition binding breakpoint
Before/After page definition attribute value binding	Before *page definition@binding id* After *page definition@binding id*	Page definition binding breakpoint
Before/After page definition table binding	Before *page definition@binding id* After *page definition@binding id*	Page definition binding breakpoint

Table 48-2 (Cont.) Breakpoints Window Display of ADF Declarative Breakpoints

Declarative Breakpoint Type	Description Column	Type Column
Before/After page definition tree binding	Before *page definition@binding id* After *page definition@binding id*	Page definition binding breakpoint
Before ADF task flow activity	Before *task flow document#task flow id@activity id*	Task flow activity breakpoint

Table 48-3 lists the step commands that can be used with ADF declarative breakpoints.

Table 48-3 ADF Declarative Debugger Step Commands

ADF Debugger Step Commands	Description
Find Execution Point	Supported for declarative breakpoints to display the current execution point open and active within the corresponding editor.
Step Over (F8)	Supported for task flow activity declarative breakpoints to step from activity to activity within a task flow. If user interaction is required (for example, page displayed), once it is received (for example, button selected), processing will resume and then will pause before the next task flow activity. Supported for page definition executable breakpoints. The application will step to the next page definition executable breakpoint. Supported for ADF lifecycle phase declarative breakpoints to step to the next Before or After ADF lifecycle phase location.
Step Into (F7)	Supported only for task flow activity declarative breakpoints defined on task flow call activities. Task flow activity declarative breakpoints pause the application just before the activity is executed. The Step Into function provides the ability to pause debugging just prior to executing the called task flow default activity. This action would be the same as placing a task flow activity declarative breakpoint on the called task flow default activity.
Step Out (Shift F7)	Supported for task flow activity declarative breakpoints to step out of the current called task flow and back into the caller (if any). If user interaction is required (for example, page displayed) once user interaction received (for example, button selected), processing will resume and will pause before the next user interaction or activity within the calling task flow.
Continue Step (Shift F8)	Not supported for declarative breakpoints.
Step to End of Method	Not supported for declarative breakpoints.
Run to Cursor	Not supported for declarative breakpoints.
Pop Frame	Not supported for declarative breakpoints, as it is for Java code, to return to a previous point of execution.

How to Set and Use Task Flow Activity Breakpoints

After you have created a task flow diagram, you can set ADF declarative breakpoints on task flow activities.

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on a task flow activity:

1. Open the task flow in the task flow diagrammer, or from the Breakpoints window, click the **Add** icon and select **ADF Task Flow Activity Breakpoint**.

   If the Breakpoints window is not already displayed, in the main menu, choose **Window** and then **Breakpoints**.

2. Set the task flow activity breakpoint.

   - If you use the task flow diagrammer, right-click and choose **Toggle Breakpoint** from the context menu, or press F5.

     A breakpoint icon appears on the task flow activity.

   - If you launched the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window, click **Browse** to select a task flow definition, select the task flow from the **Task Flow** dropdown list, select the task flow activity from the **Activity** dropdown list, and click **OK**.

3. Optionally, configure a breakpoint's settings to manage the debugger:

   a. In the main menu, choose **Window** and then **Breakpoints**.

   b. In the Breakpoints window, select the task flow activity breakpoint you want to configure and click the **Edit** icon.

   c. In the Edit ADF Task Flow Activity Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.

   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

      For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.

   - In the main menu, choose **Run** and then **Debug *<project_name>***.

   - From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.

   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the task flow activity. You can examine the application using various debugger windows.

> **Note:**
>
> Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

Task flow activity declarative breakpoints pause the application just before the task flow activity is executed (except for view activities).

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See How to Use the ADF Structure Window, and How to Use the ADF Data Window.
7. In the ADF Structure window, select a node and view pertinent information in the ADF Data window.

   Task flow activity declarative breakpoints pause the application just before the task flow activity is executed. You can use the **Step Into** (F7) function to pause the application just prior to executing the called task flow default activity.
8. Continue debugging the application as required, using the step functions as described in Table 48-3. The key step function is **Step Into** (F7).

   When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

How to Set and Use Page Definition Executable Breakpoints

If your page definition has executables, you can set breakpoints to pause the application before or after these executables. For example, you can set breakpoints to pause the application when iterators are refreshed.

> **Note:**
>
> If you are setting an After iterator breakpoint to pause the application after a view object query has been executed, be aware that the application may pause at this breakpoint multiple times. Also be aware that it may pause at this breakpoint even when the query has not been executed. If you need to know whether the query has been executed, select the relevant ADF Business Components in the ADF Structure window and view their corresponding data in the ADF Data window. For more information on how to use these windows, see How to Use the ADF Structure Window, and How to Use the ADF Data Window.
>
> For more information about using Java code breakpoints on view object query execution, see What You May Need to Know About Oracle ADF Breakpoints.

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on an executable in the page definition file:

1. In the Applications window, double-click the page definition file that contains the executable in which you want to set a breakpoint.
2. In the overview editor, click the **Bindings and Executables** tab, select an executable from the **Executables** list, and click in the breakpoint margin to the left of the item.

   A breakpoint icon appears in the margin next to the item.
3. Optionally, configure a breakpoint's settings to manage the debugger:
   a. In the main menu, choose **Window** and then **Breakpoints**.
   b. In the Breakpoints window, select the executable breakpoint you want to configure and click the **Edit** icon.
   c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

      For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.
4. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug <*project_name*>**.
   - From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears in the margin next to the breakpoint icon of the executable item. You can examine the application using several debugger windows.

   The application pauses when the executable binding is refreshed. If this is a taskFlow executable, the pause occurs in the `prepareModel` and the `prepareRender` lifecycles.

   > **Note:**
   >
   > Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Executable Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.
6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF

Structure window and its corresponding data in the ADF Data window. See How to Use the ADF Structure Window, and How to Use the ADF Data Window.

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

How to Set and Use Page Definition Action Binding Breakpoints

You can set breakpoints in the page definition file on action bindings and `methodAction` bindings. The application pauses when the binding is executed.

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on an action binding in the page definition file:

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.

2. In the overview editor, click the **Bindings and Executables** tab, select a `methodAction` binding or built-in operation item from the **Bindings** list, and click in the breakpoint margin to the left of the item.

   A breakpoint icon appears next to the item.

3. Optionally, configure a breakpoint's settings to manage the debugger:

   a. In the main menu, choose **Window** and then **Breakpoints**.

   b. In the Breakpoints window, select the action binding breakpoint you want to configure and click the **Edit** icon.

   c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.

   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

      For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.

   - In the main menu, choose **Run** and then **Debug *<project_name>***.
   - From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the action binding item. You can examine the application using several debugger windows.

   The application is paused when the binding is executed.

> **Note:**
>
> Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See How to Use the ADF Structure Window, and How to Use the ADF Data Window.
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

How to Set and Use Page Definition Value Binding Breakpoints

If the page definition has one of these values bindings, you can set breakpoints to pause the application:

- Attribute value binding
- Tree value binding
- Table value binding

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on a value binding in the page definition file:

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.
2. In the overview editor, click the **Bindings and Executables** tab, select an attribute, tree, or table binding from the **Bindings** list, and click in the breakpoint margin to the left of the item. A breakpoint icon appears next to the value binding.
3. Optionally, configure a breakpoint's settings to manage the debugger:
   a. In the main menu, choose **Window** and then **Breakpoints**.
   b. In the Breakpoints window, select the binding breakpoint you want to configure and click the **Edit** icon.
   c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug *<project_name>***.
   - From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the attribute value binding. You can examine the application using several debugger windows.

   The application pauses before an appropriate method of the ADF source code executes, as described in Table 48-1. New values will be the parameters that go into the method.

   > **Note:**
   >
   > Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See How to Use the ADF Structure Window, and How to Use the ADF Data Window.
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. Continue debugging the application as required, using the step functions as described in Table 48-3. The key step function is Step Over (F8).

   When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

How to Set and Use Page Definition Contextual Event Breakpoints

If the page definition defines contextual events, you can set breakpoints on the contextual events to pause the application.

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on a contextual event in the page definition file:

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.

2. In the overview editor, click the **Contextual Events** tab, select a contextual event from the **Events** list, and click in the breakpoint margin to the left of the item. A breakpoint icon appears next to the contextual event.
3. Optionally, configure a breakpoint's settings to manage the debugger:
   a. In the main menu, choose **Window** and then **Breakpoints**.
   b. In the Breakpoints window, select the contextual event breakpoint you want to configure and click the **Edit** icon.
   c. In the Edit ADF Contextual Events Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

      For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.
4. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug *<project_name>***.
   - From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the contextual event. You can examine the application using several debugger windows.

   The application pauses before the contextual event is raised.

   > **Note:**
   >
   > Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See How to Use the ADF Structure Window, and How to Use the ADF Data Window.
7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. Continue debugging the application as required, using the step functions as described in Table 48-3. The key step function is Step Over (F8).

   When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

How to Set and Use ADF Lifecycle Phase Breakpoints

You can set both Before and After ADF lifecycle phase breakpoints on any of the ADF lifecycle phases. For each phase, you can set Before only, After only, or both. You can set breakpoints on as many phases as you want.

You can create the breakpoint and customize the options using the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window menu. Or You can create breakpoints with the default options using the ADF Lifecycle Breakpoints window. After a lifecycle breakpoint has been set, you can edit the options using the Edit ADF Lifecycle Phase Breakpoint dialog, which is also launched from the Breakpoints window.

You can set ADF lifecycle breakpoints on any of the ADF lifecycle phases:

- JSF Restore View
- Initialize Content
- Prepare Model
- JSF Apply Request Values
- JSF Process Validations
- JSF Update Model Values
- Validate Model Updates
- JSF Invoke Application
- Metadata Commit
- Prepare Render
- JSF Render Response

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set or manage an ADF lifecycle phase breakpoint from the Breakpoints window:

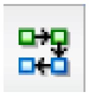
1. In the main menu, choose **Window** and then **Breakpoints**.
2. In the Breakpoints window, click **Add** and choose **ADF Lifecycle Phase Breakpoint**.
3. In the Create ADF Lifecycle Phase Breakpoint dialog **Definition** tab:
   - Select the ADF lifecycle phase where you want to set a breakpoint
   - Select **Before Phase** or **After Phase** breakpoint
4. In the **Conditions** tab, select the options you want and click **OK**.
5. In the **Actions** tab, select the options you want and click **OK**.

To set an ADF Lifecycle Phase Breakpoint using the breakpoint icon:

1. In the Applications window, double-click any task flow configuration file and in the overview editor click the **Diagram** tab.

2. In the toolbar of the task flow diagrammer or in the title bar of ADF Structure window, click the **ADF Lifecycle Breakpoints** icon, as shown in Figure 48-31.

Figure 48-31 ADF Lifecycle Breakpoints Icon



3. In the ADF Lifecycle Breakpoints window, click in the left margin next to the ADF lifecycle phase to set a Before breakpoint, and on the right margin to set an After breakpoint. A red dot icon appears to indicate the breakpoint is set, as shown in Figure 48-32. The breakpoint will be set with the default breakpoint options. To remove the breakpoint, click the red dot icon.

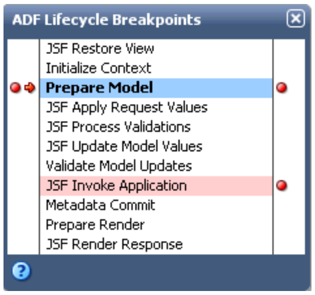
JSF Render Response

4. If you want to edit breakpoint options, select the breakpoint in the Breakpoints window and click the **Edit** icon.

To debug an application using ADF Lifecycle Phase Breakpoints:

1. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug *<project_name>***.
   - From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.
2. When the application is paused at an ADF lifecycle phase breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon and the ADF lifecycle phase is in bold in the ADF Lifecycle Breakpoints window, as shown in Figure 48-33. You can examine the application using several debugger windows.

Figure 48-33 Execution Point Displayed in the ADF Lifecycle Breakpoints Window



> **Note:**
>
> Be sure that the application has actually hit a breakpoint by checking the Breakpoints window for an breakpoint encounter or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

3. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. The current ADF lifecycle phase is displayed at the top of the ADF Structure window. For more information, see How to Use the ADF Structure Window, and How to Use the ADF Data Window.
4. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
5. Continue debugging the application as required, using the step functions as described in Table 48-3. The key step function is Step Over (F8).

   When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

How to Use the ADF Structure Window

When the application is paused at a breakpoint, the ADF Structure window displays a tree structure of the ADF runtime objects and their relationships within the application. In particular, it shows the hierarchy of view ports, which represent either the main browser window or contained regions and portlets. When you select different items in the ADF Structure window, the data display in the accompanying ADF Data window changes. For more information about the ADF Data window, see How to Use the ADF Data Window.

The ADF Structure window and the ADF Data window are shown by default during a debugging session when either of the following is true:

- The project being debugged contains a `WEB-INF/adfc-config.xml` file.
- The project being debugged contains any **ADF Faces** tag libraries.

You can launch the ADF Structure window by choosing **Window > Debugger > ADF Structure** in the main menu. From the ADF Structure window, you can launch the ADF Lifecycle Breakpoints window using the **ADF Lifecycle Breakpoints** icon.

When a breakpoint is encountered, the ADF Structure window displays the ADF lifecycle phase and a tree structure of the runtime objects, as shown in Figure 48-34.

Figure 48-34   ADF Structure Window Showing the Runtime Objects

ADF Data

Name	Value	Type
Task Flow ID	/WEB-INF/orders-flow.xml#or...	TaskFlowId
Task Flow Call Activity ID	null	ActivityId
Calling View Activity ID	null	ActivityId
View Reached	false	boolean
Transaction Started	false	boolean
Transaction Shared	true	boolean
Data Control Frame Created	false	boolean
Data Control Frame	yv4buo1il_2	DCFrameImpl
Train Model	null	TrainModel
Remote Task Flow Called	false	boolean
Remote Task Flow Return URL	null	String
pageFlowScope	0 entries	PageFlowScope

The roots of the hierarchy are the sibling nodes **Scopes** and **ADF Context**. The current view port where processing has stopped appears in bold. Default selections within the tree will be retained from the previous breakpoint, so you can monitor any changes between breakpoints. The ADF object where the ADF declarative breakpoint was defined will be opened in the corresponding JDeveloper editor, either the task flow diagrammer or the overview editor for page definition files.

The ADF Structure tree will be rebuilt each time the application breaks and at subsequent steps to reflect the changed state of the objects. Although the entire tree hierarchy will be displayed, only items within the current view port and its parent view port(s) will be available for selection and further inspection. All other items in the tree hierarchy not in the current context will be dimmed and disabled. You can still use the hierarchy to identify runtime object relationships within the application, but it will be limited to the current context (and its parent view ports).

Table 48-4 lists the different types of items that can be displayed in the ADF Structure window hierarchy tree.

Table 48-4 ADF Structure Window Items

ADF Structure Tree Item	Description
Scopes	Displayed at the top of the ADF Structure hierarchy above its sibling **ADF Context** node. There is only one **Scopes** node in the ADF Structure hierarchy. You can expand the **Scopes** node to show a list of child scope nodes (such as **viewScope** and **pageFlowScope**). If you select a child scope node, the ADF Data window displays the variables and values for that scope.
ADF context	Displayed as the root node of the ADF Structure hierarchy below its sibling **Scopes** node. There will only be one **ADF Context** within the ADF Structure hierarchy.
View port	View ports are an ADF Controller concept. For this reason, view ports appear within the ADF Structure hierarchy only when the application being debugged utilizes ADF Controller. View ports can represent one of the following: • Browser: Main browser view ports, also known as root view ports, appear as children of the root **ADF Context**. If multiple browser windows are open during the debugging runtime session, multiple browser view ports are presented within the hierarchy. The label of each browser view port displays the text "Browser". The view port also provides a tooltip for the view port ID similar to the following example: "Root View Port: 999999". • Region: Region view ports appear as the children of page or page fragments. They are also known as child view ports. The label of each region view port displays the text "Region". The region also provides a tooltip for the view port ID similar to the following example: "Child View Port: 999999".
ADF task flows	The page flow stack corresponding to each view port appears as a hierarchy of ADF task flows. The initial ADF task flow called for the stack is a direct child of its corresponding view port. The label of each ADF task flow reflects the corresponding ADF task flow display name (if any) or its task flow ID. Region view ports will not display the item in their page flow stack hierarchy for their implied unbounded task flow. The task flow also provides a tooltip displaying the ADF task flow path, and a context menu item to open to the corresponding ADF task flow within the editor workspace. If ADF Controller is not utilized in the application (or if the page is run outside the context of an ADF task flow), ADF task flows will not appear within the hierarchy.
Page	Represents the page (view) currently displayed within a browser view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, pages will be children of each browser view port. The label of each page reflects its corresponding runtime view ID. The page also provides a tooltip displaying the page path, and a context menu item to open to the corresponding page within the editor workspace. If a visual user interface in not implemented for the application, the page will not appear within the hierarchy.
Page fragment	Represents the page fragment currently displayed within a region view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, page fragments will be children of each region view port. The label of each page fragment node reflects its corresponding runtime view ID. The page fragment also provides a tooltip displaying the source file page definition path, and a context menu item to open to the corresponding page fragment within the editor workspace.

Table 48-4 (Cont.) ADF Structure Window Items

ADF Structure Tree Item	Description
Binding container	Represents the binding container for the corresponding page or page fragment. The label of each binding container reflects its corresponding file name (page definition file) without the extension. The binding container node will also provide a tooltip displaying the page fragment path. The binding container also appears under current task flows when used to represent task flow activity bindings (for example, method call activity bindings). If ADF Model is not utilized for the application, binding containers will not appear.
Application data	Represents the application data objects (for example, ADF Business Components objects or ADF Business Components business service objects) instantiated within the data control frame for the corresponding view port (or binding container if ADF Controller is not used). Application data objects don't need to be currently instantiated for the Application Data node to appear.

How to Use the ADF Data Window

When an application is paused at an ADF declarative breakpoint, the ADF Data window displays relevant data based on the selection in the ADF Structure window. You can launch the ADF Data window by choosing **Window > Debugger > ADF Data** in the main menu. The content of the ADF Data window based on the selection in the ADF Structure window is summarized in Table 48-5.

Table 48-5 ADF Data Window Content for an ADF Structure Window Selection

ADF Structure Window	ADF Data Content
Scopes	Displays memory scope values based on the current context. `pageFlowScope` will also appear within ADF task flow content for the `pageFlowScope` values specific to a selected ADF task flow (not necessarily the current context). `viewScope` will also appear within the view port content for the `viewScope` values specific to a selected view port (not necessarily the current context).
ADF context	Displays the ADF context variables and values hierarchy. ADF context variables and values can be inspected by evaluating the `#(data.adfContext)` EL expression in the EL Evaluator.
View port	Displays view port details, including the `viewScope` contents.
Page flow stack entry	Displays information for the selected page flow stack entry, including current transaction status and ADF Model save point status.
Page/page fragment	Displays the page or page fragment UI component tree hierarchy for the selected page or page fragment if the page or page fragment has been rendered.
Binding container	Displays the binding container runtime values, including parameters, bindings, and executables.
Application data	Displays application data objects (for example, ADF Business Components objects) instantiated within the current **binding context**. If the business service layer is implemented with a technology other than ADF Business Components objects (for example, EJB) the application data objects will be displayed in a more generic form.

The **Scopes** node in the ADF Structure window can be expanded to show a list of child scope nodes. When a child scope node is selected in the ADF Structure window, the ADF Data window displays the current context values for the selected memory scope, as shown in Figure 48-36.

If the **Scopes** node itself is selected, then the full list of memory scopes appears also in the ADF Data windows, which can also be expanded for inspection. Figure 48-37 shows the **Scopes** node selected in the ADF Structure window, and the **viewScope** child node being selected with its values displayed in the ADF Data window. You can inspect the values of `requestScope`, `viewScope`, `pageFlowScope`, `applicationScope`, and `sessionScope` by expanding each corresponding node. `pageFlowScope` will also appear within the ADF Task Flow content to reflect the values of the specific ADF task flow currently selected in the ADF Structure window. `viewScope` will also appear within the view port content to reflect the values of the specific view port currently selected in the ADF Structure window.

Table 48-6 ADF Data Window Content for View Port

View Port	Description
View port ID	It is displayed
Client ID	It is displayed
Initial task flow ID	Initial ADF task flow on the view ports page flow stack. Not displayed for unbounded task flows. Appears as a link to open the corresponding task flow definition in the editor workspace.

Table 48-6 (Cont.) ADF Data Window Content for View Port

View Port	Description
Current task flow ID	Displayed for bounded task flows and not displayed for unbounded task flows. Current ADF task flow on the view port's page flow stack. Appears as a link to open the corresponding task flow definition in the editor workspace.
View activity ID	Current ADF task flow view activity ID. Applicable only if the current ADF task flow activity is a view activity.
Submitted activity ID	ADF task flow activity submitting the current request.
Final activity ID	ADF task flow activity receiving the current request.
Bookmark redirect outstanding	(Boolean)
Exception	(If any)
View memory scope	View memory scope variables and values for the selected view port.

In the ADF Structure window, each individual ADF task flow within a page flow stack hierarchy is selectable. An ADF task flow selected in the ADF Structure window will display the current task flow information in the ADF Data window, as shown in Figure 48-40. Task flow templates utilized by the selected ADF task flow will be determined by manually navigating to the ADF task flow source file. This is the same way similar functionalities are handled for Java source files. Current information for a selected ADF task flow is summarized in Table 48-7.

Remote Task Flow Called	false	boolean
Remote Task Flow Return URL	null	String

Table 48-7 ADF Data Window Content for Task Flow

Task Flow	Description
ADF task flow reference	ADF task flow reference
Task flow call activity ID	Task flow activity ID for the calling task flow. Will be `null` for the first ADF task flow within each view port task flow Calls window.
Calling view activity ID	The calling view activity of the current view activity displayed by the ADF task flow, if any.
View reached	(Boolean)

Table 48-7 (Cont.) ADF Data Window Content for Task Flow

Task Flow	Description
Train model	Only applicable if the ADF task flow is created as a train.
Transaction started	(Boolean) Identifies the current status of the ADF task flow transactional state. For example, did the ADF task flow begin a new transaction?
Transaction shared	(Boolean) Identifies the current status of the ADF task flow transactional state. For example, did the ADF task flow join an existing transaction?
Save point	Identifies the current status of the ADF task flow's ADF Model save point creation state. For example, was a model save point created upon ADF task flow entry?.
Remote task flow called	(Boolean)
Remote task flow return URL	Applies only when calling an ADF task flow remotely. Identifies the URL for return once the task flow called remotely completes.
Data control frame created	(Boolean)
Data control frame	Name of data control frame associated with the ADF task flow.
Page flow memory scopes	Appears as an expandable node to allow inspection of the values of the page flow memory scopes for the task flow selected in the ADF Structure window. The page flow memory scopes will also be displayed within the ADF Structure window's **Scopes** node. However, the page flow memory scope for the **Scopes** node will always be based on the application's current context, not the selected task flow.

When you select a page or page fragment node in the ADF Structure hierarchy, the corresponding UI component tree is displayed within the ADF Data window, as shown in Figure 48-41. If a page or page fragment is based on a page template, you can include the content coming from the page template outside any facet reference elements by selecting the **Include Page Template Content** checkbox at the top of the ADF Data window. If the page template content is not included, the page or page fragment UI component tree will appear structurally similar to its source file.

When you select a binding container in the ADF Structure hierarchy, it displays within the ADF Data window the node selection listed in Table 48-8.

Table 48-8 ADF Data Window Content for Binding Container

Binding Container	Description
Page definition link	Navigates to the corresponding page definition source file and opens it within the editor workspace.
Data Controls	Displays the binding container's data controls. Data controls implemented by ADF Business Components objects and non-ADF Business Components objects will be presented slightly different. ADF Business Components-based data controls will appear similar to the actual business service implementation using row collections. Non-ADF Business Components-based data controls will typically appear as raw member variables similar to what is displayed in the ADF Declarative Debugger Data window. The ADF Data window shows only cached information such as member variables and arrays. Standard debugger functionality can also be used to customize each element. Each ADF Business Components data control will display the following information: • Row collections • Query string for each row collection • Query string with variable substitution for each row collection • Application data rows • Current row indicator • Change indicator • Current and original values (if changed within the same request)
Parameters	Current values of all binding container parameters.
Executables	Displays executables showing current row indicators, and current and original values (if changed within the same request). This includes the following types of executables: • Iterator - presents corresponding attribute bindings along with their `Refresh` and `RefreshCondition` properties. • task flow - current value of the task flow ID assigned to the task flow binding and all of its associated parameter values. Task flow IDs will appear as links navigating to open the corresponding task flow definition source file within the editor workspace. Link text consists of `<task flow source document>#<task flow id>`. • Search region - presented similar to iterators, but also displays criteria and criteria with substitution information.
Bindings	Displays value, table, tree, and method bindings. Each binding will display the following information: • Associated executables • Change indicator • Current and original values (if changed within the same request)
Binding container of page template	If the corresponding page or page fragment utilized a page template, the binding container of the page template will appear as a child of page or page fragment binding container content.

When you select a binding container for an application based on non-ADF Business Components objects, the ADF Data window displays the binding container content, as shown in Figure 48-1.

Table 48-9 ADF Data Window Content for Application Data

Binding Container	Description
Application module	The application module(s) of the corresponding view port data control frame will appear within the application data hierarchy as the root node(s). An application module design time icon will be used to identify the node(s). The application module node(s) will provide the following information: • Application module link - link to open the corresponding application module source file within the editor workspace. • Transaction - the application module current transaction status, if applicable. • View objects • Entity objects

Table 48-9 (Cont.) ADF Data Window Content for Application Data

Binding Container	Description
View object	View objects instantiated within the corresponding view port data control frame will appear underneath the corresponding application module root node as subordinate nodes. Design time icons will be used to identify them. Child view objects will appear subordinate to their parent view objects within the hierarchy. Named row sets will appear similar to view objects. Named iterators for a view object will appear similar to child view objects. Each view object node will provide the following information: • View object link - link to open the corresponding view object source file within the editor workspace. • Query - last executed view object SQL statement. Displays bind variables without value substitution. • Query with substitution - last executed view object SQL statement. Displays bind variables with value substitution. • Bind variables - last executed view object SQL statement bind variables and their values. • View object rows - each row displayed will be identified by its concatenated key values. The current row will be identified with a special icon. • Attributes - attributes contained on each row will display their current values along with their originating **entity object**. Transient attributes will also be displayed. • Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and view objects node labels. Both the old and new value of the modification will be displayed.
Entity object	Entity objects instantiated within the corresponding view port data control frame will appear underneath the application module root node as subordinate nodes. Design time icons will be used to identify them. Each entity object node will provide the following information: • Entity object link - link to open the corresponding entity object source file within the editor workspace. • Entity object rows - each row displayed will be identified by its concatenated key values. The current entity-state and post-state of the row (e.g., `STATUS_MODIFIED`) will also be presented. • Attributes - attributes contained on each row will display their current values. • Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and entity objects node labels. Both the old and new value of the modification will be displayed.

Business services implemented by non-ADF Business Components objects display application data content using raw member variables. The format is similar to the display of non-ADF Business Components content for the binding container, as shown in Figure 48-42.

What Happens When You Set an ADF Declarative Breakpoint

When you set an ADF declarative breakpoint, JDeveloper adds the breakpoint to the appropriate class, method, or other construct in the ADF source Java code that corresponds to the breakpoint. Once the breakpoint is set in the code, the standard Java debugger mechanism pauses application execution when the breakpoint is reached. When the breakpoint is reached, it will be identified by a red dot icon in the Breakpoints window. Depending on the type of declarative breakpoint that was reached, it will also appear as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window.

For task flow activity breakpoints, the debugger pauses the application within the JSF Invoke Application phase before the activity where the breakpoint is set. In other words, the activity where the breakpoint is set is not executed.

For task flow view activities, however, the application is paused within the JSF Render Response phase after the view activity is executed, but before the new page is rendered.

For a page definition Before executable breakpoint, the debugger pauses the application when the executable is refreshed. For a page definition Before action binding breakpoint, the debugger pauses the application when the binding is executed. For a page definition Before attribute value binding breakpoint, the debugger pauses the application before the attribute's `setInputValue()` method in the ADF source code is executed.

For a Before lifecycle breakpoint, the debugger pauses the application before it enters the next lifecycle phase. For an After lifecycle breakpoint, the debugger pauses the application after the lifecycle phase and before the next phase.

Setting Breakpoints in Java Code and Groovy Script

In most ADF applications, declarative breakpoints provide more than enough information to troubleshoot the application errors. But there might be situations where you may need to set breakpoints on specific classes or methods for further investigation. Using Java code and Groovy snippet breakpoints in combination with ADF declarative breakpoints will help you to identify these errors.

You can use the ADF Declarative Debugger to set breakpoints on Java classes and methods, as in any standard Java code debugger. You can use Java code breakpoints and Groovy snippet breakpoints in combination with ADF declarative breakpoints. For most ADF applications, ADF declarative breakpoints will provide enough debugging information to troubleshoot the application. For information about using ADF declarative breakpoints, see Setting ADF Declarative Breakpoints. However, you may need to set breakpoints on specific classes or methods for further inspection. Or, you may be debugging a non-ADF application, in which case, you can use Java code breakpoints.

JDeveloper provides a class locator feature that assists you in finding the class you want to break on. If you can obtain Oracle ADF source code, you can enhance your debugging by having access to various ADF classes and methods. For more information about getting ADF source code, see Using ADF Source Code with the Debugger. If you obtained the ADF source, you can further enhance the debugging experience by using the debug library version of the ADF source, as described in How to Use Debug Libraries for Symbolic Debugging.

How to Set Breakpoints in Groovy Script

When you define validation rules or attribute default values using Groovy script, you can set breakpoints on these Groovy snippets.

Before you begin:

It may be helpful to have an understanding of when to use code breakpoints instead of ADF declarative breakpoints. For more information, see Setting Breakpoints in Java Code and Groovy Script.

To set Groovy snippet breakpoints to debug an application:

1. In the Applications window, expand the entity object or view object that contains the Groovy script where you want to set a breakpoint, and then double-click the object’s `.bcs` file.
2. In the source editor, click in the margin next to the appropriate line to set a breakpoint, and then run the debugger.
3. When the application stops on the breakpoint, you can use the Data window to examine the local variables and arguments of the current context.

How to Set Java Breakpoints on Classes and Methods

You can set Java breakpoints on your classes and methods. If you have ADF source code, you can set Java breakpoints in the source as well. If you are debugging an ADF application, you should check to see whether ADF declarative breakpoints can be used instead of Java code breakpoints. For more information, see Setting ADF Declarative Breakpoints.

Before you begin:

It may be helpful to have an understanding of when to use Java code breakpoints instead of ADF declarative breakpoints. For more information, see Setting Breakpoints in Java Code and Groovy Script.

You will need to complete this task:

> Before you attempt to use breakpoints, you should try to run the application and look for missing or incomplete data, actions and methods that are ignored or incorrectly executed, or other unexpected results. If you did not find the problem, create a debugging configuration that will enable the ADF Log and send Oracle ADF messages to the Log window. For more information, see How to Create an Oracle ADF Debugging Configuration.

To set Java breakpoints to debug an application:

1. In the main menu, choose **Navigate** and then **Go To Java Type** (or press Ctrl+Minus) and use the dialog to locate the Oracle ADF class that represents the entry point for the processing failure.

> **Note:**
>
> JDeveloper will locate the class from the user interface project with current focus in the Applications window. If your workspace contains more than one user interface project, be sure that the one with the current focus is the one you want to debug.

2. Open the class file in the source editor and find the Oracle ADF method call that will enable you to step into the statements of the method.
3. Set a breakpoint on the desired method and run the debugger.
4. When the application stops on the breakpoint, use the Data window to examine the local variables and arguments of the current context.

> **Tip:**
>
> If you are using the **Go to source** context menu command in the Data, Watches, or Smart Data window, you can go back to the execution point by using the back button. You can also access the back button through the **Navigate** menu.

Once you have set breakpoints to pause the application at key points, you can proceed to view data in the Data window. To effectively debug your web page's interaction with the ADF Model layer, you need to understand:

- The ADF page lifecycle and the method calls that get invoked
- The local variables and arguments that the ADF Model layer should contain during the course of application processing

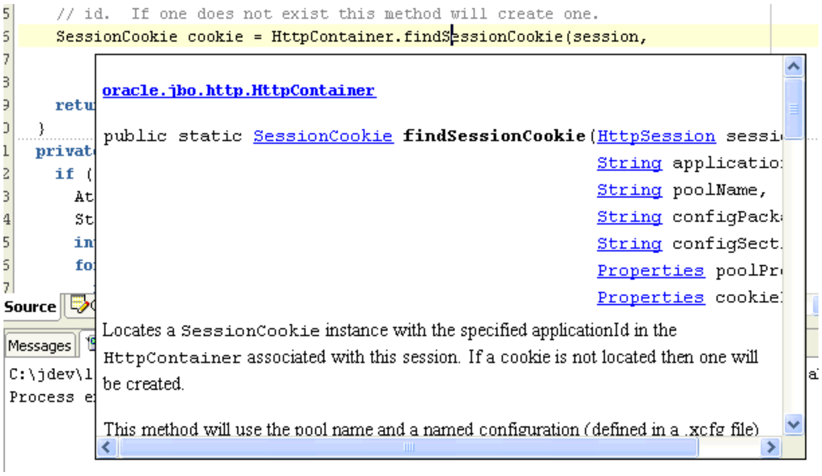
Awareness of Oracle ADF processing will give you the means to selectively set breakpoints, examine the data loaded by the application, and isolate the contributing factors.

> **Note:**
>
> JSF web pages may also use backing beans to manage the interaction between the page's components and the data. Debug backing beans by setting breakpoints for them as you would with any other Java class file.

How to Optimize Use of the Source Editor

Once you have added the ADF source library to your project, you have access to the helpful Quick Javadoc feature (Ctrl+D) that the source editor makes available. Figure 48-49 shows Quick Javadoc for a method like `findSessionCookie()`.

Figure 48-49 Using Quick Javadoc on ADF API in the Source Editor



```
    // id.  If one does not exist this method will create one.
    SessionCookie cookie = HttpContainer.findSessionCookie(session,

    retu
  }
  privat
    if (
      At
      St
      in
      fo
```

oracle.jbo.http.HttpContainer

```
public static SessionCookie findSessionCookie(HttpSession sessi
                                              String applicatio
                                              String poolName,
                                              String configPack
                                              String configSect
                                              Properties poolPr
                                              Properties cookie
```

Locates a SessionCookie instance with the specified applicationId in the HttpContainer associated with this session. If a cookie is not located then one will be created.

This method will use the pool name and a named configuration (defined in a .xcfg file)

```
C:\jdev\l
Process e
```

How to Set Breakpoints and Debug Using ADF Source Code

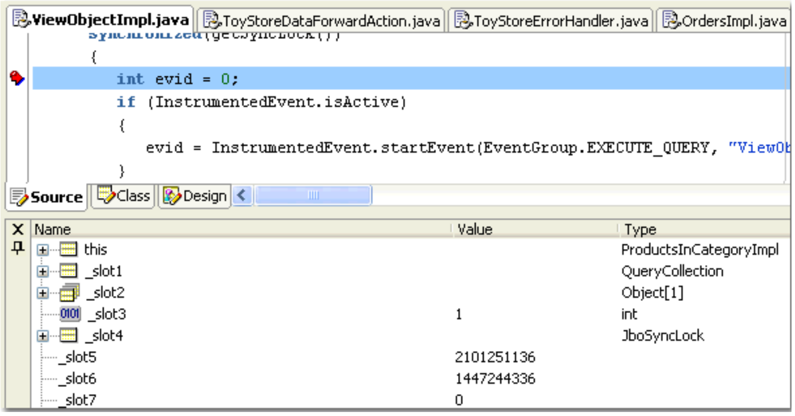
After loading the ADF source code, you can debug any Oracle ADF code for the current project the same way that you do your own Java code. This means that you can press Ctrl+Minus to type in any class name in Oracle ADF, and JDeveloper will open its source file automatically so that you can set breakpoints as desired.

How to Use Debug Libraries for Symbolic Debugging

When debugging Oracle ADF source code, by default you will not see symbol information for parameters or member variables of the currently executing method.

For example, in a debugging session without ADF source code debug libraries, you may see unrecognizable names such as "_slot", as shown in Figure 48-50.

Figure 48-50 Local Symbols Are Hard to Understand Without Debug Libraries



```
    synchronized(getSyncLock())
    {
        int evid = 0;
        if (InstrumentedEvent.isActive)
        {
            evid = InstrumentedEvent.startEvent(EventGroup.EXECUTE_QUERY, "ViewOb
        }
```

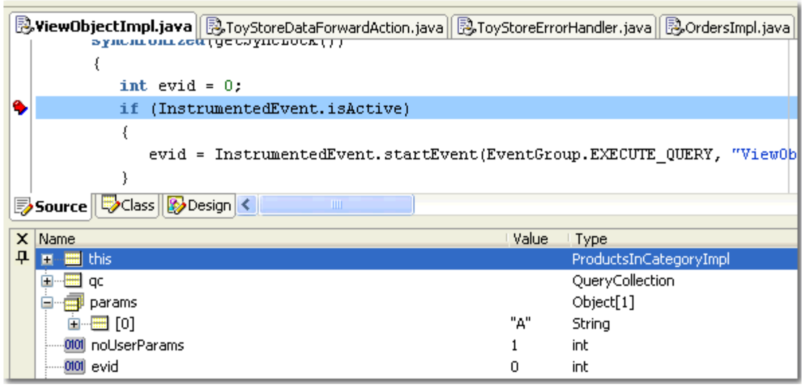
Name	Value	Type
this		ProductsInCategoryImpl
_slot1		QueryCollection
_slot2		Object[1]
_slot3	1	int
_slot4		JboSyncLock
_slot5	2101251136	
_slot6	1447244336	
_slot7	0	

These names are hard to decipher and make debugging more difficult. You can make debugging easier by using the debug versions of the ADF JAR files supplied along with the source while debugging in your development environment.

> **Note:**
>
> The supplied debug libraries should not be used in a test or production environment, since they typically have slightly slower runtime performance than the optimized JAR files shipped with JDeveloper.

The debug library JARs are versions of Oracle ADF JARs that have been compiled with additional debug information. When you use these debug JAR files instead of the default optimized JARs, you will see all of the information in the debugger. For example, the variable evid is now identified by its name in the debugger, as shown in Figure 48-51.

Figure 48-51 Symbol Information Displayed in the Debugger



```
synchronized(getSyncLock())
{
   int evid = 0;
   if (InstrumentedEvent.isActive)
   {
      evid = InstrumentedEvent.startEvent(EventGroup.EXECUTE_QUERY, "ViewOb
   }
```

Name	Value	Type
this		ProductsInCategoryImpl
qc		QueryCollection
params		Object[1]
[0]	"A"	String
noUserParams	1	int
evid	0	int

Before you begin:

It may be helpful to have an understanding of when to use Java code breakpoints instead of ADF declarative breakpoints. For more information, see Setting Breakpoints in Java Code and Groovy Script.

You will need to complete this task:

Before you replace the standard library JAR, make sure that JDeveloper is not running. If it's currently running, exit from the product before proceeding.

To replace the standard library JARs with the debug library JARs:

1. With JDeveloper closed, make a backup subdirectory of all existing optimized JAR files in the ./BC4J/lib directory of your JDeveloper installation. For example, assuming jdev11 is the JDeveloper home directory:

   ```
   C:\jdev11\BC4J\lib> mkdir backup
   C:\jdev11\BC4J\lib> copy *.jar backup
   ```

2. For each ADF library that you want debug symbols for while debugging, copy the _g.jar version of the matching library over the existing, corresponding library in the C:\jdev11\BC4J\lib directory.

   This is safe to do since you made a backup of the optimized JAR files in the backup directory in Step 2.

Since debug libraries typically run a little slower than libraries compiled without debug information, this diagnostic message is to remind you not to use debug libraries for performance timing:

```
*************************************************************************
*** WARNING: Oracle BC4J debug build executing - do not use for timing ***
*************************************************************************
```

3. To change back to the optimized libraries, simply copy the JAR file(s) in question from the `./BC4J/lib/backup` directory back to the `./BC4J/lib` directory.

What You May Need to Know About Setting Java Code Breakpoints

You first need to understand the different kinds of Java code breakpoints and where to create them.

To see the debugger Breakpoints window, choose **Window** and then **Breakpoints** in the main menu (or press Ctrl+Shift+R).

You can create a new Java code breakpoint by choosing **Create Breakpoint** from the context menu in the Breakpoints window. The **Breakpoint Type** dropdown list controls what kind of breakpoint you will create, as shown in Table 48-10.

> **Note:**
>
> You can also use the Create Breakpoint dialog to create an ADF lifecycle phase declarative breakpoint. For information about creating ADF declarative breakpoints, see How to Set and Use ADF Lifecycle Phase Breakpoints.

Table 48-10 Different Types of Java Breakpoints

Breakpoint Type	The Breakpoint Occurs Whenever	Usage
Exception	An exception of this class (or a subclass) is thrown.	An Exception breakpoint is useful when you don't know where the exception occurs, but you know what kind of exception it is (for example, `java.lang.NullPointerException`, `java.lang.ArrayIndexOutOfBoundsException`, `oracle.jbo.JboException`). The checkbox options allow you to control whether to break on caught or uncaught exceptions of this class. The **Browse** button helps you find the fully qualified class name of the exception. The Exception Class combobox remembers the most recently used exception breakpoint classes. Note that this is the default breakpoint type when you create a breakpoint in the breakpoints window.

Table 48-10 (Cont.) Different Types of Java Breakpoints

Breakpoint Type	The Breakpoint Occurs Whenever	Usage
Source	A particular source line in a particular class in a particular package is run.	You rarely create a source breakpoint in the Create Breakpoint dialog, because it's much easier to create it by first using the **Navigate > Go to Java Type** menu (accelerator Ctrl+Minus), then scrolling to the line number you want — or using **Navigate > Go to Line** (accelerator Ctrl+G) — and finally clicking in the breakpoint margin at the left of the line you want to break on. This is equivalent to creating a new source breakpoint, but it means you don't have to type in the package, class, and line number by hand.
Method	A method in a given class is invoked.	The Method breakpoint is useful for setting breakpoints on a particular method you might have seen in the call stack while debugging a problem. If you have the source, you can set a source breakpoint wherever you want in that class, but this kind of breakpoint lets you stop in the debugger even when you don't have source for a class.
Class	Any method in a given class is invoked.	The Class breakpoint can be used when you might know the class involved in the problem, but not the exact method you want to stop on. This kind of breakpoint does not require source. The **Browse** button helps you quickly find the fully qualified class name you want to break on.
Watchpoint	A given field is accessed or modified.	The Watchpoint breakpoint can be used to find a problem if the code inside a class modifies a member field directly from several different places (instead of going through setter or getter methods each time). You can pause the debugger when any field is modified. You can create a breakpoint of this type by using the **Toggle Watchpoint** menu item on the context menu when pointing at a member field in your class's source.

How to Edit Breakpoints for Improved Control

After creating a Java code breakpoint you can edit the breakpoint in the Breakpoints window by right-clicking it and choosing **Edit** in the context menu.

> **Note:**
>
> You can use the Edit Breakpoint dialog to edit an ADF declarative breakpoint. However, you cannot edit some of the other information such as the information in the **Definition** tab. You can launch the Edit Breakpoint dialog by choosing **Edit** from the context menu in the Breakpoints window. For information about creating ADF declarative breakpoints, see Setting ADF Declarative Breakpoints.

Some of the features you can use by editing your breakpoint are:

- Associate a logical "breakpoint group" name to group this breakpoint with others of the same group name. Breakpoint groups make it easy to enable/disable an entire set of breakpoints in one operation.
- Associate a debugger action to a breakpoint when the breakpoint is hit. The default action is to stop the debugger so that you can inspect the application states, but you can add a sound alert, write information to a log file, and enable or disable group of breakpoints.
- Associate a conditional expression with the breakpoint so that the debugger stops only when that condition is met. The expressions can be virtually any boolean expression, including:
  - `expr ==value`
  - `expr.equals("value")`
  - `expr instanceof.fully.qualified.ClassName`

  > **Note:**
  >
  > Use the debugger Watches window to evaluate the expression first to make sure it's valid.

How to Filter Your View of Class Members

You can use the debugger to filter the members that are displayed in the debugger window for any class. In the debugger's Data window, selecting any item and choosing **Preferences** from the context menu brings up a dialog that lets you customize which members appear in the debugger and (more importantly sometimes) which members *don't* appear. You can filter by class type to simplify the amount of scrolling you need to do in the debugger Data window. This is especially useful when you might be interested only in a handful of a class's members.

What You May Need to Know About Oracle ADF Breakpoints

If you loaded Oracle ADF source code, you can use the breakpoints listed in Table 48-11 to debug your application.

By looking at the Stack window when you hit these breakpoints, and stepping through the source, you can get a better idea of what's going on.

Table 48-11 Commonly Used ADF Breakpoints

Breakpoint	Breakpoint Type	Usage
`oracle.jbo.JboException`	Exception	This breakpoint useful for setting a breakpoint on the base class of all ADF Business Components runtime exceptions.
`oracle.jbo.DMLException`	Exception	This is the base class for exceptions originating from the database, like a failed DML operation due to an exception raised by a trigger or by a constraint violation.
`doIt()`	Method	You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition action binding. See How to Set and Use Page Definition Action Binding Breakpoints. If you prefer to use this Java breakpoint, you can find it in the `JUCtrlActionBinding` class (`oracle.jbo.uicli.binding` package). This is the method that will execute when any ADF action binding is invoked, and you can step into the logic and look at parameters if relevant.
`oracle.jbo.server.ViewObjectImpl.executeQueryForCollection`	Method	This is the method that will be called when a view object executes its SQL query.
`oracle.jbo.server.ViewRowImpl.setAttributeInternal`	Method	This is the method that will be called when any view row attribute is set.
`oracle.jbo.server.EntityImpl.setAttributeInternal`	Method	You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition attribute value binding. See How to Set and Use Page Definition Value Binding Breakpoints. This is the method that will be called when any entity object attribute is set.

Debugging Groovy Expressions in Business Components

JDeveloper allows you to debug Groovy scripts/expressions. To start the debugger, right-click on the applicationmodule.xml file to start the Oracle ADF Model Tester or right click on the Java file containing the main method to start executing the Java program.

The `.bcs` file contains Groovy expressions/scripts. The `.bcs` file is associated with an entity object or view object. When Groovy expressions are debugged, if there is an exception, the debugger pauses in the `.bcs` file at the line where the exception occurred and displays the errors. If there is no exception, the debugger proceeds to execute the Groovy expressions, and displays the necessary computational data (in the data/smart data/watch etc windows). Just as you can set breakpoints in a Java source code file, JDeveloper allows you to place breakpoints in a `.bcs` file. When the debugger is run and if the debugger encounters a breakpoint in this `.bcs` file, the debugger pauses execution at the breakpoint.

The process of debugging Groovy scripts in a `.bcs` file is similar to that of a Java file. When the debugger is in the `.bcs` file, use the various step operations, namely Step

Into, Step Over, and Step Out to control the execution of the Groovy scripts by the debugger. At any point when the debugger is in the `.bcs` file, either at a breakpoint, or when the debugger has paused execution at a line because you used the step operations, use the debugger log windows to view execution data.

How to Debug Groovy Expressions

JDeveloper allows you to debug Groovy expressions. To debug Groovy expressions, right-click on the `applicationmodule.xml` file and select Debug to start the Oracle ADF Model Tester or right-click on the Java file containing the main method to start executing the Java program.

To start debugging Groovy expressions, do any of the following two steps.

1. Right-click on an application module (`applicationmodule.xml` file) and select **Debug** to start the Oracle ADF Model Tester.
2. Right-click on the Java file containing the main method and select **Debug** from the context menu to start executing the Java program. Alternatively, double click on the Java file to open it; right-click inside the Java file and select **Debug** from the context menu.

How to Control Groovy Debugging

The application allows you to place breakpoints in the `.bcs` file and use the step operations (Step Into, Step Over, Step Out) to control the execution of the debugger.

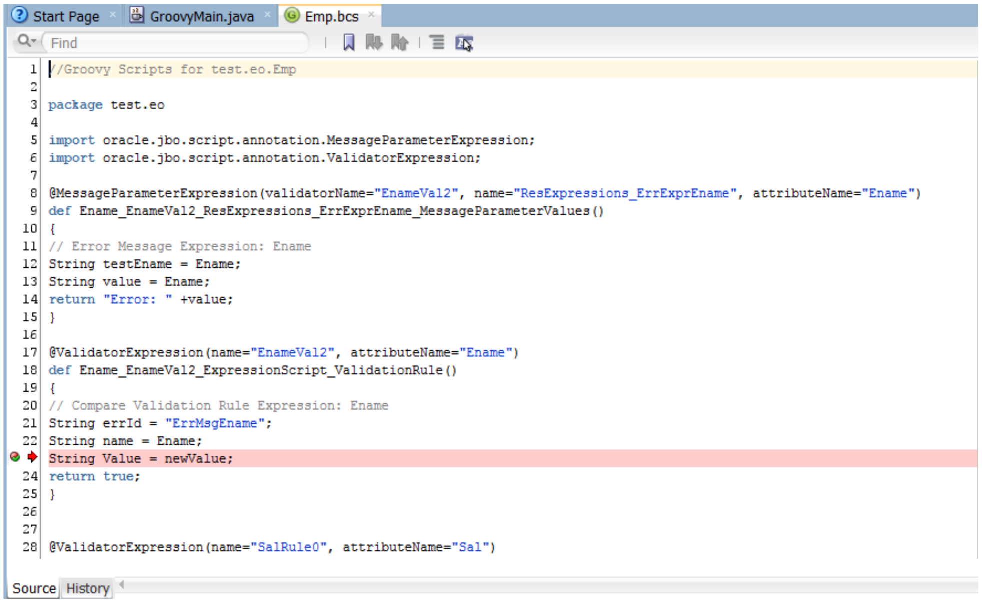
To read more about breakpoints, refer to Managing Breakpoints.

To control Groovy debugging:

1. Double-click on the `.bcs` file to open it.

   Figure 48-52 shows breakpoints placed in the `.bcs` file. The debugger executes the Groovy scripts, and if the debugger encounters a breakpoint in the `.bcs` file, the debugger pauses at this breakpoint. You also use the Step Into, Step Over, Run to Cursor to control Groovy debugging.

Figure 48-52   Breakpoints placed in `.bcs` file



```
//Groovy Scripts for test.eo.Emp

package test.eo

import oracle.jbo.script.annotation.MessageParameterExpression;
import oracle.jbo.script.annotation.ValidatorExpression;

@MessageParameterExpression(validatorName="EnameVal2", name="ResExpressions_ErrExprEname", attributeName="Ename")
def Ename_EnameVal2_ResExpressions_ErrExprEname_MessageParameterValues()
{
// Error Message Expression: Ename
String testEname = Ename;
String value = Ename;
return "Error: " +value;
}

@ValidatorExpression(name="EnameVal2", attributeName="Ename")
def Ename_EnameVal2_ExpressionScript_ValidationRule()
{
// Compare Validation Rule Expression: Ename
String errId = "ErrMsgEname";
String name = Ename;
String Value = newValue;
return true;
}

@ValidatorExpression(name="SalRule0", attributeName="Sal")
```

2. When the debugger has paused at the breakpoint in the `.bcs` file, use the Debug menu, toolbar icons, or keyboard equivalents to use step operations. They are namely Step Into, Step Over, and Step Out.

   Refer to How to Step Into a Method to read more about step operations.
   The application also allows you to run the debugger at the cursor location. Refer How to Run to the Cursor Location to read more.

   The application allows you to pause the debugger while it is running. You can then inspect the state of the program and then continue to run the debugger. Refer How to Pause and Resume the Debugger to read more on how to pause and resume the debugger.

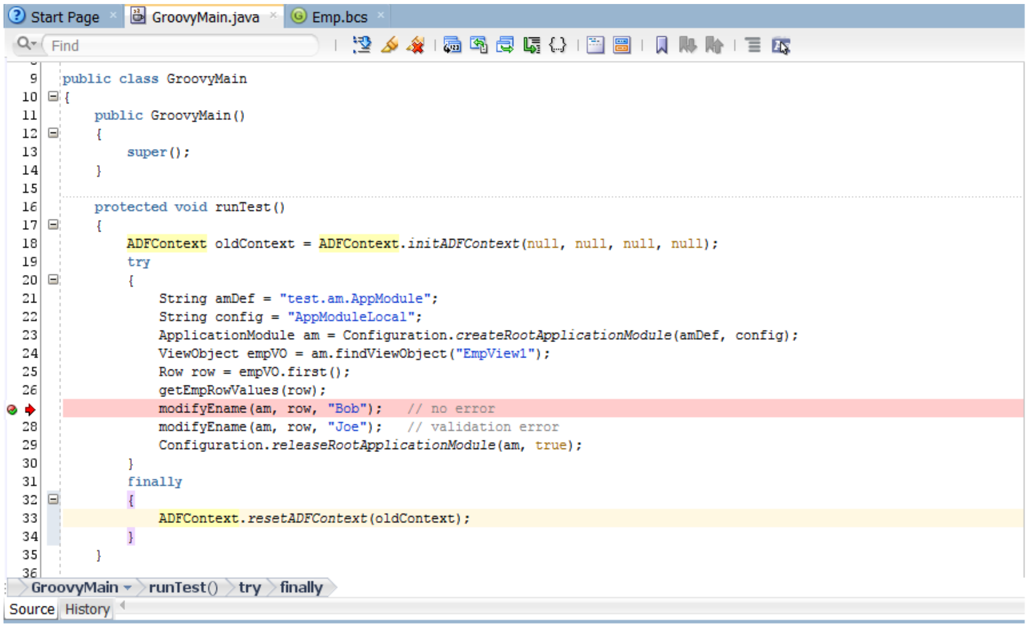
   At any point you can terminate the debugging session. Refer How to Terminate a Debugging Session to read on how to terminate a debugging session.

What Happens When You Debug Groovy Expressions

The application debugs Groovy scripts in a `.bcs` file. Place breakpoints in the `.bcs` file if required to pause the execution of the debugger at these breakpoints. Inspect the information in the data/watch/smart data etc windows whenever the debugger pauses at a breakpoint or when you step operations.

The debugger executes the Groovy scripts and displays information in the data/watch/smart data etc windows. Figure 48-53 displays a breakpoint set at line 27, and the debugger has paused at this line, which is the current execution line (indicated by the red arrow). The current execution line indicates a call to the method `modifyEname()`. This method attempts to modify the Ename attribute of the Emp entity.

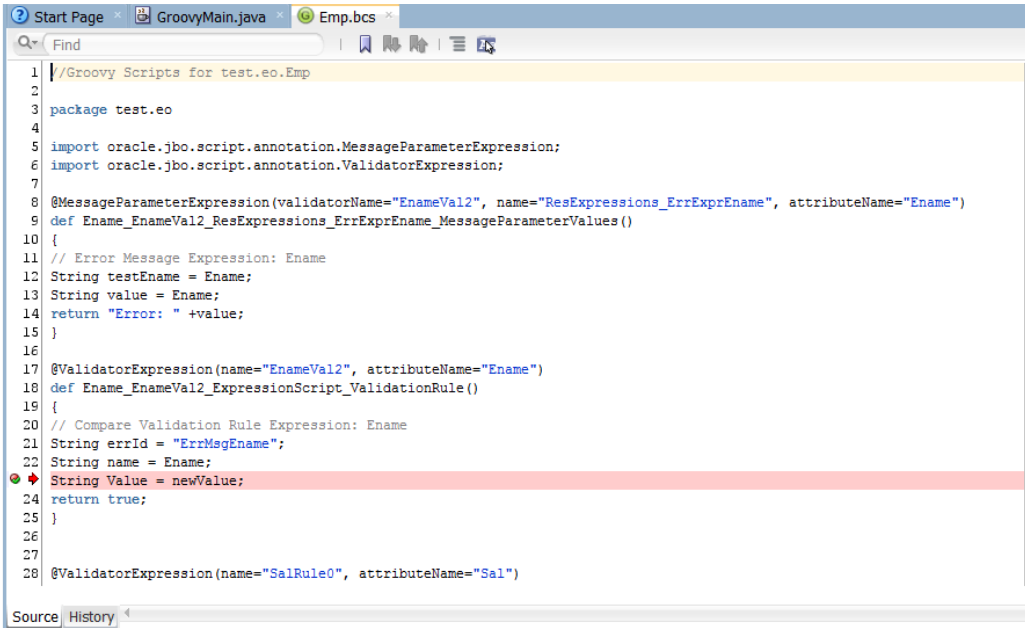
Figure 48-53   Breakpoint placed in Java file at line that references Groovy expressions



```
 9  public class GroovyMain
10  {
11      public GroovyMain()
12      {
13          super();
14      }
15
16      protected void runTest()
17      {
18          ADFContext oldContext = ADFContext.initADFContext(null, null, null, null);
19          try
20          {
21              String amDef = "test.am.AppModule";
22              String config = "AppModuleLocal";
23              ApplicationModule am = Configuration.createRootApplicationModule(amDef, config);
24              ViewObject empVO = am.findViewObject("EmpView1");
25              Row row = empVO.first();
26              getEmpRowValues(row);
                modifyEname(am, row, "Bob");   // no error
28              modifyEname(am, row, "Joe");   // validation error
29              Configuration.releaseRootApplicationModule(am, true);
30          }
31          finally
32          {
33              ADFContext.resetADFContext(oldContext);
34          }
35      }
36
```

A validator is defined for the Ename attribute. The validator is defined using Groovy script/expression. This Groovy script (along with other Groovy scripts defined for other use cases) reside in a `.bcs` file. So when you Step Into this method at line 27, the application accesses this `.bcs` file and executes the validator. Figure 48-54 shows the debugger paused at line 23 in the `.bcs` file at a pre-set breakpoint, whilst executing the validator.

Figure 48-54   Debugger navigates from Java file to .bcs file and pauses at breakpoint in `.bcs` file



```
 1  //Groovy Scripts for test.eo.Emp
 2
 3  package test.eo
 4
 5  import oracle.jbo.script.annotation.MessageParameterExpression;
 6  import oracle.jbo.script.annotation.ValidatorExpression;
 7
 8  @MessageParameterExpression(validatorName="EnameVal2", name="ResExpressions_ErrExprEname", attributeName="Ename")
 9  def Ename_EnameVal2_ResExpressions_ErrExprEname_MessageParameterValues()
10  {
11  // Error Message Expression: Ename
12  String testEname = Ename;
13  String value = Ename;
14  return "Error: " +value;
15  }
16
17  @ValidatorExpression(name="EnameVal2", attributeName="Ename")
18  def Ename_EnameVal2_ExpressionScript_ValidationRule()
19  {
20  // Compare Validation Rule Expression: Ename
21  String errId = "ErrMsgEname";
22  String name = Ename;
    String Value = newValue;
24  return true;
25  }
26
27
28  @ValidatorExpression(name="SalRule0", attributeName="Sal")
```

At this point, resume debugging, or terminate debugging, or use step operations. Refer How to Control Groovy Debugging to read more.

Regression Testing with JUnit

JUnit is an open source regression testing framework for Java which is used to write and run tests that verify Java code. Tests written in JUnit help you write code at an extreme pace and spot defects quickly. In JDeveloper, you can use wizards to create test fixtures, cases, and suites.

Testing your business services is an important part of your application development process. By creating a set of JUnit regression tests that exercise the functionality provided by your application module, you can ensure that new features, bug fixes, or refactorings do not destabilize your application. JDeveloper's integrated support for creating JUnit regression tests makes it easy test your application. Its integrated support for running JUnit tests means that any developer on the team can run the test suite with a single mouse click, greatly increasing the chances that every team member can run the tests to verify their own changes to the system. Furthermore, by using JDeveloper's integrated support for creating and running Apache Ant build scripts, you can easily incorporate running the tests into your automated build process as well. You can create a JUnit test for your application module, run it, and integrate the tests into an Ant build script.

JDeveloper provides the ability to generate JUnit test cases, test fixtures, and test suites. You can create test cases to test individual Java files containing single or multiple Java classes. You can create JUnit test fixtures that can be reused by JUnit test cases. You can group all these test cases into a JUnit test suite, which you can run together as a unit.

You can also use the JUnit BC4J Test Suite wizard to generate a test suite when there is an application module in the project. The wizard generates a test suite, test fixture, and a test case for each view object in the application module.

You can create a separate project to contain your regression tests or to integrate the test files into an existing project. If you are creating an ADF Business Components test, you should create a separate project for testing.

Creating separate projects for testing has the following advantages:

- The ability to compile the base project without having a dependency on JUnit
- The ability to package the base project for deployment without having to exclude the test classes.

If you are creating separate projects for JUnit testing, you should create directory structures that mirror the structure of the packages being tested. You may want to name the test classes using a naming convention that can easily identify the package being tested. For example, if you are testing `myClass.java`, you can name the test class `myClassTest.java`.

Although having separate projects has many advantages, in certain cases it may be easier to include the tests within the project.

You can use the Create Test wizards in the context of the project to create a JUnit test case, test fixture, or test suite. However, if you do not want to include these tests as part of the deployment, you may want to separate the tests out in their own project.

Tip:

If you don't see the Create Test wizards, use JDeveloper's **Help > Check for Updates** feature to install the JUnit Integration extension before continuing.

Each test case class contains a `setUp()` and `tearDown()` method that JUnit invokes to allow initializing resources required by the test case and to later clean them up. These test case methods invoke the corresponding `setUp()` and `tearDown()` methods to prepare and clean up the test fixture for each test case execution. Any time a test in the test case needs access to the application module, it uses the test fixture's `getApplicationModule()` method. The method returns the same application module instance, saved in a member field of the test fixture class, between the initial call to `setUp()` and the final call to `tearDown()` at the end of the test case.

JDeveloper supports JUnit 4, which allows annotations to be used instead of explicitly having to name the methods `setUp()` and `tearDown()`.These annotations — `@Before`, `@After` — allow you to have multiple setup and teardown methods, including inherited ones if required.

The generated `ExampleModuleConnectFixture` is a JUnit test fixture that encapsulates the details of acquiring and releasing an application. It contains a `setUp()` method that uses the `createRootApplicationModule()` method of the `Configuration` class to create an instance of an application module. Its `tearDown()` method calls the matching `releaseRootApplicationModule()` method to release the application module instance.

Your own testing methods can use any of the programmatic APIs available in the `oracle.jbo` package to work with the application module and view object instances in its data model. You can also cast the `ApplicationModule` interface to a custom interface to have your tests invoke your custom service methods as part of their job. During each test, you will call one or more `assertXxx()` methods provided by the JUnit framework to assert what the expected outcome of a particular expression should be. When you run the test suite, if any of the tests in any of the test cases contains assertions that fail, the JUnit Test Runner window displays the failing tests with a red failure icon.

The JUnit test generation wizard generates skeleton test case classes for each view object instance in the data model, each of which contains a single test method named `testAccess()`. This method contains a call to the `assertNotNull()` method to test that the view object instance exists.

```
// In ViewInstanceNameTest.java test case class
  public void testSomeMeaningfulName() {
  // test assertions here
  }
```

Each generated test case can contain one or more test methods that the JUnit framework will execute as part of executing that test case. You can add a test to the test case simply by creating a public void method in the class whose name begins with the prefix `test` or use the annotation `@Test`.

How to Obtain the JUnit Extension

JUnit must be loaded as an extension to JDeveloper before it becomes available and appears in the menu system.

Before you begin:

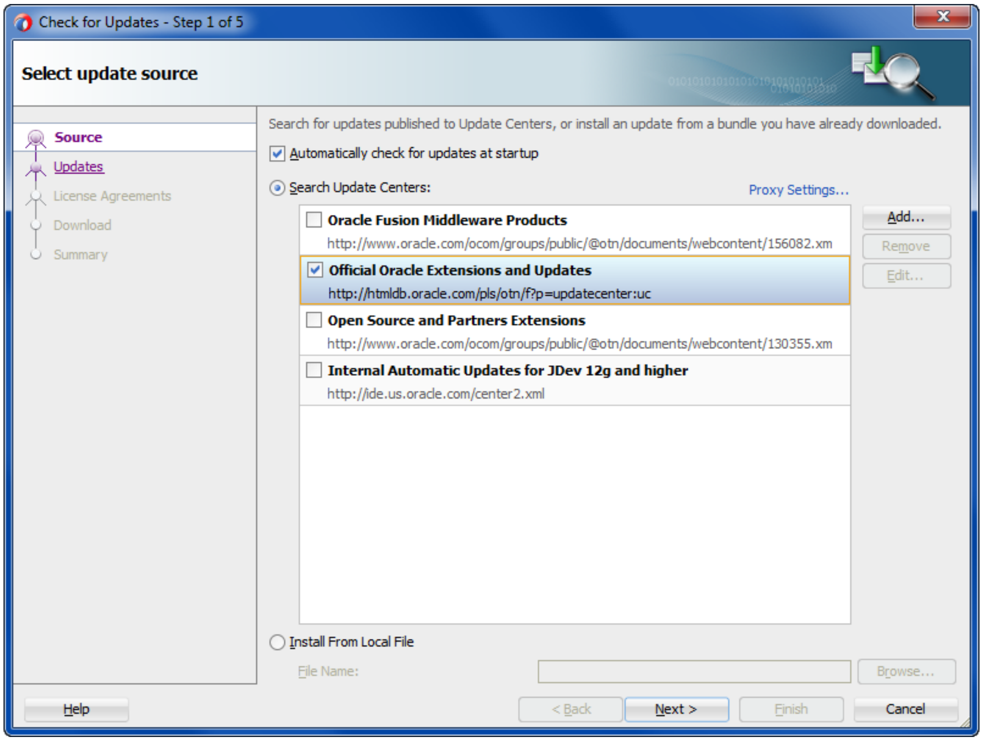
It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

To load the JUnit extension:

1. In the main menu, choose **Help** and then **Check For Updates**.
2. In the Source page of the Check for Updates dialog, select **Search Update Centers** and **Official Oracle Extensions and Updates** and click **Next**.

   If you have the JUnit zip file or if the JUnit selection does not appear in the **Available Updates** list, select **Install From Local File** to load the JUnit zip file.
3. In the Updates page, select **JUnit Integration** and click **Next**, as shown in Figure 48-55.

Figure 48-55   Check for Updates Wizard for Adding JUnit Extension



Check for Updates - Step 1 of 5

Select update source

Search for updates published to Update Centers, or install an update from a bundle you have already downloaded.

☑ Automatically check for updates at startup

● Search Update Centers:

☐ Oracle Fusion Middleware Products
http://www.oracle.com/ocom/groups/public/@otn/documents/webcontent/156082.xm

☑ Official Oracle Extensions and Updates
http://htmldb.oracle.com/pls/otn/f?p=updatecenter:uc

☐ Open Source and Partners Extensions
http://www.oracle.com/ocom/groups/public/@otn/documents/webcontent/130355.xm

☐ Internal Automatic Updates for JDev 12g and higher
http://ide.us.oracle.com/center2.xml

○ Install From Local File

File Name:

4. On the License Agreements page, click **I Accept** and click **Finish**.

How to Create a JUnit Test Case

Before you create a JUnit test case, you must have created a project that is to be tested.

Before you begin:

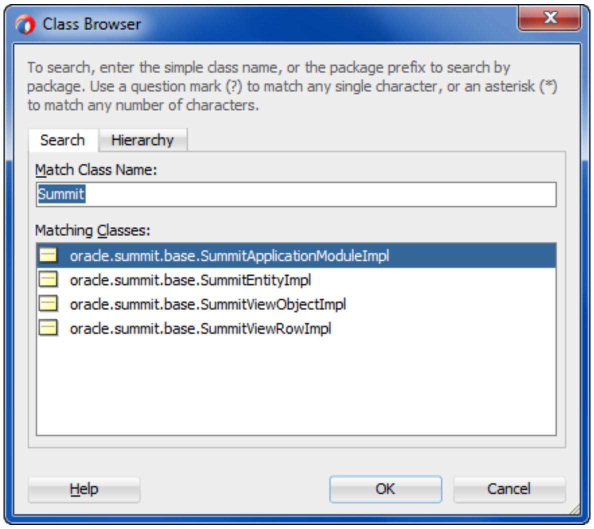
It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

To generate a JUnit test case:

1. In the Applications window, right-click the project in which want to create a test case and choose **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, select **Unit Tests** and then **Test Case**, and click **OK**.
3. In the Select the Class to Test page of the Create Test Case dialog, enter the class under test or click **Browse**.
4. In the Class Browser dialog, locate the class you want to test or enter the beginning letters in the **Match Class Name** field. The **Match Class** list will be filtered for easier identification.

   For example, entering `Summit` filters the list down to four items, as shown in Figure 48-56.

Figure 48-56 Class Browser for Selecting Class Files to Test



To search, enter the simple class name, or the package prefix to search by package. Use a question mark (?) to match any single character, or an asterisk (*) to match any number of characters.

Match Class Name: Summit

Matching Classes:

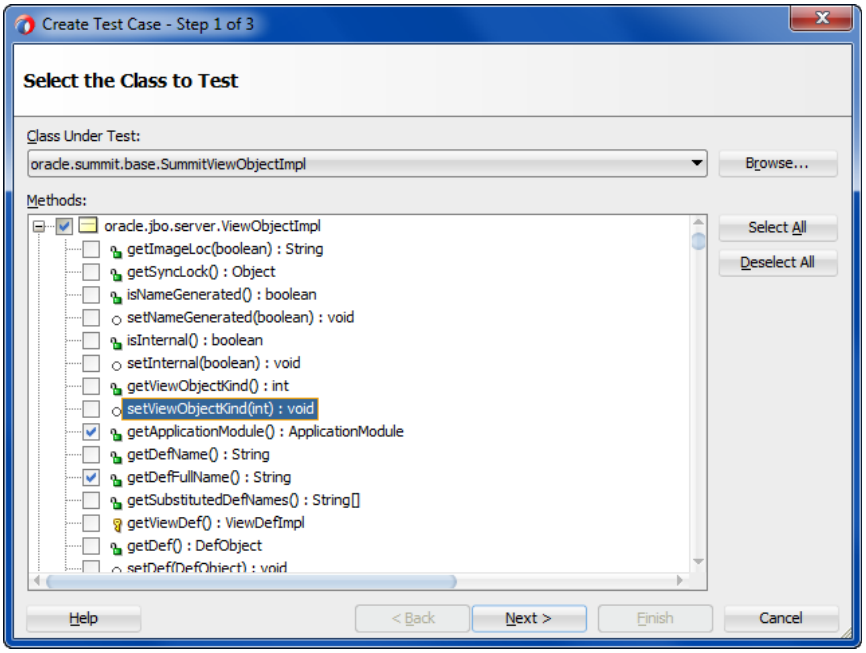
oracle.summit.base.SummitApplicationModuleImpl
oracle.summit.base.SummitEntityImpl
oracle.summit.base.SummitViewObjectImpl
oracle.summit.base.SummitViewRowImpl

   Select the class and click **OK** to close the dialog. Click **Next**.

5. Select the individual methods you want to test, and click **Next**.

   For example, in Figure 48-57, the four methods that are checked are to be tested.

Figure 48-57 Create Test Case Dialog for Selecting Methods to Test



Create Test Case - Step 1 of 3

Select the Class to Test

Class Under Test: oracle.summit.base.SummitViewObjectImpl

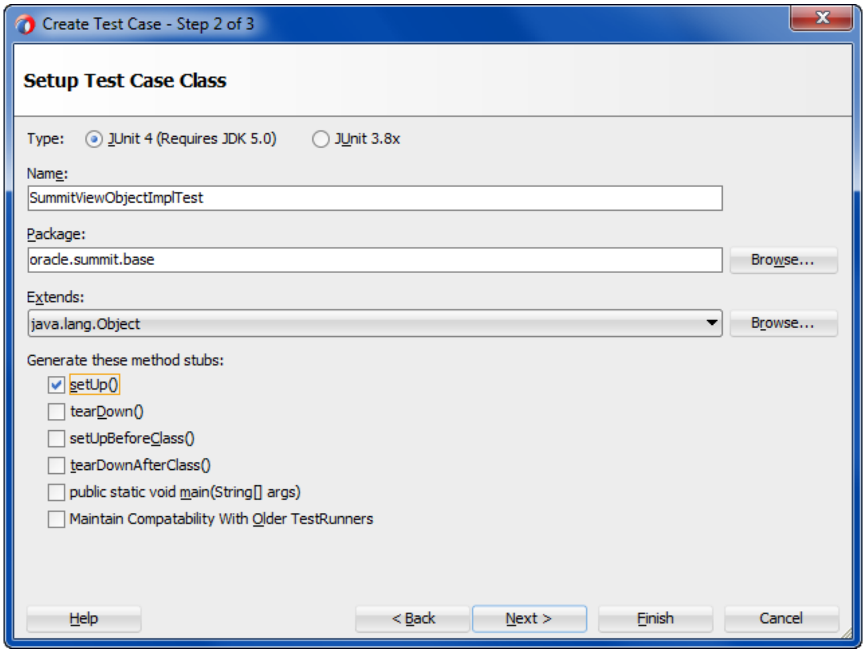
Methods:

- ☑ oracle.jbo.server.ViewObjectImpl
  - □ getImageLoc(boolean) : String
  - □ getSyncLock() : Object
  - □ isNameGenerated() : boolean
  - □ setNameGenerated(boolean) : void
  - □ isInternal() : boolean
  - □ setInternal(boolean) : void
  - □ getViewObjectKind() : int
  - □ setViewObjectKind(int) : void
  - ☑ getApplicationModule() : ApplicationModule
  - □ getDefName() : String
  - ☑ getDefFullName() : String
  - □ getSubstitutedDefNames() : String[]
  - □ getViewDef() : ViewDefImpl
  - □ getDef() : DefObject
  - □ setDef(DefObject) : void

6. In the Setup Test Case Class page, enter the name of the test case, the package, and the class it extends and select the list of built-in functions JUnit will create stubs for. Click **Next**.

   For example, in Figure 48-58, JUnit will create a stub for the `setUp()` method for the `SummitViewObjectImplTest` test case in the `oracle.summit.base` package of the Summit sample application for Oracle ADF.

Figure 48-58 Create Test Case Dialog for Setting Up Classes to Test



Create Test Case - Step 2 of 3

Setup Test Case Class

Type: ● JUnit 4 (Requires JDK 5.0) ○ JUnit 3.8x

Name: SummitViewObjectImplTest

Package: oracle.summit.base

Extends: java.lang.Object

Generate these method stubs:

- ☑ setUp()
- □ tearDown()
- □ setUpBeforeClass()
- □ tearDownAfterClass()
- □ public static void main(String[] args)
- □ Maintain Compatability With Older TestRunners

7. In the Select Test Fixtures page, select any test fixtures you want to add to the test case or click **Browse**.
8. Make sure that all the test fixtures you want to add to the test case are selected in the list and click **Finish**.

How to Create a JUnit Test Fixture

You should create a JUnit test fixture if you require more than one test for a class or method. A JUnit text fixture allows you to avoid duplicating test code that is needed to initialize testing.

Before you begin:

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

To generate a JUnit test fixture:

1. In the Applications window, right-click the project in which want to create a test fixture and choose **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, select **Unit Tests** and then **Test Fixture**, and click **OK**.
3. In the Create Test Fixture dialog, enter the name of the test fixture, the package, and any class it extends.
4. Click **OK**.

How to Create a JUnit Test Suite

Before you create a JUnit test suite, you should have already created JUnit test cases that can be added to the test suite.

Before you begin:

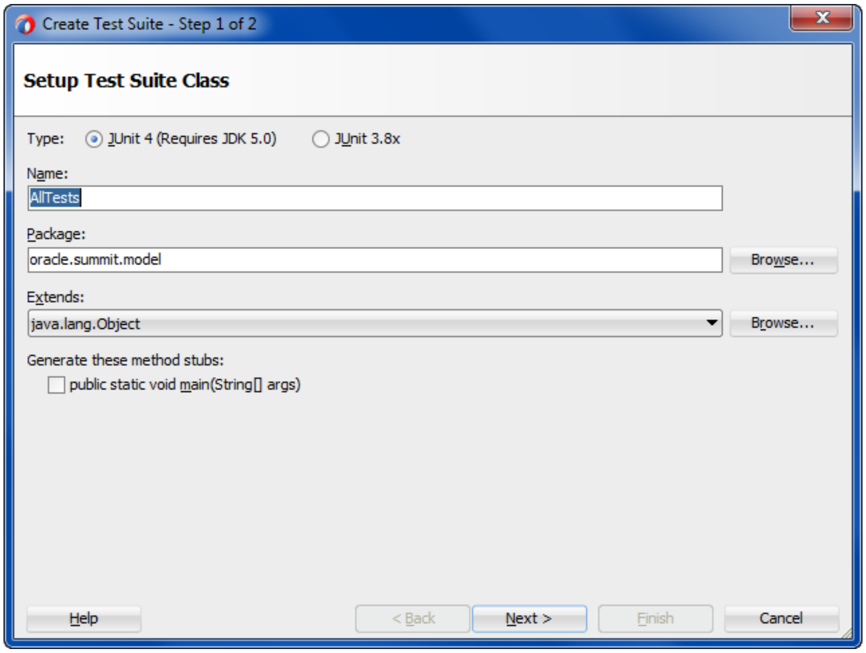
It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

To generate a JUnit test suite:

1. In the Applications window, right-click the project in which want to create a test suite and choose **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, select **Unit Test** and then **Test Suite**, and click **OK**.
3. In the Setup Test Suite Class page of the Create Test Suite dialog, enter the name of the test suite, the package, and the class it extends. Click **Next.**

   For example, in Figure 48-59, an `AllTests` test suite is created that extends the `java.lang.Object` class.

Figure 48-59 Create Test Suite Wizard



Create Test Suite - Step 1 of 2

Setup Test Suite Class

Type: ● JUnit 4 (Requires JDK 5.0) ○ JUnit 3.8x

Name: AllTests

Package: oracle.summit.model

Extends: java.lang.Object

Generate these method stubs:

□ public static void main(String[] args)

4. In the Select Test Cases page of the Create Test Suite dialog, check that all the test cases you want included in the test suite have been selected. The test cases you have created will populate the list. Deselect any test cases that you do not want included. Click **Finish.**

How to Create a Business Components Test Suite

The test fixture that is created is a singleton class to reduce the number of connections. If you want to connect or disconnect for each test case, customize the test case using the JUnit 4 annotations `@Before` and `@After`.

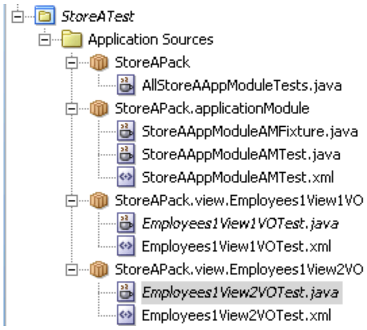
The JUnit BC4J Test Suite wizard will generate tests for each view object in the application module. If the application module does not have exported methods, the wizard will also generate a test for the application module itself. A generated view object class has the format *`view_object`*`VOTest.java` and is placed into a package with the format *`package`*`.view.`*`viewobject`*`VO`, where *`package`* is the application module package. A generated application module test has the format *`application_module`*`AMTest.java` and is placed into a package with the format *`package`*`.applicationModule`. A generated test fixture class has the format *`applicationmodule`*`AMFixture.java` and is placed in the same package as the application module test.

The generated all test suite class has the format `All`*`applicationmodule`*`Test.java` and is placed into the package with the same name as the application module package name.

A test case XML file is also generated for each application module or view object test. The XML file contains test methods defined in the application module or view object test cases. It does not include the test methods from the base classes (if any) because there may be too many duplicates.

For instance, after you created a test suite for an application module named `StoreAAppModule` with view objects `Employees1View1` and `Employees1View2` in the package StoreAPack, the Applications window displays the test hierarchy as shown in Figure 48-20.

Figure 48-60 Business Components Test Suite in the Applications Window



StoreATest
Application Sources
StoreAPack
AllStoreAAppModuleTests.java
StoreAPack.applicationModule
StoreAAppModuleAMFixture.java
StoreAAppModuleAMTest.java
StoreAAppModuleAMTest.xml
StoreAPack.view.Employees1View1VO
Employees1View1VOTest.java
Employees1View1VOTest.xml
StoreAPack.view.Employees1View2VO
Employees1View2VOTest.java
Employees1View2VOTest.xml

Before you begin:

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

You will need to complete this task:

> Create the application modules in the data model project, as described in Implementing Business Services with Application Modules.

To create a business components test suite:

1. In the main menu, choose **File** and then **New** and then **From Gallery**.

   You will create a separate project for the business components tests.
2. In the New Gallery, expand **General**, select **Projects** and then **Java Application Project**, and click **OK**.
3. In the Project Name page of the Create Java Project wizard, enter a name and the directory path for the test project, and click **Next**.
4. In the Project Java Settings page, enter the package name, the directory of the Java source code in your project, and output directory where output class files will be placed, and click **Finish.**
5. In the Applications window, double-click the application module you want to test.
6. In the overview editor, click the **Java** navigation tab.
7. In the Java page of the overview editor, click the **Edit** icon for the **Java Class** section.
8. In the Select Java Options dialog, select **Generate Application Module Class** and click **OK**.
9. In the Java page of the overview editor, click the **Edit** icon for the **Class Interface** section.
10. In the Edit Client Interface dialog, shuttle the methods you want to test to the **Selected** pane, and click **OK**.
11. In the Applications window, right-click the test project you have created and choose **New** and then **From Gallery**.

12. In the New Gallery, expand **General**, select **Unit Tests** and then **Business Components Test Suite**, and click **OK**.
13. In the Configure Tests page of the JUnit BC4J Test Suite wizard, select values for the following and click **Next**:
    - **Business Component Project**: Select the project that has the application module you want to test.
    - **Application Module**: Select the application module you want to test.
    - **Configuration**: Choose a local or shared application module.
    - **Test Base Class-Application Module Extends**: You can specify different base cases. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.
    - **Test Base Class-View Object Extends**: You can specify which class the view object extends. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.
14. In the Summary page, verify the selections and click **Finish**.

How to a Create Business Components Test Fixture

When you create a business components test suite, a business components test fixture is created with it. You can also create Business Components test fixtures independently.

A generated test fixture class has the format `*applicationmodule*AMFixture.java` and put into a package with the format `*package*.applicationModule`, where *package* is the application module package.

Before you begin:

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

You will need to complete this task:

> Create the application modules in the data model project, as described in Implementing Business Services with Application Modules.

To create a business components test fixture:

1. In the main menu, choose **File** and then **New** and then **From Gallery**.

   You will create a separate project for the business components tests.
2. In the New Gallery, expand **General**, select **Projects** and then **Java Application Project**, and click **OK**.
3. In the Project Name page of the Create Java Project dialog, enter a name and the directory path for the test project, and click **Next**.
4. In the Project Java Settings page, enter the package name and the source and output directories, and click **Finish.**
5. In the Applications window, double-click the application module you want to test.

6. In the overview editor, click the **Java** navigation tab and then click the **Edit** icon for the **Java Class** section.
7. In the Select Java Options dialog, select **Generate Application Module Class**, and click **OK**.
8. In the Java page of the overview editor, click the **Edit** icon for the **Class Interface** section.
9. In the Edit Client Interface dialog, shuttle the methods you want to test to the **Selected** pane, and click **OK**.
10. In the Applications window, right-click the test project you have created and choose **New** and then **From Gallery**.
11. In the New Gallery, expand **General**, select **Unit Tests** and then **Business Components Test Fixture**, and click **OK**.
12. In the Configure Tests page of the JUnit BC4J Test Fixture wizard, select values for the following and click **Next**:
    - **Business Component Project**: Select the project that has the application module you want to test.
    - **Application Module**: Select the application module you want to test.
    - **Configuration**: Choose a local or shared application module.
13. In the Summary page, verify the test fixture class and click **Finish**.

How to Run a JUnit Test Suite as Part of an Ant Build Script

Apache Ant is a popular, cross-platform build utility for which JDeveloper offers design time support. You can incorporate the automatic execution of JUnit tests and test output report generation by using Ant's built-in `junit` and `junitreport` tasks. The following example shows a task called `tests` from an Ant `build.xml` file. It depends on the `build` and `buildTests` targets that Ant ensures have been executed before running the `tests` target.

```
<target name="testCustomizations" depends="compileExtensionClasses">
  <junit printsummary="yes" haltonfailure="yes">
    <classpath refid="customization.classpath">
      <pathelement location="${customization.build.dir}"/>
    </classpath>
    <formatter type="plain"/>
    <test name="oracle.customization.tests.AllTests"/>
  </junit>
</target>
```

The `junit` tag contains a nested `test` tag that identifies the test suite class to execute and specifies a directory in which to report the results. The `junitreport` tag allows you to format the test results into a collection of HTML pages that resemble the format of Javadoc.

To try running the JUnit test from Ant, select the `build.xml` file in the Applications window, and choose **Run Ant Target >** ***tests*** from the context menu.

49
Refactoring a Fusion Web Application

This chapter describes considerations for renaming, moving, and deleting source files, configuration files, objects, attributes, and elements in a Fusion web application. In most cases, JDeveloper can perform the complete refactoring. However, in some cases, you might need to complete some manual steps to refactor.
This chapter includes the following sections:

About Refactoring a Fusion Web Application

JDeveloper offers extensive support for refactoring Fusion web application components, available through the Refactor main menu selections or via context menus for selected ADF components. The refactoring of ADF application components in most cases includes renaming, moving, and deleting these components.

JDeveloper provides refactoring options that allow you to make changes to the name and location of attributes, named elements, files, and **ADF Business Components** objects that your application uses. These refactoring options synchronize your changes with other parts of the application that are dependent on the changes. For example, renaming an ADF Business Components object such as a **view object** using the **Rename** option renames any references to it in other XML source files.

In a Fusion Web Application, you can use the refactoring actions (move, rename, and delete) in JDeveloper to make changes to the names and locations of objects. These actions are available from the main menu under **Refactor**, as well as the context menu for each type of object in the Applications window. The move, rename, and delete operations are available for most (but not all) objects and file types. When an object or file is selected in the Applications window, the applicable refactoring operations are enabled in the Refactor menu.

Additionally, there are limitations to what you can refactor in JDeveloper. In some cases, such as moving a project configuration file, there are manual procedures that you can follow. For more information, see Refactoring Limitations .

Refactoring Use Cases and Examples

During the course of development, you will create objects such as entity objects, as needed, to satisfy the needs of the application. Then you might find that you need to subsequently need to delete an object that is no longer used, rename an object to fit a naming convention, or move a set of objects into a different package to consolidate their location. Using JDeveloper, you can refactor these objects so that they are updated and the references to these objects in other objects are also updated to maintain the integrity of the whole application.

Additional Functionality for Refactoring

You may find it helpful to understand other refactoring features available from JDeveloper. Following are links to other functionality that may be of interest.

- For additional information about using JDeveloper features for refactoring Java code, see the Refactoring Java Projects section of *Developing Applications with Oracle JDeveloper*.

Renaming Files

You can display the Refactor menu when you right-click on the ADF Business Component in the Applications window. If you choose to rename a component, JDeveloper will present a Rename dialog. In this dialog you can specify the new name for the object and choose to preview the changes that will be generated by the refactoring process.

You can rename files, such as configuration files, using the following methods:

- In the Applications window, select the file and choose **File** > **Rename** from the main menu.
- In the Applications window, right-click the file and choose **Refactor > Rename**.
- In the source editor, select a class name, right-click it, and choose **Rename**.

To move a file between directories, use the **Move** menu item.

When you rename or move a file, all references to the file are updated as well. For example when you rename a page definition file, its entry in the `DataBindings.cpx` file is updated accordingly.

You cannot rename the XML file or Java files associated with an ADF Business Components object independently of the object, as these files must be kept in synch. See Refactoring ADF Business Components .

Moving JSF Pages

You can change the package of the JSF page with the Refactor menu. This updates the faces-config.xml file, DataBindings.cpx mappings to the page, and the ADF task flows containing page views.

In addition to the other refactoring operations, you can change the package of a JSF page. In the Applications window, right-click a JSF page and choose **Refactor** > **Move** to move the page to another package. Moving the JSF page to another package updates:

- `faces-config.xml` files that reference the page and its package
- ADF task flows containing views associated with the page
- `DataBindings.cpx` mappings to the page

Refactoring pagedef.xml Bindings Objects

The pagedef.xml file defines bindings and executables that populate the data in UI components at runtime. You can choose any data binding or executable and rename or delete it using the Refactor menu.

The `pagedef.xml` binding objects that you can refactor include bindings and executables. See Working with Page Definition Files.

Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. See About Refactoring a Fusion Web Application .

In JDeveloper, open the application that contains the objects you want to refactor.

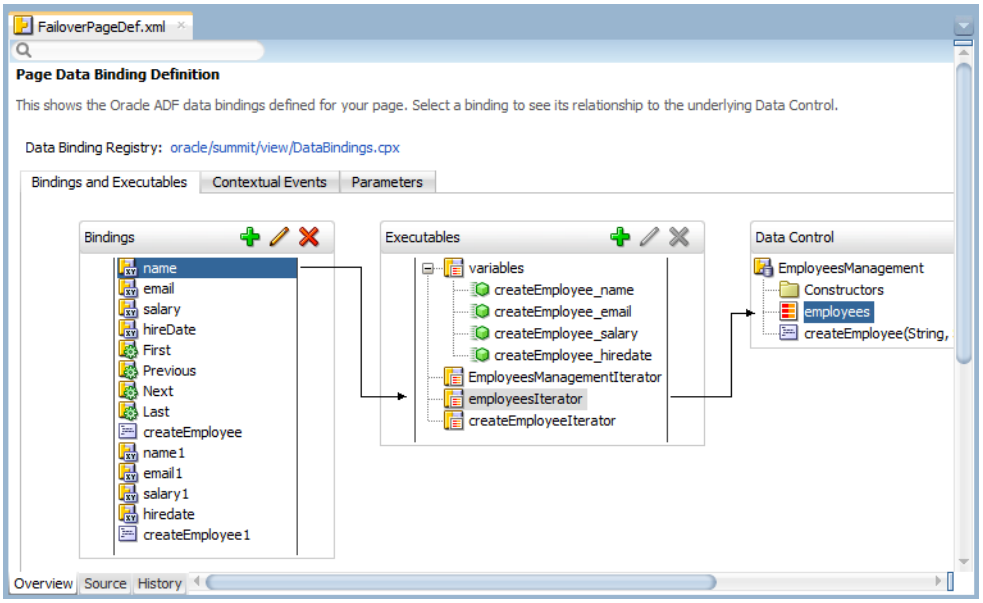
To refactor pagedef.xml binding objects:

1. In the Applications window, select the page node on which you have added a bound object such as an ADF Form or selection list.
2. Right-click the page node and choose **Go to Page Definition**.

   If the page does not already have a page definition, the Create Page Definition dialog appears. Click **OK** to create a page definition for the page.
3. In the overview editor, click the **Bindings and Executables** tab.

   Data bindings such as list bindings and iterator bindings defined for the page display under **Bindings and Executables**, as shown in Figure 49-1.

Figure 49-1 Page Data Binding Definition Overview Tab



Page Data Binding Definition

This shows the Oracle ADF data bindings defined for your page. Select a binding to see its relationship to the underlying Data Control.

Data Binding Registry: oracle/summit/view/DataBindings.cpx

4. In the Structure window, right-click a data binding or executable, choose **Refactor** and a refactoring option, such as **Rename** or **Delete**.

5. To display the usages between bindings, executables, and data controls, right-click a binding or executable and choose **Find Usages**.

Refactoring ADF Business Components

When it comes to refactoring ADF components in JDeveloper, the common refactoring features that are used are rename, move or delete ADF Business Components objects.

ADF Business Components includes objects such as view objects and entity objects. Table 49-1 shows support for refactoring ADF Business Components.

Table 49-1 Refactoring ADF Business Components

Action	Result
Move	Moves the object to a different package or directory and updates all references.
Delete	JDeveloper shows all dependencies on the object and permits a forced delete. The application may not work at this point. You may need to resolve broken references.
Rename	ADF Business Components objects are defined by an XML file. The XML file has a file name identical to the object name. For example, the name of the XML file for a view object named `Persons1View` is `Persons1View.xml`. Renaming results in changing the `Name` attribute, renaming the XML file, and updating all references. For example, the name of an entity (`Customer`) is stored as an attribute in the XML file (`name=Customer`). The XML file has the same name the entity name (`Customer.xml`).

Table 49-1 (Cont.) Refactoring ADF Business Components

Action	Result
Find Usages	JDeveloper shows all dependencies on the object.

> **Note:**
>
> Refactoring does not cross abstraction layers. For example, when a view object is created based on the `Dept` entity object, it is named `DeptView` by default. Renaming the `Dept` entity object updates the entity usage in `DeptView`, but does not change the name of the view object.

Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. For more information, see About Refactoring a Fusion Web Application .

In JDeveloper, open the application that contains the object you want to refactor.

To refactor ADF Business Components objects:

1. In the Applications window, expand the project and then the **Application Sources** node and then the package containing the object you want to refactor.
2. Right-click the object and choose **Refactor** and a refactoring option.
   - To change the name of the object, choose **Rename**.

     The Rename dialog displays the current name of the object. Enter the new object name and click **OK** to proceed with the refactoring or **Cancel** to cancel.

     You can optionally select **Preview** and click **OK** to display the usages in the Log window, which allows you to proceed with the refactoring or cancel. When you click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.
   - To change the location of the object, choose **Move**.

     The Move dialog displays the current location of the object. Enter the new package name, or click **Browse** to navigate to it. Click **OK** to proceed with the refactoring or **Cancel** to cancel.
   - To remove the object, choose **Delete**.

     The Confirm Delete dialog displays the name of the object and searches for usages. Click **Show Usages** to display where the object is used. Click **Yes** to proceed with the refactoring or **No** to cancel. Click **Preview** to display the results in the Log window, which allows you to proceed with the refactoring or cancel. When you click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.

     By default JDeveloper searches in the current application for usages of the object. You can change the scope of the search by choosing from the **Finding Usages In** dropdown list, or by clicking the **Manage Working Sets** icon.

Refactoring ADF Business Component Object Attributes

You can refactor attributes of ADF Business Components entity objects and view objects.

Table 49-1 shows support for refactoring attributes of ADF Business Component entity objects and view objects.

Table 49-2 Refactoring Attributes

Action	Result
Move	Not supported.
Delete	JDeveloper shows all dependencies on the attribute and permits a forced delete. The application may not work at this point. You may need to resolve broken references.
Rename	Attributes share data elements represented in entity and view objects (see About Entity Objects for more information). References to the attribute are updated when you rename the attribute. Renaming results in changing the `Name` attribute and updating all references. This includes updating the service implementation of view attributes used in the generated service of an **application module**. Renaming an attribute does not change the data it represents, nor does it rename the underlying table column.
Find Usages	JDeveloper shows all dependencies on the attribute.

Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. See About Refactoring a Fusion Web Application .

In JDeveloper, open the application that contains the attribute you want to refactor.

To refactor attributes:

1. In the Applications window, double-click the entity object or view object that contains the attribute you want to refactor.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the **Name** column, right-click the attribute and choose a refactoring option.
   - To change the name of the attribute, choose **Rename**.

     The Rename dialog displays the current name of the attribute. Enter the new attribute name and click **OK** to proceed with the refactoring or **Cancel** to cancel.

     You can optionally select **Preview** and click **OK** to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.
   - To see where the attribute is used, choose **Find Usages**.

     The Log window displays usages of the attribute. When you click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.
   - To remove the attribute, choose **Delete**.

In the Confirm Delete dialog, click **Show Usages** to display where the attribute is used. Click **Yes** to proceed with the refactoring or **No** to cancel. Click **Preview** to display the results in the Log window, which allows you to proceed with the refactoring or cancel.

- To change the type of the attribute, choose **Change Type**.

  In the Change Type dialog, choose the new type from the **Type** dropdown list, or click **Browse** to find the type. Click **OK** to proceed with the refactoring or **Cancel** to cancel.

  You can optionally select **Preview** and click **OK** to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.

Refactoring Named Elements

A named element is not an object or attribute. Named elements are elements in the XML schema that can be referenced by a Name attribute. JDeveloper allows you to refactor a named element.

Named elements are any elements in the XML schema that can be referenced by a `Name` attribute. A named element is not an object or an attribute. Table 49-3 shows support for refactoring named elements in an XML schema.

Table 49-3 Refactoring Named Elements

Action	Result
Move	Not supported.
Delete	Not supported.
Rename	One exception to the definition of named elements is the design time element `Attr`, which does have a `Name` attribute. `Attr` is a name-value pair, is not accessible from the code editor, and should not be renamed.
Find Usages	JDeveloper shows all dependencies on the named element.

Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. See About Refactoring a Fusion Web Application.

In JDeveloper, open the application that contains the named element you want to refactor.

To refactor named elements:

1. In the Applications window, double-click the entity object or view object that contains the named element you want to refactor.
2. In the editor window, click the **Source** tab, and search or scroll to find the named element.

   Named elements are indicated by `Name="<element>"` in the source code, for example:

   ```
   <Key Name="PersonsAffContactChk">
   ```

A named element is not an object or attribute.

3. Right-click the named element you want to refactor and choose **Refactor** and a refactoring option.

   - To change the name of the element, choose **Rename**.

     The Rename dialog displays the current name of the element. Enter the new element name and click **OK** to proceed with the refactoring or **Cancel** to cancel.

     You can optionally select **Preview** and click **OK** to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.

   - To remove the element, choose **Delete**.

     In the Confirm Delete dialog, click **Show Usages** to display where the element is used. Click **Yes** to proceed with the refactoring or **No** to cancel. Click **Preview** to display the results in the Log window, which allows you to proceed with the refactoring or cancel.

Refactoring ADF Task Flows

You can refactor existing activities, JSF page flows, and JSF pages into new ADF Controller components such as bounded task flows and task flow templates using JDeveloper.

For more information, see Refactoring to Create New Task Flows and Task Flow Templates.

Refactoring the DataBindings.cpx File

In order to rename or move the DataBindings.cpx file, you need to create the new one and delete the existing one. While doing this you must not forget to update the adfm.xml file which is the registry of registries and the id property must be similar to the DataBindings.cpx file name otherwise you will get an error message.

The `DataBindings.cpx` file defines the Oracle ADF **binding context** for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime (see DataBindings.cpx Syntax for more information). This file is a registry used to quickly find all `.cpx`, `.dcx`, `.jpx`, and `.xcfg` files, which are themselves registries of metadata.

If you rename the `DataBindings.cpx` file to a new name, such as `DataBindingsNew.cpx`, the change is added to the `adfm.xml` file.

The following example shows the contents of the `adfm.xml` file after `DataBindings.cpx` is refactored to `DataBindingsNew.cpx`.

```
<?xml version="1.0" encoding="UTF-8" ?>
<MetadataDirectory xmlns="http://xmlns.oracle.com/adfm/metainf"
version="11.1.1.0.0">
<DataBindingRegistry path="adf/sample/view/DataBindingsNew.cpx"/>
</MetadataDirectory>
```

Additionally, to enable the application to access the correct bindings file, the ID value is changed to an ID similar to the one shown in the following example.

```
<Application xmlns="http://xmlns.oracle.com/adfm/application"
version="11.1.1.49.28" id="DataBindingsNew" SeparateXMLFiles="false"
Package="adf.sample.view" ClientType="Generic">
```

Refactoring Limitations

JDeveloper has set of refactoring issues and limitations that are listed here.

Table 49-4 summarizes the limitations of JDeveloper's refactoring support.

Table 49-4 Refactoring Limitations

Area	Limitation
Database	When a database artifact used in an ADF Business Components object is renamed, the object needs to be updated. This type of refactoring is currently not supported.
Service interface	A service interface defines a contract between two separate pieces of software. For example, the ADF Business Components service interface is responsible for exposing business components to the view and model layers. Changing the name of a service interface can cause a conflict. While developing the application, consider removing the service interface, refactoring the object, and regenerating the service interface. Additionally, if your service interface defines a find operation based on a **view criteria** that specifies bind variables, changing the number or order of the bind variables in the underlying view criteria will require that you regenerate the service interface. See Creating SOAP Web Services with Application Modules.
Java literal references	The Java code generated by ADF Business Components has literal references to the XML metadata. These literal references are updated during refactoring operations. Generated (type safe) methods are also updated. Also, the refactor delete operation is available for local Java variables. However, if the application code directly refers to the metadata, these references are not updated.
Domain	If a domain needs to be renamed or moved, you must create the new domain, then change the type of existing domain usages.For example, you might rename a domain called `EmployeeID` to `EmployeeNumber`. In addition, the entity `Emp` has an attribute called `Empno` that is of type `EmployeeID`.After creating the new domain `EmployeeNumber`, go to the attributes page for the entity, right-click **Empno** and choose **Change Type**. This switches `Empno` from `EmployeeID` to `EmployeeNumber`.
Security	Security policies in the policy store may reference the name of an entity object, attribute, page, or task flow. These policy definitions are not updated in response to the refactoring of the object itself.

Table 49-4 (Cont.) Refactoring Limitations

Area	Limitation
Resource Bundles	Entity object definitions can reference a resource in one or more arbitrary resource bundle (`.properties`) files that you create. You can use this file to define labels for the attributes of entity objects. However, if you rename the `.properties` file you created, JDeveloper will not update the entity object definitions to reflect the new file name. As an alternative to resource bundle files that you create, you can specify a project setting to generate a single, default resource bundle file for the data model project. In this case, JDeveloper will not allow you to rename this generated file. However, if you attempt to change the project-level default resource bundle file, JDeveloper will warn you about the change. The data model project will honor the new ADF Business Components project-level setting for any objects that have not yet been linked to the default resource bundle file; all existing Business Components that have already been linked to the original default file will continue to use it instead.
`.jpx` project configuration file	Renaming the ADF Business Components project configuration file (`.jpx`) is not supported. In previous versions of JDeveloper, ADF Business Components project configuration `.jpx` files were created only in the root package of the `src` directory of a project and were named with the same base name as the project. The ADF Business Components objects (entity objects, view objects, and application modules) were all created in the model package (for example, `/model/AppModule.xml`), but the `/Model.jpx` is not.This may cause a reusability problem when attempting to package them in ADF JAR files for use on the class path. There may be name conflicts because several projects are named `Model`.

Moving the ADF Business Components Project Configuration File (.jpx)

If the ADF Business Components Project file (.jpx) is moved to a different package, then the jbo.project property available in bc4j.xcfg file must be changed accordingly. However, it is not always changed automatically.

Although refactoring the ADF Business Components project configuration file (`.jpx`) is not supported, you may need to change its name or location to avoid conflicts when sharing your project contents as an ADF library. The `.jpx` file contains configuration information that JDeveloper uses in the design time to allow you to create the data model project with ADF Business Components. If you need to refactor this file, you must do so manually.

Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. See About Refactoring a Fusion Web Application.

To manually move the ADF Business Components project configuration file (.jpx):

1. Move the `.jpx` file to the new source tree location.

For example, you can move the `Model.jpx` file from `src/Model.jpx` to `src/newpackage/name/here/Model.jpx`.

2. Change the `.jpx` file contents. The `PackageName` attribute of the root element `JboProject` needs to have the correct value.

   For example, you can specify `PackageName="newpackage.name.here"`.

3. Change the `jbo.project` attributes in all `common/bc4j.xcfg` files that contain elements referred to in the `.jpx` file to include the new package name.

   For example:

   ```
   <AppModuleConfig name="ScottDeptAMLocal"
   ApplicationName="newpackage.name.here.ScottDeptAM"
   DeployPlatform="LOCAL" JDBCName="scottdb"
   jbo.project="newpackage.name.here.Model">
   ```

4. Change the contents of the JDeveloper project file (the `.jpr` file):

   - Set the new `.jpx` package location. If you later change the default package in the project properties, you will again raise a `NotFound` error for the `.jpx` file.

     For example:

     ```
     <value n="defaultPackage" v="newpackage.name.here"/>
     ```

   - Fix any `ownerURL` elements in the `ownerMap` that contain references to the old location of the `.jpx` file.

     For example:

     ```
     <url n="ownerURL" path="src/newpackage/name/here/Model.jpx"/>
     ```

50 Reusing Application Components

This chapter describes how to package certain Oracle ADF components into the ADF Library for reuse in Fusion web applications. Reusable ADF components are application modules, business components (entity objects, view objects, associations), data controls, task flows, page templates, and declarative components.
This chapter includes the following sections:

About Reusable Components

In the course of ADF application development, certain components will often be reused. Creating and consuming reusable components should be included in the early design and architectural phases of the application development. It is advantageous to package these reusable components into a library that can be shared between different teams. These shared libraries can be added to a repository. Later if you need a component, you may look into the repository for something to be reused.

In the course of application development, certain components will often be used more than once. Whether the reuse happens within the same application, or across different applications, it is often advantageous to package these reusable components into a library that can be shared between different developers, across different teams, and even across departments within an organization.

In the world of Java object-oriented programming, reusing classes and objects is just standard procedure. With the introduction of the model-view-controller (MVC) architecture, applications can be further modularized into separate model, view, and controller layers. By separating the data (model and **business services layer**) from the presentation (view and controller layers), you ensure that changes to any one layer do not affect the integrity of the other layers. You can change business logic without having to change the UI, or redesign the web pages or front end without having to recode domain logic.

Oracle ADF and JDeveloper support the MVC design pattern. When you create an application in JDeveloper, you can choose many application templates that automatically set up data model and user interface projects. Because the different MVC layers are decoupled from each other, development can proceed on different projects in parallel and with a certain amount of independence.

ADF Library further extends this modularity of design by providing a convenient and practical way to create, deploy, and reuse high-level components. When you first design your application, you design it with component reusability in mind. If you created components that can be reused, you can package them into JAR files and add them to a reusable component repository. If you need a component, you may look into the repository for those components and then add them into your project or application.

For example, you can create an **application module** for a domain and package it to be used as the data model project in several different applications. Or, if your application will be consuming components, you may be able to load a page template component from a repository of ADF Library JARs to create common look and feel pages. Then you can put your page flow together by stringing together several task flow components pulled from the library.

An ADF Library JAR contains ADF components and does not, and cannot, contain other JARs. It should not be confused with the JDeveloper library, Java EE library, or Oracle WebLogic shared library.

Table 50-1 lists the reusable components supported by ADF.

Table 50-1 Oracle ADF Reusable Components

Reusable Component	Description
Data control	Any data control can be packaged into an ADF Library JAR. Some of the data controls supported by Oracle ADF include application modules, Enterprise JavaBeans, web services, URL services, JavaBeans, and placeholder data controls.
Application module	When you are using **ADF Business Components** and you generate an application module, an associated **application module data control** is also generated. When you package an application module data control, you also package up the ADF Business Components associated with that application module. The relevant entity objects, **view objects**, and associations will be a part of the ADF Library JAR and available for reuse.
Business components	Business components are the entity objects, view objects, and associations used in the ADF Business Components data model project. You can package business components by themselves or together with an application module.
Task flows and taskflow templates	Task flows can be packaged into an ADF Library JAR for reuse. If you drop a bounded task flow that uses page fragments, JDeveloper adds a region to the page and binds it to the dropped task flow. ADF bounded task flows built using pages can be dropped onto pages. The drop will create a link to call the bounded task flow. A task flow call activity and control flow will automatically be added to the task flow, with the view activity referencing the page. If there is more than one existing task flow with a view activity referencing the page, it will prompt you to select the one to automatically add a task flow call activity and control flow. If an ADF task flow template was created in the same project as the task flow, the ADF task flow template will be included in the ADF Library JAR and will be reusable.
Page templates	You can package a page template and its artifacts into an ADF Library JAR. If the template uses image files and they are included in a directory within your project, these files will also be available for the template during reuse.
Declarative components	You can create declarative components and package them for reuse. The tag libraries associated with the component will be included and loaded into the consuming project.

You can also package up projects that have several different reusable components if you expect that more than one component will be consumed. For example, you can create a project that has both an application module and a bounded task flow. When this ADF Library JAR file is consumed, the application will have both the application module and the task flow available for use. You can package multiple components into one JAR file, or you can package a single component into a JAR file. Oracle ADF and JDeveloper give you the option and flexibility to create reusable components that best suit you and your organization.

You create a reusable component by using JDeveloper to package and deploy the project that contains the components into a ADF Library JAR file. You use the components by adding that JAR to the consuming project. At design time, the JAR is added to the consuming project's class path and so is available for reuse. At runtime, the reused component runs from the JAR file by reference. For the procedure to add the JAR manually, see How to Add an ADF Library JAR into a Project Manually. For the procedure to add the JAR using the JDeveloper Resource Catalog, see How to Add an ADF Library JAR into a Project using the Resources Window.

Before you proceed to create reusable components, you should review the guidelines for creating reusable components.

Creating Reusable Components

Creating and consuming reusable components should be included in the early design and architectural phases of software projects. You and your development team should consider which components are candidates for reuse, not only in the current applications but also for future applications and including those applications being developed in other departments.

You and your team should decide on the type of repository needed to store the library JARs, where to store them, and how to access them. You should consider how to organize and group the library JARs in a structure that fits your organizational needs. You should also consider creating standardized naming conventions so that both creators and consumers of ADF Library JARs can readily identify the component functionality.

> **Tip:**
>
> If, in the midst of development, you and your team find a module that would be a good candidate for reuse, you can use the extensive refactoring capabilities of JDeveloper to help eliminate possible naming conflicts and adhere to reusable component naming conventions.

Naming Conventions

When you create reusable components, you should try to create unique and relevant names for the application, project, application module, task flow, connection, or any other file or component. Do not accept the JDeveloper wizard default names such as Application, Project, ViewController, AppModule, `task-flow-defintion.xml`, or Connection. You want to try to have unique names to avoid naming conflicts with other projects, components, or connections in the application. Naming conflicts could arise from components created in the consuming application and those loaded from other JAR files. Table 50-2 lists the objects that you may be required to rename.

Table 50-2 Example Unique and Relevant Names for Reusable Components

Type	JDeveloper Default	Example
Application	Application	`SummitADF`
Project	Model ViewController Project	`BackOfficService` `OrderTrackingUI`
Package	Various possibilities. For more information, see Naming Considerations for Packages .	`oracle.summit`
Application module	AppModule	`SummitAppModuleDataControl`
Connection	Connection1	`summit_adf`
Task flow	`task-flow-defintion.xml`	`customer-task-flow-definition.xml`
Page template	`templateDef`.jspx	`SummitTemplate.jspx`
Declarative Component	`componentDef` `componentDef.jspx`	`SummitsuperwidgetDef` `SummitsuperwidgetDef.jspx`
ADF Library JAR file	adflib<string or 3-digit random number>*N* For more information, see The Naming Process for the ADF Library JAR Deployment Profile.	`SummitADF_Model_adflibSummitADF1`

Naming Considerations for Packages

Be aware that some components use the default package name of the project without allowing the name to be explicitly set. In this situation, you must take extra care to avoid package name collisions. You can set the package name in the application creation wizard and you should check the names in the Project Properties dialog afterwards. If you don't set the package name, it will default to a variant of the project name, typically with the first letter being lowercase. For example, a project with the name `Project1` will have a default package name of `project1`. You should manually change the package name to a more unique name before you proceed to build the project.

> **Note:**
>
> The basic package naming requirement is that ADF metadata registries (`.dcx`,`.cpx`, and so on) are generated based on the project's package name, and you should avoid metadata naming conflicts between projects that will be combined at runtime.

When you are creating a reusable component's web resource files (such as JSPs, HTMLs, and task flows), you should create them in their own relative directories. When the JAR is deployed into another application, there will be less chance for conflict between the reusable component's files and the consuming application's files.

> **Note:**
>
> You can override the staleness period setting of 364 days for all static web application resources in ADF Libraries by adding initialization parameters to the web.xml file. For more information, see web.xml.

Naming Considerations for Connections

Often, several modules in an application will connect to the same data source. You should standardize the connection name to the same data source to avoid confusion because there is only one namespace for connections across the application. This would require coordination with other developers, component producers, and component consumers. For example, if customers and suppliers both have a connection to the same database, the connection name should be standardized to an agreed upon name, such as orders_db.

ADF Library JARs (with connections) may be used in different applications with different connection requirements. ADF Library JAR producers should choose connection names that are at least representative of the connection source, if not the actual standardized connection name. Be aware that consumers of the JAR that was created with connections will be required to satisfy the connection requirements when they add the component to the application.

For example, for a database connection, choosing an endpoint host name is usually not appropriate. The most appropriate name is a complete representative for the schema. Acceptable example names for connections are oracle-appsdb and oracle-customersdb. You should realize that if many reusable components use different names for the same logical connection, then the consumer of the component will have to satisfy each one individually with duplicate information. The consumer will have to supply connection details for several different connection names, when in fact they all refer to the same instance.

Naming Considerations for Applications with EJB Projects

If an application has both EJB projects and a web application project with data binding, you should check to see that the EJB component names are not in conflict with any other web application project component names. The EJB project components may have global scope because the project is automatically added to the global class path of all web projects in the application. The web application project may mistakenly access a component with the same name in the EJB project rather than within its own project.

For example, if both an EJB project and a web-based project have a test1.jspx page, when the web-based project is run, it may try to run the EJB project test1.jspx page.

At runtime, JDeveloper detects if there are EJB projects and web application projects with data binding in the same application. If there are both types in the application, when the project is run and the server starts up, a warning message will appear in the Log window.

The Naming Process for the ADF Library JAR Deployment Profile

Before you package the project, you must create a deployment profile with the name and path for the JAR file. You should choose a name that follows you and your development team's naming convention and that is descriptive of the function of the component. You should realize that the consuming project may also include other JAR files from other software authors.

For example, if the component is a task flow for self-service paying, you might name it `mycompany.hcm.pay.selfservice.taskflows.jar`. Other examples are `oracle.apps.hcm.pay.model.jar` and `mycompany.hcm.pay.model.overrides.jar`.

When you create the deployment profile, JDeveloper will present a default name with the following format:

`adflib`*`identifierN`*

Where *`identifier`* is random number up to three-digits and *`N`* is a number that starts with 1 and increments by 1 for each iteration of the profile.

For example, the default name for a profile may be `adflib7491(`random number is `749` and suffix is `1)`. The default name for the another profile may be `adflib51` (random number is `5` and suffix is `1)`.

You can change this default name to a name of your choice.

Keeping the Relevant Project

When you are creating reusable components, you should eliminate any projects that are not relevant to the reusable component. For example, if you want to create a reusable application module, you would need a data model project, but you would not need a user interface project. In this instance, if you had created an application with both a data model and a user interface project, you could delete the user interface project. Of course, you should rename the default name `Model` to something more relevant, such as `BackOfficeService`. Similarly, if you are creating a reusable task flow that is not databound, you can delete any data model project from the application.

Selecting the Relevant Feature

If you know the technology scope of your consuming projects, you can design your component with technologies that will be compatible. For example, if the consuming application uses only standard JSF Faces, then it may not be compatible with a declarative component that is built with ADF Faces.

When you create your application, you can define the features using the Create Application Wizard by selecting from the application template.

After the project has been created, you can define the technology using the Features page of the Project Properties dialog.

Selecting Paths and Folders

If you are using the file system to store your ADF Library JARs, you should select file system locations that can function as repositories. You may want to put groups of JARs into a common directory folder, for example, `C:\ADF\jdev\DevTeamADFRepository`. If your team or organization plans to share ADF Library JARs, you should consider setting up network-accessible repository folders, directories, or services. The Resources window has provisions to connect to different repository sources and make multiple connections. For more information about accessing ADF Library JARs using the Resources window, see Using the Resources Window.

Including Connections Within Reusable Components

If the project you are packaging into an ADF Library JAR includes a connection, that information can be included in the JAR and may be available to the consuming project. Oracle ADF uses connection architecture which defines a connection as two parts, the connection name and the connection details (or endpoint definition). JDeveloper will present the producer of the JAR the option to package the connection name only or to include connection details with the connection name.

If a connection is present in the project, the packaged ADF Library JAR will contain a `jar-connections.xml` file and a `jar-adf-config.xml` file. They will be added to the `META-INF` directory. The `jar-connections.xml` file contains the connection name and other relevant connection information. The `jar-adf-config.xml` file stores the information about the credentials used for the connections. If connection credentials were also specified, then a `jar-credential-jazn-data.xml` will also be included for the credential store. You can select the individual connections or connection types that you want to be packaged with the ADF Library JAR when you create the ADF Library JAR deployment profile. You make connection selections in the Create or Edit ADF Library Deployment Profile Properties dialog Connections page, as described in How to Package a Component into an ADF Library JAR.

When an ADF Library JAR is being added to a project, JDeveloper checks for conflicts between the application's connections and the JAR's connections. A dialog will be presented to allow you to decide whether to proceed with adding the JAR to the project. Connections defined in the ADF Library JAR may be added to the consuming project, depending on the following conditions:

- If the connection defined in the JAR is fully configured and there are no connection name conflicts with the consuming project, a new connection will be added.
- If the connection defined in the JAR is partially configured, a new connection will be added to the consuming project but it must be configured before use. Connection dialogs may appear to allow the user to enter connection information. This partially configured connection may be indicated by an incomplete icon.
- If the connection defined in the JAR has the same name as the application's connection, it will not be added to the project. The application's existing connection will be used.
- If the connection defined in the JAR has the same name as the application's connection but is of different type, the JAR's connection will not be added to the project. For example, if a database connection in the JAR and a URL connection in the application have the same name, the database connection will not be added to the application.

For instructions on how to add an ADF Library to a project that includes connections, see How to Add an ADF Library JAR into a Project using the Resources Window.

> **Note:**
>
> In the process of adding the ADF Library to a project, you will see one message displayed in the Log window for each connection defined in the JAR. The messages indicate the merge action taking place in the project.

Reusable ADF Components Use Cases and Examples

Packaging projects into ADF Library JARs allows components to be reused multiple times in the same or in different applications. Different development teams can create and consume projects and create libraries of reusable modules. ADF Library JARs support the M-V-C design pattern. You can create ADF Libraries and access them using drag and drop from the Resources window.

For instance, you can package up an application module into an ADF Library JAR and place it in a public folder for other team to use. Different implementation teams may access that JAR to create their applications. They may use the application module to create different pages for their use instead on having to create their own application modules. When there is a change in the model, the original developer can repackage the application module and republish the ADF Library JAR. The other implementation teams can update their application using the updated ADF Library.

Additional Functionality for Reusable ADF Components

You may find it helpful to understand other ADF features before you work with reusable ADF components. Following are links to other functionality that may be of interest.

- You can package business components for reuse. For more information on application modules, see Getting Started with ADF Business Components.
- You can package application modules for reuse. For more information on application modules, see Implementing Business Services with Application Modules.
- You can package task flows for reuse. For more information on task flows, see Getting Started with ADF Task Flows .
- You can package page templates for reuse. For more information on task flows, see Getting Started with Your Web Interface .
- You can package page templates for reuse. For more information, see the Using Declarative Components section of the *Developing Web User Interfaces with Oracle ADF Faces*.

Common Functionality of Reusable ADF Components

When you package or consume an ADF Library JAR, you also include and consume the extension libraries that are associated with the project. When you consume an ADF Library, you can use the Resources window.

Using Extension Libraries

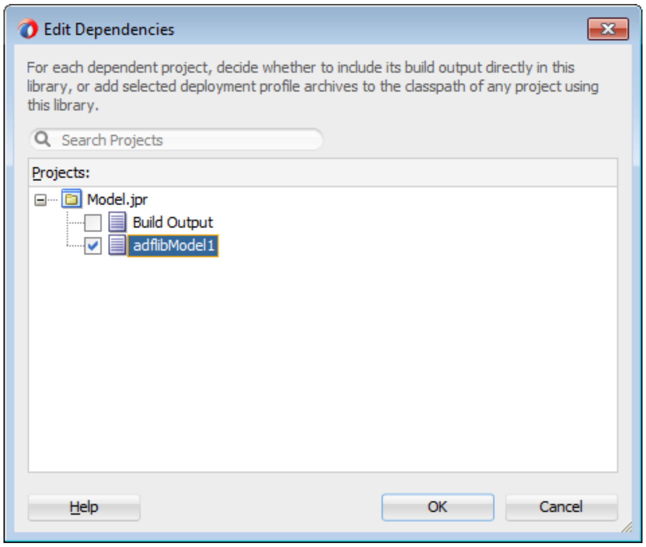
An ADF project usually includes a list of extension libraries that it needs to run. These libraries are loaded in the class path of the project. You can view a project's dependent libraries by selecting the **Libraries and Classpath** node of the Project Properties dialog. Some of the libraries that may appear are JSP Runtime, ADF Page Flow Runtime, Connection Manager, and Oracle JDBC.

When a project is packaged into an ADF Library JAR, its extension libraries are packaged with it. And when an ADF Library JAR is being consumed by another project, JDeveloper automatically resolves any extension library conflicts between them. During the consuming process, JDeveloper checks to see whether the consuming project already has the extension libraries of the ADF Library JAR in its class path and loads only those libraries that it does not have. For example, if JSP Runtime already exists in the consuming project, it will not be loaded again if the ADF Library JAR also includes it. The consuming project's extension libraries will be a union of its own libraries and the libraries in the ADF Library JAR.

If the project you want to package into an ADF Library has a dependent project, you can include the dependent project's extension libraries directly in the JAR or, if the dependent project has a deployment profile, you can add the dependent project's JAR to the ADF Library. For more information about setting up the deployment process, see How to Package a Component into an ADF Library JAR.

For example, suppose that project `View` is being packaged into ADF Library `adflibView1.jar` and that has a dependency on the `Model` project. For project `View`, the `Model` project is a dependent project with the deployment profile option (`adflibmodel1`) selected, as shown in Figure 50-1.

Figure 50-1 Edit Dependencies Dialog with Deployment Profile Option



Edit Dependencies

For each dependent project, decide whether to include its build output directly in this library, or add selected deployment profile archives to the classpath of any project using this library.

Search Projects

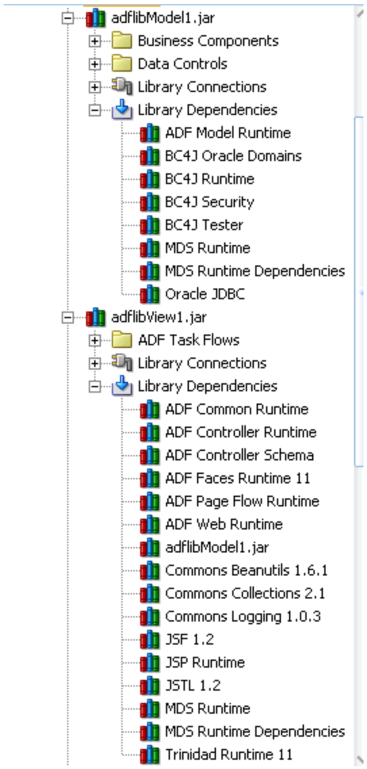
Projects:

- Model.jpr
  - □ Build Output
  - ☑ adflibModel1

When the deployment profile is selected, the dependent project's JAR file will be added to the ADF Library JAR. As a result, the extension libraries of the dependent project will also be made available to any consuming project. In Figure 50-2, the ADF

Library being packaged, `adflibView1.jar`, includes the dependent `adflibModel.jar` as listed under the Library Dependencies node.

Figure 50-2 Resources Window Showing adflibView1.jar and adflibModel.jar Extension Libraries

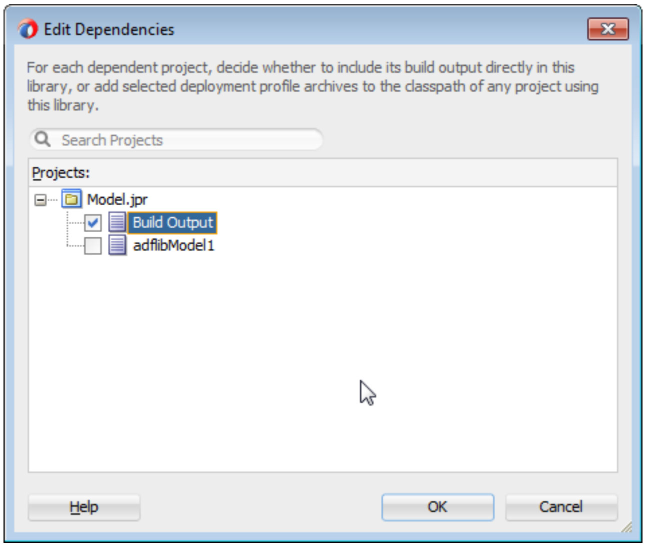


- adflibModel1.jar
  - Business Components
  - Data Controls
  - Library Connections
  - Library Dependencies
    - ADF Model Runtime
    - BC4J Oracle Domains
    - BC4J Runtime
    - BC4J Security
    - BC4J Tester
    - MDS Runtime
    - MDS Runtime Dependencies
    - Oracle JDBC
- adflibView1.jar
  - ADF Task Flows
  - Library Connections
  - Library Dependencies
    - ADF Common Runtime
    - ADF Controller Runtime
    - ADF Controller Schema
    - ADF Faces Runtime 11
    - ADF Page Flow Runtime
    - ADF Web Runtime
    - adflibModel1.jar
    - Commons Beanutils 1.6.1
    - Commons Collections 2.1
    - Commons Logging 1.0.3
    - JSF 1.2
    - JSP Runtime
    - JSTL 1.2
    - MDS Runtime
    - MDS Runtime Dependencies
    - Trinidad Runtime 11

Alternately, you can include the dependent project's artifacts and extension libraries directly into the ADF Library JAR.

For example, project `View` can also be packaged into ADF Library `adflibView2.jar`. It also has a dependency on the `Model` project. But in this second deployment profile, the `Model` project is a dependent project with the **Build Output** option selected (as opposed to the deployment profile (`adflibmodel1`) being selected), as shown in Figure 50-3.

Figure 50-3 Edit Dependencies Dialog Used to Built adflibview2.jar

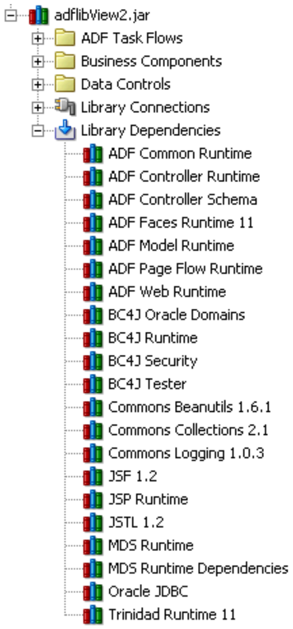


Edit Dependencies

For each dependent project, decide whether to include its build output directly in this library, or add selected deployment profile archives to the classpath of any project using this library.

When **Build Output** is selected, the dependent project's classes and extension libraries will be added directly to the ADF Library JAR. Figure 50-4 shows the ADF Library `adflibView2.jar`, which includes artifacts of the `Model` project and its extension libraries. Note that the extension libraries under the `adflibView2.jar` Library Dependencies node are the same as the combined extension libraries under the `adflibView1.jar` and `adflibModel.jar` shown in Figure 50-2.

Figure 50-4 Resources Window Showing adflibView2.jar Extension Libraries



How you decide to package the dependent project depends on how you intend the ADF Library to be used. Including the dependent project as a JAR may be advantageous when the dependent project is itself a reusable component, or when it is a dependent project for several projects that will be packaged into an ADF Library JAR. In the example, the dependent project `Model` may be a dependent project for several view projects. On the other hand, packaging the dependent project as **Build Output** is straightforward and eliminates the need for multiple JARs.

> **Note:**
>
> If you are creating an ADF Library JAR that is included in a JDeveloper extension library, you should include the additional manifest `JDevLibrary:` *`extension_library_name`* entry in the JAR. When you use **Add to Project** from the Resources window to add a ADF Library JAR that has a `JDevLibrary` manifest entry, the JDeveloper extension library containing this JAR will be added instead of the ADF Library JAR itself.

Using the Resources Window

ADF Library JARs can be packaged, deployed, discovered, and consumed like any other Oracle Library component. Creating an ADF Library JAR is the action of packaging all the artifacts (and additional control files) of a project into a JAR. Consuming a reusable component from an ADF Library JAR is the action of loading that ADF Library JAR into the project's set of libraries.

However, the easiest way to manage and use ADF Library JAR components is by using JDeveloper's Resources window. With the Resources window, developers who want to consume reusable components can easily find and discover available components and add them to their projects. The Resources window provides search and browse functions across different data management systems to locate the component. It provides multiple connections to access different sources. It has a structure tree view for displaying different connections and the ADF Library JAR component types. Figure 50-5 shows the Resources window with several file system connections.

The Resources window tree structure displays each JAR as subcategories. Separate nodes are created for each type of reusable component. For example, application modules are under the Data Controls node, and task flows are under the ADF Task Flows node.

The tree structure for the ADF Library JAR lists any connection information under a Library Connections node and lists all the producing project's extension libraries under the Library Dependencies node.

Packaging a Reusable ADF Component into an ADF Library

These reusable components can be packaged into the ADF Library for reuse in applications. An ADF Library JAR is like another JAR file, but it contains ADF related components and project dependent libraries. The purpose of the ADF Library JAR file is for reuse.

Once you have decided that a certain component or components can be reused, create an application and a project to develop that component. Follow the guidelines in Creating Reusable Components to name your application, project, package, and other objects and files. A project corresponds to one ADF Library JAR. If you create multiple projects and want to reuse components from each of the projects, you may need to create an ADF Library JAR for each project. In other situations, you may be able to involve multiple components under one project to create a single ADF Library JAR. For example, you may be able to create application modules, business components (entity object, view objects, associations), task flows, and page templates all under one project and create one ADF Library JAR.

Creating an ADF Library JAR involves compiling the project and validating the components, creating a resource service file, control files, an `adflibREADME.txt`, and adding the relevant project files into a JAR. For more information about the ADF Library JAR, see What Happens When You Package a Project to an ADF Library JAR.

If you are packaging a component that itself uses another ADF Library component, the final consuming project must have both ADF Library JARs added to the project. For example, say you created a reusable task flow that contains tables dropped from a data control in another ADF Library JAR. When you add the task flow from an ADF

Library JAR into a consuming project, that project will also require the data control ADF Library JAR.

If you are packaging a component that has dependent JARs, such as third-party JARs, you have two options:

- If the consuming environment has control over the placement of JARs, you can place the ADF Library JAR and its dependent JARs in a JDeveloper Extension Library. The advantage of using a JDeveloper Extension Library is that it does not clutter the consuming project with specific references to the dependent JARs.
- If using JDeveloper Extension Library is not possible, you can place the dependent JARs in the same location as the ADF Library JAR and include a manifest classpath entry for each dependent JAR.

How to Package a Component into an ADF Library JAR

To package up a reusable component, you first create a deployment profile that specifies the archive type, the name of the JAR file, and the directory path where the JAR will be created. Then you deploy the project using the deployment profile.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Packaging a Reusable ADF Component into an ADF Library.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

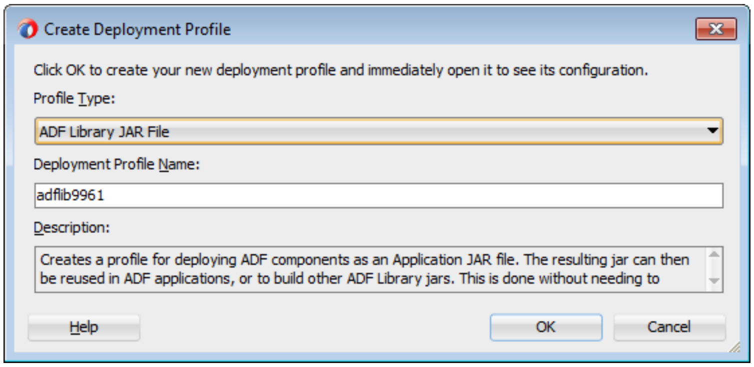
You will need to complete this task:

> Create a project and determine whether it has dependent projects and JAR that need to be packaged. For more information, see Packaging a Reusable ADF Component into an ADF Library.

To package and deploy a project into the ADF Library JAR:

1. In the Applications window, double-click the project that contains the component you want to make reusable.
2. In the Project Properties dialog, select **Deployment** and then click **New**.
3. In the Create Deployment Profile dialog, select **ADF Library JAR file** for **Profile Type**, enter a name or accept the default name for **Deployment Profile Name**, and click **OK**.

Figure 50-6   Create Deployment Profile Dialog with Default Name



Create Deployment Profile

Click OK to create your new deployment profile and immediately open it to see its configuration.

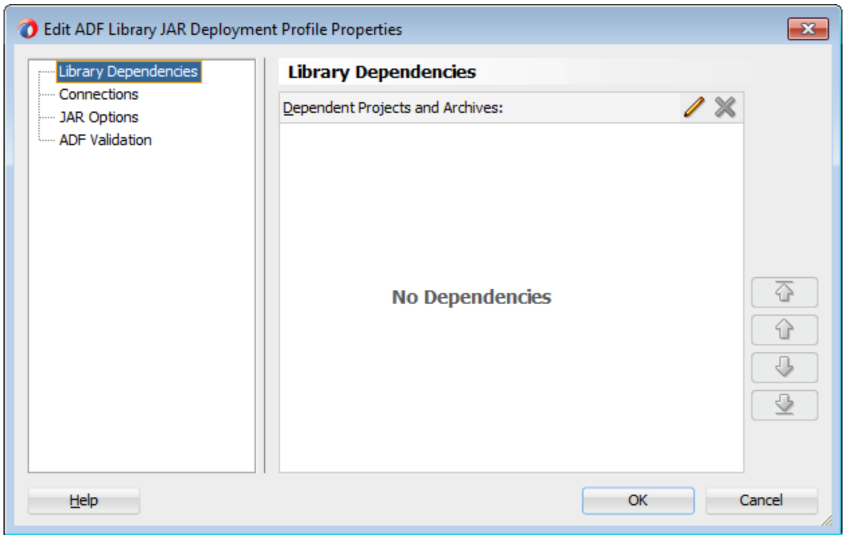
Profile Type: ADF Library JAR File

Deployment Profile Name: adflib9961

Description: Creates a profile for deploying ADF components as an Application JAR file. The resulting jar can then be reused in ADF applications, or to build other ADF Library jars. This is done without needing to

4. In the Project Properties dialog, select the deployment profile and click **Edit**.
5. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Library Dependencies** node, as shown in Figure 50-7.

Figure 50-7   ADF Library JAR Deployment Profile Properties Dialog



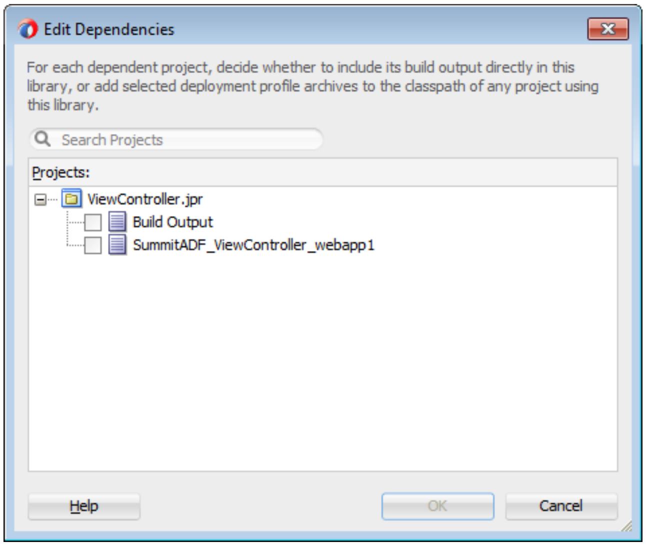
The Library Dependencies pane shows a list of dependent projects for the project being packaged. You can add the dependent project's build output directly into the packaging project's library, or you can add selected deployment profile archives to the class path.

a. To add dependent projects, click the **Edit** icon to bring up the Edit Dependencies dialog, as shown in Figure 50-8.

   If you select **Build Output**, the dependent project's extension libraries will be added directly to the ADF Library JAR. If you select deployment profile, the dependent project's JAR file (which includes its own extension libraries) will be added to the ADF Library JAR. For more information about library dependencies, see Using Extension Libraries.

   In this example, the `Model` project can be set as a dependency only as **Build Output**. However, the `ViewController` project can be set as a dependency either as **Build Output**, or as a deployment profile (`SummitADF_ViewController_webapp`).

Figure 50-8 ADF Library Deployment Edit Dependencies Dialog



Edit Dependencies

For each dependent project, decide whether to include its build output directly in this library, or add selected deployment profile archives to the classpath of any project using this library.

b. For each dependent project, select the **Build Output** node for the project or select the dependent profile and click **OK**.

6. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Connections** node, as shown in Figure 50-9.

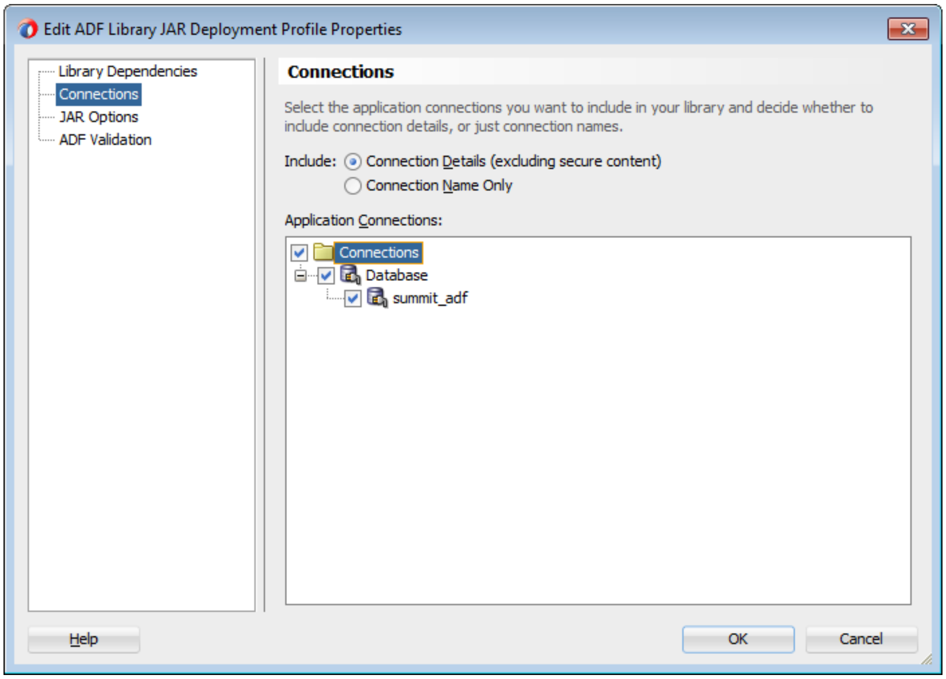
   You can select:

   - **Connection Details (excluding secure content)**: If the project has a connection, select this checkbox if you want to include any available connection details in addition to the connection name. Connection details include hostname, port number, sid, driver type, and user name. For more information, see Including Connections Within Reusable Components.
   - **Connection Name Only**: Select this checkbox if you want to add the connection name without any connection details.

   > **Note:**
   >
   > The connection options available depends on the JDeveloper role. **Connection Details (excluding secure content)** and **Connection Name Only** are the selections available for the Studio Developer role. If your JDeveloper is set to a different role, you may have different options and defaults.

   In the Applications Connections tree structure, select the checkbox for the level of connection you want to include.

Figure 50-9 Connections Page of the Edit ADF Library JAR Deployment Profile Properties Dialog



Connections

Select the application connections you want to include in your library and decide whether to include connection details, or just connection names.

Include: ● Connection Details (excluding secure content)
○ Connection Name Only

Application Connections:

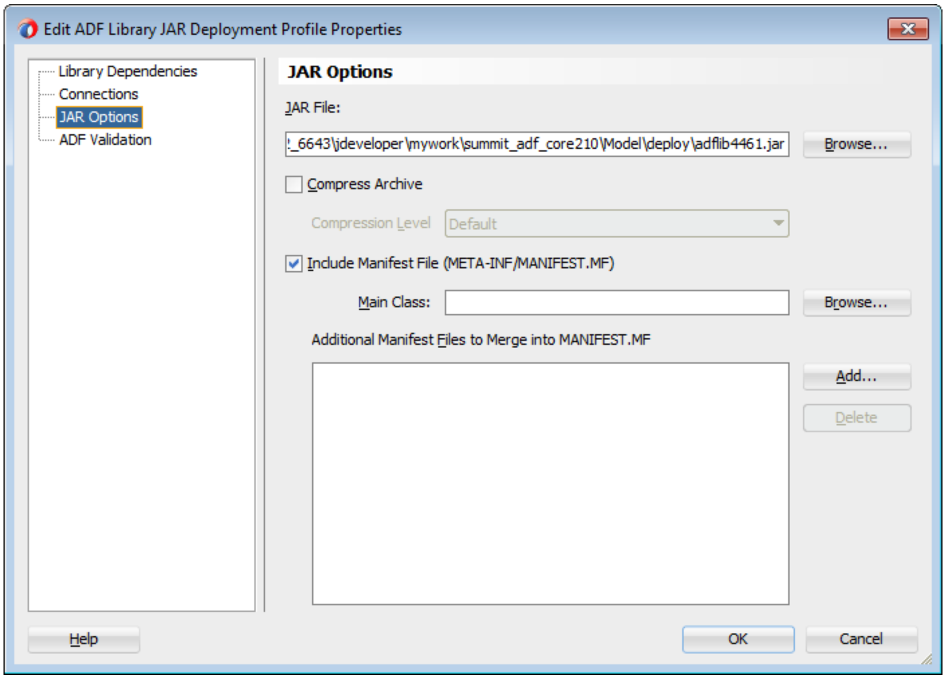
☑ Connections
☑ Database
☑ summit_adf

7. Select the **JAR Options** node, as shown in Figure 50-10, verify the default directory path or enter a new path to store your ADF Library JAR file.

   If the ADF Library JAR is to be included in a JDeveloper extension library, create a text file with a `JDevLibrary:` *`extension_library_name`* entry and place the file in the project root directory. Click **Add** to locate and merge that file into the `Manifest.mf` file.

   When you create your manifest text file, make sure the `JDevLibrary` entry starts in column 1 with a space after the colon, and that there is a blank line at the end of the file.

Figure 50-10 ADF Library JAR Deployment Profile Properties Dialog JAR Option



JAR File: !_6643\jdeveloper\mywork\summit_adf_core210\Model\deploy\adflib4461.jar

□ Compress Archive

Compression Level: Default

☑ Include Manifest File (META-INF/MANIFEST.MF)

Main Class:

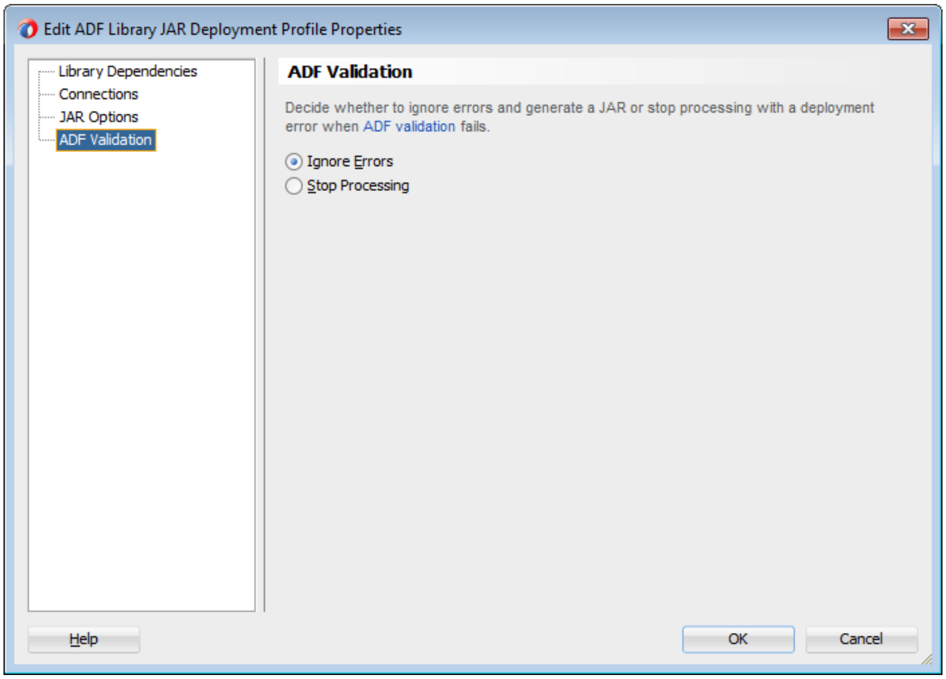
Additional Manifest Files to Merge into MANIFEST.MF

8. Select the **ADF Validation** node.

   You can select:

   - **Ignore Errors**: To create the JAR file even when validation fails. This is the default option.
   - **Stop Processing**: To stop processing when validation fails.

Figure 50-11 ADF Library JAR Deployment Profile Properties Dialog ADF Validation



Decide whether to ignore errors and generate a JAR or stop processing with a deployment error when ADF validation fails.

● Ignore Errors
○ Stop Processing

9. Click **OK** to finish setting up the deployment profile.
10. In the Applications window, right-click the project and choose **Deploy >** ***deployment***, where ***deployment*** is the name of the deployment profile.
11. In the Deploy dialog Deployment Action page, click **Next** and then click **Finish**.

    JDeveloper will create the ADF Library JAR in the directory specified in Step 7. You can check that directory to see whether the JAR was created.

What Happens When You Package a Project to an ADF Library JAR

When you deploy the library JAR, JDeveloper packages up all the necessary artifacts, adds the appropriate control files, generates the JAR file, and places it in the directory specified in the deployment profile. During deployment, you will see compilation messages in the Log window.

When you deploy a project into an ADF Library JAR, JDeveloper performs the following actions:

- Package the HTML root directory artifacts into the JAR. When the JAR is added to the consuming project, JDeveloper will make the reusable component's `public_html` resources available by adding it to the class path.
- Add the `adfm.xml` file to the JAR. If there are multiple `META-INF/adfm.xml` files in the workspace, only the `adfm.xml` in the project being deployed is added. JDeveloper modifies this file to include relevant content from any dependent project's `adfm.xml` file.
- Add a service resources file, `oracle.adf.common.services.ResourceService.sva`, into the `META-INF` directory of the JAR. The addition of this file differentiates an ADF Library JAR file from

standard JAR files. This file defines the service strategies of the JAR and allows the Resources window to properly discover and display the contents of the JAR.

- Add a `Manifest.mf` file to the JAR. The `Manifest.mf` file is used to specify dependencies between JAR files, and to determine whether to copy and include the contents of a JAR file or to reference it. JDeveloper will create a default manifest file. For example:

  ```
  Manifest-Version: 1.0
  ```

- Adds a `jar-connections.xml` file to the JAR for components that require a connection and that use the connections architecture. Note that in the consuming application, connection information in configuration files that are defined in the class path and accessible at runtime may be merged together. If the same connection is named multiple times in the class path, the connection in the main application will be given priority.

Different types of reusable components have different artifact files and different entries in the service resource file.

Application Modules Files Packaged into a JAR

For application modules, JDeveloper adds these control files to the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf, adfm.xml`, and the business components `.jpx` file. The service resource file for an application module includes entries for the business components associated with the application module, as well as an entry for the application module data control.

The `jar-connections.xml` file may appear for components that use the connection architecture and that contain connection information regarding the data source.

Data Controls Files Packaged into a JAR

For data controls such as placeholder data controls, JDeveloper includes three control files in the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `DataControl.dcx` file. Data controls are used when the data source is not based on ADF Business Components, and so business components are not included in the JAR file, as is the case in an application module JAR file. The service resource file for a standard data control has an entry for the data control.

The JAR also includes the `Datacontrol.dcx` file from the project to describe the data control type.

Task Flows Files Packaged into a JAR

For task flows, JDeveloper includes three control files in the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `task-flow-registry.xml`. The service resource file for a task flow includes an entry that indicates that one or more task flows are in the JAR.

Page Templates Files Packaged into a JAR

For page templates, JDeveloper includes two control files in the JAR: `oracle.adf.common.services.ResourceService.sva` and `Manifest.mf`.

Declarative Components Files Packaged into a JAR

For declarative components, JDeveloper includes two control files in the JAR: `oracle.adf.common.services.ResourceService.sva` and `Manifest.mf`.

How to Place and Access JDeveloper JAR Files

If you have JAR files that can be reused by other projects, such as third-part JAR files, you can use JDeveloper to place them in an accessible location and create a library file (`.library`) to designate them. The consumer can use JDeveloper to navigate to this location and add the JAR to the project.

An ADF Library JAR contains ADF components and does not and cannot contain other JARs.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Packaging a Reusable ADF Component into an ADF Library.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

> Place the JAR files in a accessible location for both the producer and the consumer of these JAR files. For example, the directory may be on a network drive where other shared files are located. For more information, see Packaging a Reusable ADF Component into an ADF Library.

To place and access a JDeveloper LIbrary JAR:

1. From the main menu, choose **Tools > Manage Libraries.**
2. In the Manage Libraries dialog, click **Load Dir**.
3. In the Load Directory dialog, select the directory where the secondary JAR files are located.
4. In the Manage Libraries dialog, click **New**.
5. In the Create Library dialog, enter a library name and click **Add Entry**.

   You have created a library file (with a `.library` extension). You should place library files in source control systems.
6. In the Select Path Entry dialog, select the JARs you want to add and click **OK**.
7. In the Create Library dialog, be sure that the **Deployed by Default** option is set correctly for your JAR, click **OK** and then click **OK** again.
8. In the consuming project.
   a. From the main menu, choose **Tools > Manage Libraries.**
   b. In the Manage Libraries dialog, click **Load Dir**.
   c. In the Load Directory dialog, select the directory where the secondary JAR files are located and click **Select**. This should be the same location specified in Step 3.

d. Right-click the project and select **Project Properties**.

e. In the Project Properties window, select **Libraries and Classpath** and click **Add Library**.

f. In the Add Library dialog, select the library, click **OK** and then click **OK** again.

Adding ADF Library Components into Projects

You can add an ADF Library JAR into your project manually or by using the Resources window. The project will access and consume the components in the JAR as the ADF Library JAR file will be added to the class path of the project.

After ADF Library JARs are created, they must be distributed to the developers who will use these JARs. Distributing the ADF Library JARs may include putting the JARs into a network file system to be searched, browsed, and discovered. It may include using other forms of data store or services to access and retrieve these JARs. Since ADF Library JARs are simply binary files, they can distributed like any other file such as ftp and email.

Once you have access to the ADF Library JARs, you can use JDeveloper to access them and add them to your consuming projects. Using the JDeveloper Resources window is the easiest and most efficient way. You can also use JDeveloper to manually add the JARs into the project by entering them into the class path.

When a project is packaged into an ADF Library JAR, it captures the list of dependent JARs the project needs for deployment and runtime. This list is based on the project's dependent profiles and the information in the project's Libraries and Classpath with **Deployed By Default** selected. When the ADF Library JAR is added to the consuming project, this list of dependent JARs is placed in a library called *ADF Library Dependencies*. This is a locked library in the consuming project and its content will not be shown in the Data Controls panel, Components window, or other places in JDeveloper. The library is maintained and updated as different ADF Library JARs are added and deleted from the project. If the dependencies have changed (for example, the producer project was rebuilt), then you can refresh the dependencies in the consuming project using a JDeveloper menu command.

Once reusable components have been added, how they are used depends on the type of component.

How to Add an ADF Library JAR into a Project using the Resources Window

You can use the Resources window to search, discover, and add the ADF Library JAR to your project.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Adding ADF Library Components into Projects.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

Create an ADF Library JAR in a repository folder. If you do not already have a Resources window connection to this repository, you must know the location of this folder. For more information, see Adding ADF Library Components into Projects.

To add a component to the project using the Resources Window:

1. From the main menu, choose **Window > Resources**.
2. In the Resources window, click the **New** icon, and then choose **IDE Connections > File System**.
3. In the Create File System Connection dialog, enter a name and the path of the folder that contains the JAR.

   For file path guidelines, see Selecting Paths and Folders.
4. Click **OK**.

   The new ADF Library JAR appears under the connection name in the Resources window.
5. To examine each item in the JAR structure tree, use tooltips. The tooltip shows pertinent information such as the source of the selected item.

   Figure 50-12 shows a Resources window with a tooltip message that shows package information for a business component.

Figure 50-12 Tooltip Message for a Connection in the Resources Window

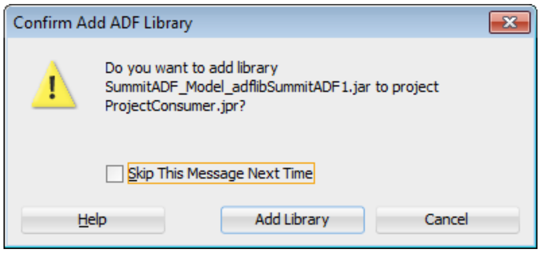
Library Dependencies

6. To add the ADF Library JAR or one of its items to the project, right-click the item and choose **Add to Project**. In the confirmation dialog that appears, click **Add Library**, as shown in Figure 50-13.

Figure 50-13 Confirm Add ADF Library Dialog



Confirm Add ADF Library

Do you want to add library SummitADF_Model_adflibSummitADF1.jar to project ProjectConsumer.jpr?

If you had previously added that library JAR, you will get a Confirm Refresh ADF Library dialog asking you whether you want to refresh the library.

7. If the ADF Library JAR has changes to its dependencies, you can refresh the project with the new changes. From the Applications window, right-click the project and select **Refresh ADF Library Dependencies in *project*.jpr**.

For application modules and data controls, you have the option to drag and drop the application module or data control from the Resources window into the Data Controls panel.

> **Note:**
>
> JDeveloper will load whichever ADF Library JAR extension libraries are not already in the consuming project. Extension libraries from the ADF Library's dependent JARs will also be checked and loaded if not already part of the consuming project. For more information, see Using Extension Libraries

How to Add an ADF Library JAR into a Project Manually

You can add an ADF Library JAR in the same way as you would other library JARs.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Adding ADF Library Components into Projects.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

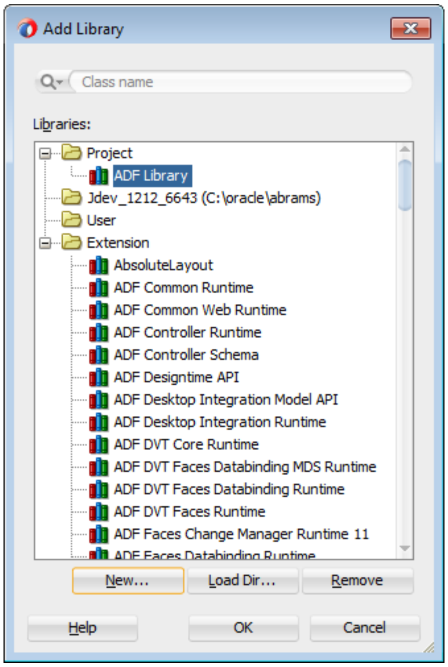
Create an ADF Library JAR. For more information, see Adding ADF Library Components into Projects.

To add a component to a project manually:

1. In the Applications window, double-click the project to which the component is to be added.
2. In the Project Properties dialog, select the **Libraries and Classpath** node and then click **Add Library**.

3. In the Add Library dialog, click **New**.
4. In the Create Library dialog, in the **Location** dropdown list, select **Project** and enter a name for the ADF Library. The preferable name is "ADF Library". Select **Deploy by Default**, and click **Add Entry**.
5. In the Select Path Entry dialog, enter or browse to the ADF Library JAR file and click **Open**.
6. The Create Library dialog reappears with the path of the JAR file filled in under the **Class Path** node. Click **OK**.
7. The Add Library dialog reappears with the ADF Library entry filled in under the **Project** node. Click **OK**.

Figure 50-14 Add Library Dialog



8. The Project Properties dialog reappears with the JAR file added to the list of libraries. Click **OK**.

What Happens When You Add an ADF Library JAR to a Project

When you add an ADF Library JAR to a project, either by using the Resources window or by manually adding the JAR, an ADF Library definition is created in the project. The ADF Library JAR file will be added to the class path of the project. The project will access and consume the components in the JAR by reference.

By default, the **ADF Library Deployed by Default** option in the Create Library dialog is set to true. If this option is set, when the application or module is further archived or built into a WAR file, the contents of the ADF Library JAR will be copied to that archive or WAR file. If the Deploy by Default option is not set, then the JARs in the ADF Library must be loaded in some other way, such as by deploying them in a shared library.

Figure 50-15 shows the empty Data Controls panel for a consuming project before the ADF Library was added.

Figure 50-15 Data Controls Panel of the Consuming Project

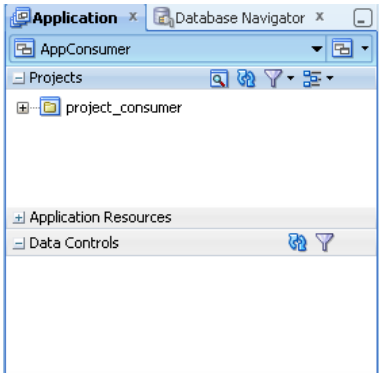


Figure 50-16 shows the `adflibview1` ADF Library being added to the consuming project.

Figure 50-16 Adding the ADF Library JAR to the Project

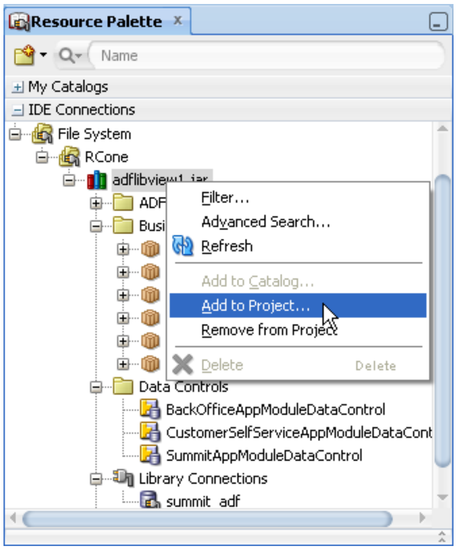

Figure 50-17 shows several data controls from the ADF Library added to the Data Controls panel in the consuming project.

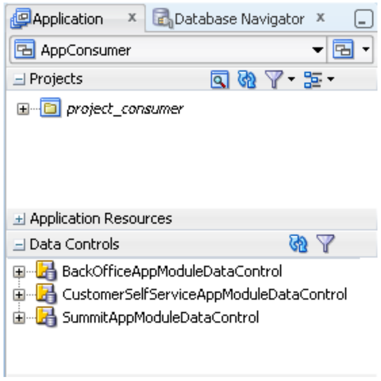
Figure 50-17 Consuming Project Data Controls Panel with Added Application Modules



After adding the ADF Library JAR, you may notice some changes to some of the JDeveloper windows. These changes are different depending on the type of components being added. Table 50-3 lists the effects on several JDeveloper windows.

Table 50-3 JDeveloper Window After Adding an ADF Library

Added Component	Data Controls Panel	Creation Wizards	Components window
Data controls	Data control appears.		
Application module	Application module appears.		
Business components		Entity objects available in view object creation wizard. View objects in JAR also available for use.	
Task flows			Task flows appear in Components window.
Page template		Page template available during JSF creation wizard.	
Declarative components			Tag library appears in Components window. Declarative component appears in the list.

What You May Need to Know About Using ADF Library Components

Although the procedure to add an ADF Library JAR to a project is standardized, the component type determines where it appears in JDeveloper and how it can be reused.

Using Data Controls

When you add a data control to a project, the data control appears in the Data Controls panel. If you are using the Resources window, you have the option of dragging and dropping the data control from the Resources window onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

Using Application Modules

When you add an application module to a project, the application module appears in the Data Controls panel. If you are using the Resources window, you have the option of dragging and dropping the application module item from the Resources window onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

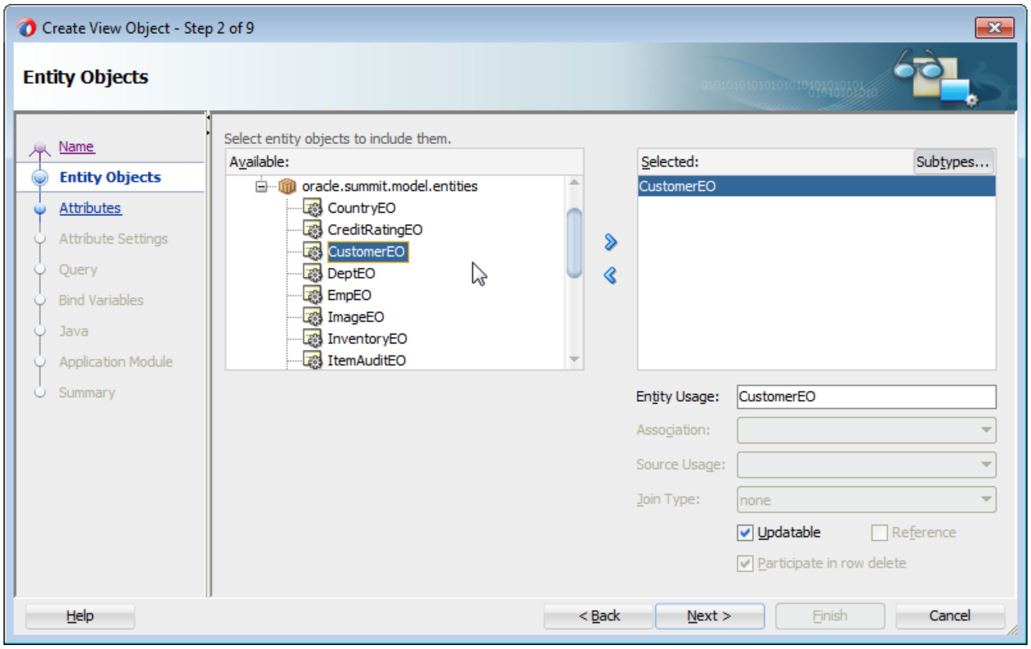
Application modules are associated with business components. When the reusable application module was packaged, the JAR includes the business components used to create the application module. These components will be available for reuse.

Using Business Components

Business components can also be packaged and reused. The entity objects, view objects, and associations can be packaged together and added to a consuming project. By default, packaged application modules will include the business components in the JAR, but business components can be reused by themselves without the accompanying application module.

One way to reuse business components is to create new view objects using the entity objects from an ADF Library JAR. When you add view objects using the wizard, the entity objects will become available within the wizard to support view object generation. For instructions on creating view objects, see How to Create an Entity-Based View Object. When the wizard presents a screen for entity objects used to create view objects, the entity objects from the ADF Library will be available in the shuttle window, as shown in Figure 50-18.

Figure 50-18 Creating View Object Using Entity Objects from ADF Library



Select entity objects to include them.

Selected: CustomerEO

Entity Usage: CustomerEO

Association:

Source Usage:

Join Type: none

☑ Updatable □ Reference

☑ Participate in row delete

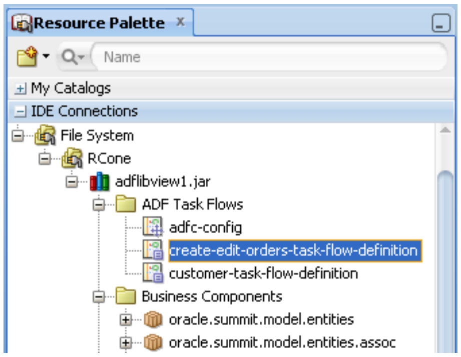
If the consuming project has the **Initialize Project for Business Component** option selected (in the Project Properties dialog Business Components page) before the ADF Library JAR is added, the business components within the JAR will automatically be made available to the project.

If you add the ADF Library JAR first, and then select **Initialize Project for Business Component**, JDeveloper will automatically load the business components.

Using Task Flows

Task flows added to a project will appear in the Components window when you are adding components to a JSF page. If you are using the Resources window, you can also drag and drop the task flow directly from the Resources window onto another task flow or page, as shown in Figure 50-19.

Figure 50-19 Using the Resources Window to Drag and Drop Task Flows



Resource Palette
Name
My Catalogs
IDE Connections
File System
RCone
adflibview1.jar
ADF Task Flows
adfc-config
create-edit-orders-task-flow-definition
customer-task-flow-definition
Business Components
oracle.summit.model.entities
oracle.summit.model.entities.assoc

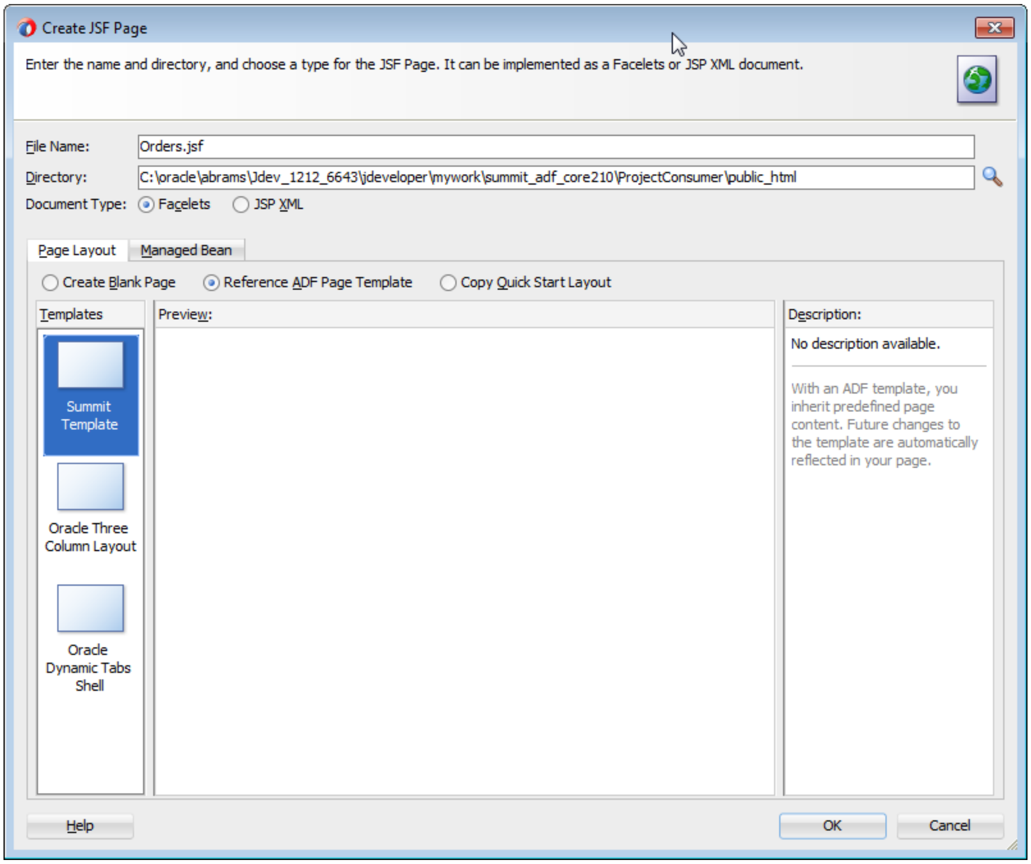
For more information about creating task flows, see Getting Started with ADF Task Flows .

Using Page Templates

When you add a page template to a project, the template will not be exposed in the Applications window. You will not have direct access to individual supporting files, such as image files. However, the template retains its access to its supporting files inside the JAR and is fully reusable within the project. When you apply the template, it will retain all the images that were loaded with the template.

The page template is exposed and accessible when you create a new JSF page using the wizard. When the wizard presents you with the option to use a page template, the ADF Library template will appear in the dropdown list. For example, if you loaded a page template called `SummitTemplate` from an ADF Library, when you use the wizard to create a JSF page, `SummitTemplate` will appear in the wizard, as shown in Figure 50-20. For information on how to use page templates and create a JSF page, see Using Page Templates and the *Developing Web User Interfaces with Oracle ADF Faces*.

Figure 50-20 Using a Page Template from ADF Library



Create JSF Page

Enter the name and directory, and choose a type for the JSF Page. It can be implemented as a Facelets or JSP XML document.

File Name: Orders.jsf

Directory: C:\oracle\abrams\Jdev_1212_6643\jdeveloper\mywork\summit_adf_core210\ProjectConsumer\public_html

Document Type: ● Facelets ○ JSP XML

○ Create Blank Page ● Reference ADF Page Template ○ Copy Quick Start Layout

Description:

No description available.

With an ADF template, you inherit predefined page content. Future changes to the template are automatically reflected in your page.

Using Declarative Components

When you add a declarative component to a project, the JSP tag libraries that contain the component will be added to the project. The tag libraries will appear in the

Components window, and the declarative components will be available for selection. For information about creating and using declarative components, see the Using Declarative Components section of the *Developing Web User Interfaces with Oracle ADF Faces* .

What You May Need to Know About Differentiating ADF Library Components

If you mix components created during application development with components imported from the ADF Library, you may be able to differentiate between them by using the tooltips feature of JDeveloper.

Move the cursor over an application module or data control and you will see the full path of the source. If you see the ADF Library JAR file in the path, that means the component source is the ADF Library.

> **Note:**
>
> The tooltip for items in the Data Controls panel varies depending on whether or not the node has ever been opened in this session. To ensure that you are seeing the most complete tooltip, you should expand the item.

What Happens at Runtime: How ADF Libraries are Added to a Project

After an ADF Library JAR has been added to a project and to the class path, it behaves like any other library file. During runtime, any component that uses the component in the ADF Library JAR will reference that object. The process is transparent and there is no need to distinguish between components that were developed for the project and those that are in ADF Library JARs. Figure 50-21 shows the ADF Library and the path to the JAR as defined for a project.

Figure 50-21 Edit Library Definition Dialog Showing the ADF Library in the Class Path

> **Note:**
>
> Once an ADF Library JAR is created, any Java source used to create the component is not available in the JAR. If you want your consumers to have access to the source, such as for debugging, they must be delivered separately (usually in ZIP files). The consumer can then designate those ZIP files as the related component source for the **Source Path** entry in their ADF Library **Libraries and Classpath** entry in their own projects.

Removing an ADF Library JAR from a Project

You can remove an ADF Library JAR from your project manually or by using the Resources window.

You can use the Resources window to remove an ADF Library JAR from a project, or you can manually remove the JAR using the Project Properties dialog. You can remove an ADF Library JAR only if the components in the project do not have any dependencies on the components in the ADF Library JAR.

When you remove a JAR, it will no longer be in the project class path and its components will no longer be available for use.

How to Remove an ADF Library JAR from a Project Using the Resources Window

The Resources window allows you to remove previously added ADF Library JARs from a project using a simple command.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Removing an ADF Library JAR from a Project.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

> Add the ADF Library JAR using the Resources window. For more information, see Adding ADF Library Components into Projects.

To remove an ADF Library JAR from the project using the Resources Window:

1. From the main menu, choose **Window** > **Resources**.
2. In the Applications window, select the project that has the ADF Library JAR you want to remove.
3. In the Resources window, locate the ADF Library JAR you want to remove from the current project.
4. Right-click the JAR and choose **Remove from Project**.

How to Remove an ADF Library JAR from a Project Manually

When you remove an ADF Library JAR manually, be sure to remove the correct library. Be aware of other libraries that are critical to the operation of the project.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Removing an ADF Library JAR from a Project.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

> Add the ADF Library JAR manually. For more information, see Adding ADF Library Components into Projects.

To remove an ADF Library JAR from the project manually:

1. In the Applications window, double-click the project.
2. In the Project Properties dialog, select the **Libraries and Classpath** node.
3. In the **Classpath Entries** list, select **ADF Library** and click **Edit**.

4. In the Edit Library Definition dialog, select the ADF Library JAR you want to remove under the **Class Path** node, and click **Remove**.
5. Click **OK** to accept the deletion, and click **OK** again to exit the dialog.

51
Customizing Applications with MDS

This chapter describes how to develop Fusion web applications that can be customized and subsequently deployed by a customer, using the customization features provided by Oracle Metadata Services (MDS) framework. It also covers how to implement customizations on such applications.
This chapter includes the following sections:

For information on how to deploy customized applications, see Deploying the Application.

About Customization and MDS

Oracle Metadata Services (MDS) is the framework for handling ADF application customizations. Customizations are stored in a metadata repository and merged with base metadata at runtime.

Using the customization features provided by MDS, you can create applications that fall into the following customization patterns:

- Seeded customization

  Seeded customization of an application is the process of taking a generalized application and making modifications to suit the needs of a particular group, such as a specific industry or site. Seeded customizations exist as part of the deployed application, and endure for the life of a given deployment. This chapter describes how to create a customizable application, and then customize the application using JDeveloper.

- User customization (change persistence)

  User customization allows an end user to change the content of the application at runtime to suit individual preferences (for example, which columns are visible in a table), and have those changes "remembered" the next time the user opens the application. For information about user customization, see Allowing User Customizations at Runtime .

For more information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see Managing the MDS Repository in *Administering Oracle Fusion Middleware*.

Customization and Layers: Use Cases and Examples

A customized application contains a base application and one or more layers containing customizations. MDS stores the customizations in a metadata repository and retrieves them at runtime to merge the customizations with the base metadata to reveal the customized application. Since the customizations are saved separately from the base, the customizations are upgrade safe; a new patch to base can be applied without breaking customizations. When a customized application is launched, the customization content is applied over the base application.

For example, say you have a generalized payroll application with a validation rule that limits the salary field to 4000. Then you create a customization of that validation rule that limits the salary field to 3300. At runtime, the customization is applied to the base application and the validation rule for the salary field limits it to 3300.

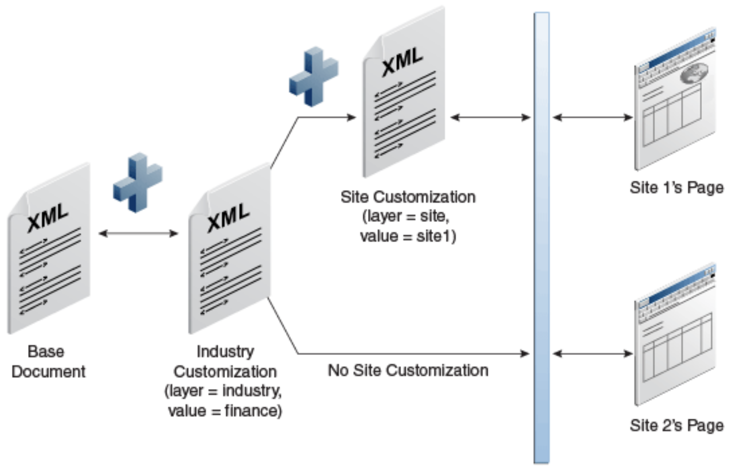
A customizable application can have multiple **customization layer**s. Examples of customization layers are `industry` and `site`. Each layer can have multiple **customization layer value**s, but typically only one such layer value from each layer is applied at runtime. For example, the `industry` layer for a customizable application can contain values for `healthcare` and `financial` industries; but in the deployed customized application, only one of the values from this layer is used at a time.

Layer values from multiple customization layers can be applied, in a specified order of precedence, on top of the base metadata. For example, a customized application can contain customizations in the `financial` layer value of the `industry` layer and the `Financial Company #1` layer value of the `site` layer. Each customization layer corresponds to a customization document that contains a set of instructions that change the underlying metadata.

The **customization context** of a customized application is defined by the set of customization layer values applied to it.

Figure 51-1 illustrates how layers are applied in a customized application.

Figure 51-1 Example of Layered Customization



To support this, you use JDeveloper to create customization classes, define layers and values, and specify the order of precedence. These processes are described in Developing a Customizable Application.

Static and Dynamic Customization Content

Customizations can be categorized as either static or dynamic. Static customizations have only one layer value in effect for all executions of the application, while dynamic customizations can have values that vary based on the execution context of the application. If a customization can vary for different users executing the application, then it is dynamic. If a customization has the same value for all users executing the application then it is static.

When you implement customizations in **ADF Business Components** objects, the customizations remain the same for entire runtime of the application. This is because these objects are loaded only once for an application and reused for the duration of the application. For example, you can have a customized validation rule in the Healthcare Company #1 value of the site layer that limits salaries for that site to 3300. This is static customization content.

However, you can also implement customizations at the controller or view level that allow the layer value to be determined at runtime, based on user roles (responsibilities) or other application-specific criteria. For example, you can design an application so that users from different organizations see different sets of fields on a given screen. This is dynamic customization content.

The determination of whether a customization is static or dynamic is made in the customization class. In the customization class, if the `getCacheHint()` method returns `ALL_USERS`, then the customization layer is static. For more information about `CacheHint` values, see What You May Need to Know About Customization Classes.

All objects could have a static customization layer, depending on how the customization classes are implemented. But for ADF Business Components objects, customizations can only be static.

Additional Functionality for Customization

You may find it helpful to understand other features before you start working with customization. Following are links to other functionality that may be of interest.

- For information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see Managing the MDS Repository in *Administering Oracle Fusion Middleware*.
- You can use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime. See Allowing User Customizations at Runtime .

Developing a Customizable Application

If you want to customize an ADF application, you must follow certain procedures after creating the base application.

To create a customizable application, create the base application and perform the following procedures:

To prepare an application for customization:

1. Create the customization classes that will be used, as described in How to Create Customization Classes.
2. Enable seeded customization in the application, as described in How to Enable Seeded Customizations for User Interface Projects.
3. Specify the customization classes in the `adf-config.xml` file, as described in How to Configure the adf-config.xml File .
4. You can optionally restrict runtime customizations on the application, as described in How to Edit Extended Metadata Properties.
5. After you have prepared the application for customization, you must prepare JDeveloper so you can use it to implement the customizations, as described in How to Configure Customization Layers.

How to Create Customization Classes

A customization class is the interface that MDS uses to define which customization applies to the base definition metadata. Each customization class defines a customization layer (for example, `industry` or `site`) and can contain multiple layer values. The customization classes that are used in the application must be available to JDeveloper when customizing the application, and included in the deployed application.

Customization Classes

A customization class evaluates the current context and returns a String result. This String result is used to locate the customization layer.

The customization class provides the following information:

- A name, that represents the name of the layer.
- An array of values, that represent the customization layer values. Typically, each layer returns a single value. If multiple values are returned, the customizations available in the MDS repository for those values are applied in the order in which they appear in the array. A null value or an array containing an empty string ("") indicates there is no customization layer to apply. For more information, see Implementing the getValue() Method in Your Customization Class.
- An IDPrefix, for objects created in the layer. When new objects are created in a customization layer they need a unique ID. The IDPrefix is added to the autogenerated identifier for the object to create an ID for the newly added object. Each layer needs a unique IDPrefix so that objects created at different customization layers will have unique IDs.
- A cache hint, for the layer defined by the customization class. The cache hint defines whether a layer is static or dynamic. If the `getCacheHint()` method returns `ALL_USERS`, then the customization layer is static. For more information about dynamic customizations, see Static and Dynamic Customization Content. For more information about `CacheHint` values, see What You May Need to Know About Customization Classes.

Customizations can be used to tailor an application to suit a specific industry domain (verticalization). Each such domain denotes a customization layer and is depicted using a customization class.

To implement seeded customizations using your customization classes:

- The cust-config section (under mds-config) in the adf-config.xml must contain a reference to the customization classes (as described in How to Configure the adf-config.xml File).

  The customization configuration (cust-config) section provides the customization classes and their precedence for a customized application. See How to Configure the adf-config.xml File .

- The customization classes must be included in the application to support seeded customizations.

  For more information, see Making Customization Classes Available to JDeveloper at Design Time. At runtime, your customization classes must be available in the EAR-level application class loader.

- The layer values must be listed in the CustomizationLayerValues.xml file.

  This file is located in the *jdev_install*\jdev directory. The names of the layers in this file must be consistent with the customization classes. (For more information, see How to Configure Customization Layers.) JDeveloper uses this file to retrieve layer values at design time.

When JDeveloper is launched in the **Customization Developer** role, the Customization Context window displays the available customization layers and layer values. You can select the layer and value to which you want to apply customizations in the Customization Context window. For more information about working in the **Customization Developer** role, see Introducing the Customization Developer Role. The layer you choose to customize is called the **tip layer**. For more information, see Introducing the Tip Layer.

The following example shows a sample customization class. Note that all customization classes should have a single, no-argument constructor.

```
package mycompany;

import java.io.IOException;
import java.io.InputStream;
import java.util.Properties;
import oracle.mds.core.MetadataObject;
import oracle.mds.core.RestrictedSession;
import oracle.mds.cust.CacheHint;
import oracle.mds.cust.CustomizationClass;

public class IndustryCC extends CustomizationClass {
  private static final String DEFAULT_LAYER_NAME = "industry";
  private String mLayerName = DEFAULT_LAYER_NAME;

  public IndustryCC() {
  }
  public CacheHint getCacheHint() {
    return CacheHint.ALL_USERS;
  }
  public String getName() {
    return mLayerName;
  }

  public String generateIDPrefix(RestrictedSession sess, MetadataObject mo) {
      return "I";
  }
  public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    // This needs to return the appropriate value at runtime.
    return new String[] {"financial"};
  }
}
```

This example shows the four methods that define how the customization class will work: `getCacheHint()`, `getName()`, `generateIDPrefix()`, and `getValue()`.

The return value for `getCacheHint()` indicates to MDS how widely visible a metadata object with this customization is, and therefore its likely duration in memory. It also defines whether or not a layer is static or dynamic. In this example, the `getCacheHint()` method returns `ALL_USERS`, which means the customization layer is static. For more information about `CacheHint` values, see What You May Need to Know About Customization Classes.

The `getName()` method returns the name of the customization layer. A SiteCC customization class, for example, might return "site." In this example, the `getName()` method returns "industry."

The `generateIDPrefix()` method creates an IDPrefix. The IDPrefix is a unique, abbreviated string that identifies the name and value of the layer. It is used as the prefix of the ID for objects created in the customization layer. The default implementation (if no IDPrefix is specified) returns name of the layer concatenated with customization value. For performance reasons, the IDPrefix should be kept short (4 characters or less). Therefore, the default implementation should be overridden. The related `getIDPrefix()` method returns the IDPrefix of the customization layer. In this example, the `getIDPrefix()` method would return "I" (for "industry").

The `getValue()` method returns the customization value (or values) for the customization class. In this example, the `getValue()` method returns a single value, "financial," that defines the customization context when combined with the layer name. There are additional techniques for using the `getValue()` method described in Implementing the getValue() Method in Your Customization Class.

Note:

The possible layer values corresponding to a layer name are retrieved by JDeveloper in the **Customization Developer** role from the `CustomizationLayerValues.xml` file. The precedence of layers is defined by the order of the customization classes specified in the `adf-config.xml` file. The names of the layers must be consistent in these files and in the customization classes.

Implementing the getValue() Method in Your Customization Class

The `getValue()` method is used to retrieve the layer value(s) of the customization class based on the application context and the metadata. For example, calling `getValue()` on a `SiteCC` customization class might return an array with single entry "`headquarters`." Typically, the `getValue()` method returns an array with a single value, as described in Customization Classes.

You can also return multiple values from the `getValue()` method, as shown in the following example.

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    return new String[]{"North America", "US", "CA"}
}
```

When multiple values are returned, customizations applicable to all values are applied. Customizations are applied in the order in which they appear in the array. In this example, North America customizations are applied over the base application, then US customizations are applied, and finally CA.

Note:

Returning multiple values for a customization layer is an advanced concept that is typically unnecessary.

The getValue() method can return a layer value based on the current execution context for the current user, pulled either from static or thread local state maintained by the client, or from properties set by the client on the MDS session and based on the metadata object name. The following example shows this type of implementation.

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    if (mo.getName().equals("/sample/abc.jspx"))
    {
        return new String[]{"Headquarters"};
    }
     else
    {
        return new String[]{"RemoteSite"};
    }
}
```

In this example, the getValue() method uses the getName() method on the metadata object to determine if the name of the metadata document is "/sample/abc.jspx". If so, getValue() returns Headquarters to apply headquarters customizations. If not, it returns RemoteSite to apply customizations for remote sites.

Note:

Coding the getValue() method to return a value based on the metadata object is an advanced concept that is typically unnecessary. Customization context for dynamic layers is typically determined through facets of the application context, such as user name or responsibility.

An additional technique that can be useful during the development cycle is to use an external properties file to specify layer values. The following example references a properties file (customization.properties) that stores the layer values.

```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
  Properties properties = new Properties();
    String configuredValue = null;
    Class clazz = IndustryCC.class;
    InputStream is = clazz.getResourceAsStream("/customization.properties");
    if (is != null){
      try {
        properties.load(is);
        String propValue = properties.getProperty(mLayerName);
        if (propValue != null){
          configuredValue = propValue;
        }
      } catch (IOException e) {
          e.printStackTrace();
      }
      finally {
        try {
          is.close();
        } catch (IOException e) {
        e.printStackTrace();
        }
      }
    }
  return new String[] {configuredValue};
}
```

When an application using this technique is run in JDeveloper, you can change the layer value in the properties file and refresh the browser to see new customizations being applied. This customization class and properties file combination allows you to maintain the layer value in a separate file so you don't need to modify and recompile Java code to change it for a particular deployment. If you use a `customization.properties` file, it must be packaged with the customization classes so that they are loaded from the same class loader.

The following example shows a sample `customization.properties` file. When the `IndustryCC` class is loaded with this properties file, the layer value `healthcare` is applied.

```
#Configured values for the default layer values
industry=healthcare
site=headquarters
```

Creating a Customization Class

When creating customization classes, put them in a separate project. This allows you to deploy them to a JAR and to import the JAR into your customizable application. This approach increases modularity, making it easier to include the customization classes in multiple applications across your company, and easier to patch them centrally. For more information about this approach, see How to Consume Customization Classes.

Alternatively, you can put the customization classes in the data model project if you are creating customization classes that will be used in a single application only, or if you just want to run the application locally from JDeveloper or to deploy remotely with MDS configuration.

Make sure that there is only one copy of the customization classes in the application and that they are packaged in a JAR file so that they are loaded at the EAR-level application class loader. By default, adding project dependencies will add the customization classes to the WAR profile, which will not work correctly after the application is packaged and deployed. For more information about packaging your application for deployment, see How to Create Deployment Profiles.

Use the following procedure to create a customization class.

Before you begin:

It may be helpful to have an understanding of the features of customization classes. For more information, see Customization Classes.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will need to launch JDeveloper using the **Studio Developer** role, and open (or create) the application that will hold the customization classes.

To create a customization class:

1. From the main menu, choose **File** and then **From Gallery**.
2. In the New Gallery, expand **General**, select **Projects** and then **Java Application Project**, and click **OK**.
3. In the Create Java Project dialog, specify the appropriate settings for your project, and click **Finish**.

   > **Note:**
   >
   > You should use a single project to hold all of your customization classes.

   For more information about the options in the Create Java Project dialog, see the online help.
4. In the Applications window, right-click your project and choose **Project Properties**.
5. In the Project Properties dialog, select **Libraries and Classpath**, and then click **Add Library**.
6. In the Add Library dialog, select **MDS Runtime**, and click **OK**, and then click **OK** to close the Project Properties dialog.
7. In the Applications window, right-click the project and choose **New** and then **Java Class**.
8. In the Create Java Class dialog, enter a name for the class and the appropriate package.

   > **Note:**
   >
   > Customization classes are typically named for the layer name they return. For example, a customization class that returns the layer name `industry` would be named `IndustryCC`.
9. In the **Extends** field, enter `oracle.mds.cust.CustomizationClass`.

   For more information about this class, refer to the Javadoc.
10. Make sure that **Implement Abstract Methods** is selected and click **OK**.
11. Replace the code in the generated file with code like that described in Customization Classes.

12. Save your changes and rebuild the project.

    This creates the customization class. The sample code uses the package name `mycompany` and the class name `IndustryCC`. You will need to change these as appropriate for your application.

What You May Need to Know About Customization Classes

As described in Customization Classes, the customization class defines a `CacheHint` which specifies the visibility of metadata objects in a customization layer, and therefore its likely duration in memory. This information is used by MDS to decide whether or not to cache a customization, and where to cache it. Any customization layers constructed using this customization class have this cache hint.

The following constants are supported values of `CacheHint`:

- `ALL_USERS` — The customization is applied globally (unconditionally) for a given deployment. This constant is used for static customization layers.
- `MULTI_USER` — The customization is applied to multiple users.
- `REQUEST` — The customization is applied for the duration of the request only.
- `USER` — The customization is applied for a single user to documents which are accessed throughout the user's application session. (In web applications the application session is typically a servlet session.)

> **Note:**
>
> Customization classes are likely to be executed frequently, once for each document being accessed to get the layer name and layer value, so take care to ensure their efficiency.

How to Consume Customization Classes

After you have created your customization classes, you can use them at design time in the **Customization Developer** role, and at runtime in the application. To be consumed in an application or in JDeveloper, the classes must be packaged appropriately.

Making Customization Classes Available to JDeveloper at Design Time

After you create the customization classes, you must make them available to JDeveloper so that you can use them when implementing customizations while working in the **Customization Developer** role.

Because the customization classes are reusable components, you can create a separate project to contain them, and package them into their own JAR file.
You can then import the JAR into the consuming application, which makes the customization classes available to JDeveloper. For more information about creating the customization classes in a separate project, see Creating a Customization Class. For more information about packaging the customization classes into a JAR file, see Adding Customization Classes into a JAR.

> **Note:**
>
> This procedure is not required if you created your customization classes in the data model project of the consuming application.

Use the following procedure to make the customization classes visible to the application, and then add the customization classes to the `cust-config` section of the `adf-config.xml` file, as described in How to Configure the adf-config.xml File.

Before you begin:

It may be helpful to have an understanding of how customization classes are packaged. For more information, see Customization Classes.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes in an external project, as described in Creating a Customization Class.
- Create a JAR using the procedure described in Adding Customization Classes into a JAR.
- Launch JDeveloper using the **Studio Developer** role, and open the application that you want to customize.

To use customization classes from an external project:

1. In the Applications window, click the **Application Menu** icon and choose **Application Properties**.
2. In the Application Properties dialog, select **Libraries and Classpath**, and click **Add JAR/Directory**.
3. In the Add Archive or Directory dialog, select the JAR file you created that contains the customization classes, and click **Open**.
4. Click **OK**.

   Now the customization classes are available to JDeveloper for customization, and for running your project locally in JDeveloper. They will also be packaged to the EAR class path when you package the application.

Making Customization Classes Available to the Application at Runtime

When you package and deploy your customized application, the customization classes must be available at the application level on the application's class path.

When you define the deployment profiles for your application, you need to add the customization classes JAR file to the EAR assembly, and to avoid duplication, you need to make sure that the WAR profile does not include the customization classes JAR file. For more information, see Creating an Application Level EAR Deployment Profile.

How to Enable Seeded Customizations for User Interface Projects

Like all customizable components, the XML elements of a customizable metadata object must be uniquely identifiable by MDS, and therefore must have a unique, non-null identifier. The component's identifier is used to refer to the element in the customization instructions in the customization layer. The ID property is the identifier for each type of component in an ADF Faces `.jspx` or `.jsff` file.

To allow for customizations on your JSF and JSP pages, you must enable seeded customizations in the application's user interface project, which drives some defaults for your pages. This is not necessary for your model and controller projects.

> **Note:**
>
> MDS requires that pages be XML-based to be customized. Therefore, customizations are not allowed on `.jsp` files; use `.jspx` files instead.
>
> Additionally, facelets files must have a `.jsf` extension to be customizable. MDS uses this extension to recognize it as a Facelets file.

Before you begin:

It may be helpful to have an understanding of how seeded customization works. For more information, see Customization and Layers: Use Cases and Examples.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to launch JDeveloper using the **Studio Developer** role, and open the application that you want to make customizable.

To enable seeded customizations in your user interface project:

1. In the Applications window, right-click the user interface project and choose **Project Properties**.
2. In the Project Properties dialog, select **ADF View** and then select the **Enable Seeded Customizations** checkbox, as shown in Figure 51-2.
3. Click **OK**.
4. Save the changes to your project.

Figure 51-2 Project Properties - Enable Seeded Customizations

□ Enable Runtime Skin Updates

How to Enable Seeded Customizations in Existing Pages

If you have pages in your project that were created in an earlier version of JDeveloper, you must make sure that these preexisting pages are also enabled for seeded customizations. This is only necessary if you migrated the application from an earlier version of JDeveloper and did not generate IDs during migration.

Before you begin:

It may be helpful to have an understanding of how seeded customization works. For more information, see Customization and Layers: Use Cases and Examples.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to launch JDeveloper using the **Studio Developer** role, and open the application that you want to make customizable.

To enable seeded customizations in an existing page:

1. Create an audit profile to implement ID tokens for all XML objects in your page:
   a. From the main menu, choose **Tools > Preferences**.
   b. In the Preferences dialog, select **Audit > Profiles**.
   c. On the Profiles page, click **Rules** and deselect all rules.
   d. Expand **Application Development > ADF Faces > Component ID Rules**.
   e. Select the rule **Check for ID When ADF Faces is Present**.
   f. From the **Default Fix** dropdown list, select **Generate a unique ID**.

g. Click **Save As**, then enter an identifiable name for the profile (such as Generate Unique IDs). and click **Save**.

h. Click **OK** to close the Preferences dialog.

2. In the Applications window, select the page for which you want to enable seeded customizations. Alternatively, you can select a project to run the audit on all the files it contains.
3. From the main menu, choose **Build > Audit**.
4. In the Audit dialog, select the profile you created to generate IDs and click **Run**.
5. Use the Log window to review issues and apply fixes.
6. When the audit is complete, save your changes.

How to Enable Customizations in Resource Bundles

If you plan to create new resource keys when implementing customizations, you can specify the affected resource bundles using the Application Properties dialog.

Before you begin:

It may be helpful to have an understanding of how seeded customization works. For more information, see Customization and Layers: Use Cases and Examples.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to launch JDeveloper using the **Studio Developer** role, and open the application that you want to make customizable.

To enable customizations in resource bundles:

1. From the Applications window context menu, choose **Application Properties**.
2. In the Application Properties dialog, click **Resource Bundles**, and then click **Add**.
3. In the Select Resource Bundle dialog, navigate to and select the resource bundles for which you want to enable customization.
4. Click **Open**.
5. In the Application Properties dialog, select the checkbox in the **Overridden** column of the **Bundle** table.
6. Click **OK**.

How to Configure the adf-config.xml File

The application's `adf-config.xml` file must have an appropriate `cust-config` element in the `mds-config` section. The `cust-config` element allows clients to define an ordered and named list of customization classes. You use the overview editor for the `adf-config.xml` file to add customization classes (see Figure 51-3).

Before you begin:

It may be helpful to have an understanding of how customization classes are created and packaged. For more information, see Customization Classes.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

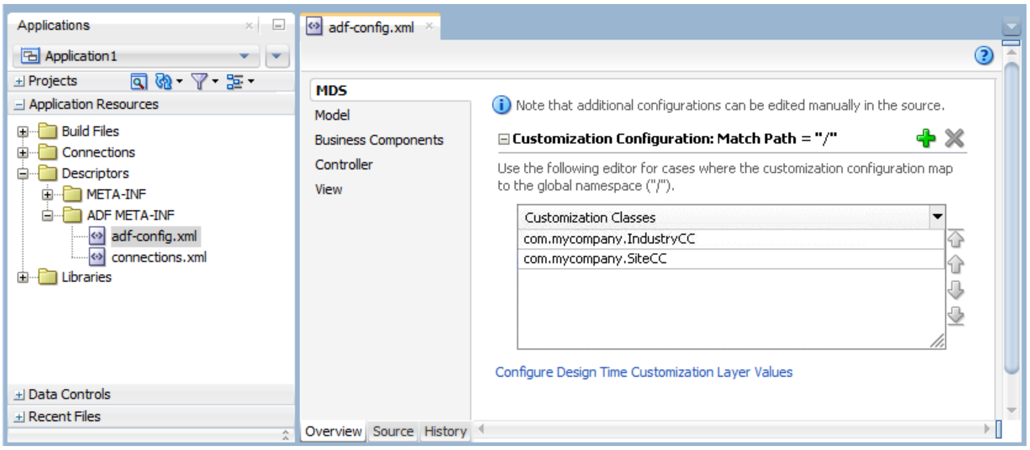
- Create your customization classes, as described in Creating a Customization Class.
- Create a JAR using the procedure described in Adding Customization Classes into a JAR.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.
- Launch JDeveloper using the **Studio Developer** role, and open the application that you want to customize.

To identify customization classes in the adf-config.xml file:

1. In the Application Resources panel, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click **adf-config.xml**.
2. In the overview editor, click the **MDS Configuration** navigation tab and then click the **Add** icon.
3. In the Edit Customization Class dialog, search for or navigate to the customization classes you have already created.
4. Select the appropriate classes and click **OK**.
5. After you have added all of the customization classes, you can use the arrow icons to put them in the appropriate order.

Figure 51-3 shows the overview editor for the `adf-config.xml` file with two customization classes added.

Figure 51-3 adf-config.xml Overview Editor



Note that additional configurations can be edited manually in the source.

Customization Configuration: Match Path = "/"

Use the following editor for cases where the customization configuration map to the global namespace ("/").

Customization Classes
com.mycompany.IndustryCC
com.mycompany.SiteCC

Configure Design Time Customization Layer Values

The order of the customization-class elements defines the precedence of customization layers. For example, in the code shown in the following example, the `IndustryCC` class is listed before the `SiteCC` class. This means that customizations at the industry layer are applied to the base application, and then customizations at the site layer are applied.

```
<adf-config xmlns="http://xmlns.oracle.com/adf/config">
  <adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
    <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
      <cust-config>
        <match path="/">
          <customization-class name="com.mycompany.IndustryCC"/>
          <customization-class name="com.mycompany.SiteCC"/>
        </match>
      </cust-config>
    </mds-config>
  </adf-mds-config>
</adf-config>
```

What Happens When You Create a Customizable Application

When you create a customizable application, you have a base application that includes the pieces necessary for you or someone else to use as the basis for a customized application.

To perform the customization, you must open the application in JDeveloper using the **Customization Developer** role, as described in Customizing an Application.

What You May Need to Know About Customizable Objects and Applications

Oracle ADF components (such as controller, model, and business components objects) must have a unique identifier so that they can be customized. ADF components generated by JDeveloper are created with identifiers by default, with the exception of JSP and JSF pages in your user interface projects. To cause JDeveloper to generate identifiers for components on pages in your user interface projects, you must explicitly specify this at the project level (as explained in How to Enable Seeded Customizations for User Interface Projects).

Before you implement customizations in an application, make sure that all objects that you intend to customize have the necessary identifiers. In many cases, you can run an audit rule to catch and fix any omissions (as explained in How to Enable Seeded Customizations in Existing Pages).

Also, take care to ensure the efficiency of your customization classes, because they can be executed frequently, once for each document being accessed to get the layer name and layer value.

Customizing an Application

Customizations are made with Oracle JDeveloper’s Customization Developer role. Customizations are made for each defined layer and only existing metadata is customizable.

Using the **Customization Developer** role, you can create customizations in a customizable application.

Introducing the Customization Developer Role

The **Customization Developer** role is used to customize the metadata in a project. Customization features are available only in this role. When you are in the **Customization Developer** role, you can do the following:

- Create and update customizations
- Select and edit the tip layer of a customized application
- Remove existing customizations

When you are in the **Customization Developer** role, the source editor is read-only and the following JDeveloper features are disabled:

- Workspace migration
- Creation, deletion, and modification of application and IDE connections. You must configure connections in Default role before opening an application in Customization Developer role.

When working with an application in the **Customization Developer** role, new objects cannot be created, and noncustomizable objects cannot be modified. However, the following content types are customizable:

- Portal modules
- ADF modules, including ADF Faces, ADF Model, ADF Business Components, and ADF Controller

> **Note:**
>
> ADF Business Components objects are customizable only if a static customization class is selected in the Customization Context window. Otherwise, business components objects are read-only.

When working in the **Customization Developer** role, you cannot edit noncustomizable files, such as Java classes, resource bundles, security policies, deployment descriptors, and configuration files. Noncustomizable files are indicated by a lock icon when you are working in the **Customization Developer** role.

> **Note:**
>
> Facelets files must have a `.jsf` extension to be customizable. MDS uses this extension to recognize it as a Facelets file.

You are also restricted from modifying project settings and customizing certain ADF Business Components features, including service interfaces and business event definitions. Additionally, you cannot refactor, or make changes to customizable files that would, in turn, necessitate changes in noncustomizable files.

How to Switch to the Customization Developer Role in JDeveloper

The customization features of JDeveloper are available to you in the **Customization Developer** role. To work in this role, you can either choose it when you start JDeveloper or, if JDeveloper is already running, you can use the **Switch Roles** menu to switch to the **Customization Developer** role.

Before you begin:

It may be helpful to have an understanding of the features of the **Customization Developer** role. For more information, see Introducing the Customization Developer Role.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to launch JDeveloper.

To switch to the Customization Developer role in JDeveloper:

- From the main menu, choose **Tools > Switch Roles > Customization Developer**.

> **Note:**
>
> You can optionally toggle the **Tools > Switch Roles > Always Prompt for Role Selection at Startup** menu item, to specify whether or not you want to choose the role when JDeveloper is launched. If deselected, JDeveloper launches in the role it was in when you last closed it.

Introducing the Tip Layer

When working in the **Customization Developer** role, the layer and layer value combination that is selected in the Customization Context window is called the **tip layer**. The changes you make while in the **Customization Developer** role are applied to this layer.

> **Note:**
>
> When working in the **Customization Developer** role, if the Customization Context window is not displayed, you can access it from the **Window** menu.

The metadata displayed in the JDeveloper editors is a combination of the base metadata and the customization layers up to and including the tip layer, according to the precedence set in `adf-config.xml`, with the values specified in the Customization Context window for each layer.

When working in the **Customization Developer** role, you can also see the noncustomized state of the application. When you select **View without**

Customizations in the Customization Context window, there is no current tip layer. Therefore, what you see is the noncustomized state. While you are in this view, all customizable files show the lock icon (in the Applications window), indicating that these files are read-only.

When you make customizations in a tip layer, these customizations are indicated by an orange icon in the Properties window. A green icon indicates non-tip layer customizations. When you see an orange icon beside a property, you have the option of deleting that customization by choosing **Remove Customization** from the dropdown menu for that property.

How to Configure Customization Layers

To customize an application, you must specify the customization layers and their values in the `CustomizationLayerValues.xml` file so that they are recognized by JDeveloper.

When you open a customizable application in the **Customization Developer** role, JDeveloper reads the `adf-config.xml` file to determine the customization classes to use and their order of precedence. JDeveloper also reads the `CustomizationLayerValues.xml` file to determine the layer values to make available in the Customization Context window. If there are layer values defined in the `CustomizationLayerValues.xml` file that are not defined in the customization classes listed in the `adf-config.xml` file, they are not displayed in the Customization Context window.

Therefore, you can have a comprehensive list of layer values for all of your customization projects in the `CustomizationLayerValues.xml` file, and only those appropriate for the current application are available in the Customization Context window. Conversely, you could have a comprehensive list of customization classes for an application in the `adf-config.xml` file, and only the subset of layer values that you will work on in your `CustomizationLayerValues.xml` file.

> **Note:**
>
> At design time, JDeveloper retrieves customization layer values from the `CustomizationLayerValues.xml` file. But at runtime, the layer values are retrieved from the customization class.

The names of the layers and layer values that you enter in the `CustomizationLayerValues.xml` file must be consistent with those specified in your customization classes. The following example shows the contents of a sample `CustomizationLayerValues.xml` file.

```
<cust-layers  xmlns="http://xmlns.oracle.com/mds/dt">
  <cust-layer name="industry" id-prefix="i">
    <cust-layer-value value="financial" display-name="Financial" id-prefix="f"/>
    <cust-layer-value value="healthcare" display-name="Healthcare" id-
prefix="h"/>
  </cust-layer>
  <cust-layer name="site" id-prefix="s">
    <cust-layer-value value="headquarters" display-name="HQ" id-prefix="hq"/>
    <cust-layer-value value="remoteoffices" display-name="Remote" id-
prefix="rm"/>
```

```
  </cust-layer>
</cust-layers>
```

For each layer and layer value, you can add an id-prefix token. This helps to ensure the uniqueness of the id, so that customizations are applied accurately. When you add a new element (such as a command button) to a page during customization, JDeveloper adds the id-prefix of the layer and layer value (determined by the selected tip layer) to the autogenerated identifier for the element to create an id for the newly added element in the customization metadata file. As the example above shows, the site layer has an id-prefix of "s" and the headquarters layer value has an id-prefix of "hq". So, when you select site/headquarters as the tip layer and add a command button to a page, the command button will have an id of "shqcb1" in the metadata customization file.

For each layer value, you can also add a display-name token to provide a human-readable name for the layer value. When you are working in the **Customization Developer** role, the value of the display-name token is shown in the Customization Context window for that layer value.

For each layer, you can optionally provide a value-set-size token that defines the size of the value set for the customization layer. This can be useful, for example, when using a design-time, application-specific CustomizationLayerValues.xml file. By setting value-set-size to "no_values" you can exclude runtime-only layers at design time.

```
<cust-layer name="runtime_only_layer" value-set-size="no_values"/>
```

You can define the customization layer values either globally for JDeveloper or in an application-specific file. If you use an application-specific file, it takes precedence over the global file. For more information on configuring layer values globally for JDeveloper, see Configuring Layer Values Globally. For more information on configuring application-specific layer values, see Configuring Workspace-Level Layer Values from the Studio Developer Role.

Configuring Layer Values Globally

The following procedure describes how to configure the CustomizationLayerValues.xml file globally for JDeveloper.

Before you begin:

It may be helpful to have an understanding of layers and layer values. For more information, see How to Configure Customization Layers.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes, as described in Creating a Customization Class.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.

To configure design time customization layer values globally for JDeveloper:

1. Locate and open the CustomizationLayerValues.xml file.

You can find this file in the jdev subdirectory of your JDeveloper installation directory (*jdev_install*\jdev\CustomizationLayerValues.xml).

2. For each layer, enter a cust-layer element, as described in How to Configure Customization Layers.
3. For each layer value, enter a cust-layer-value element, as described in How to Configure Customization Layers.
4. Save and close the CustomizationLayerValues.xml file.
5. After you have made changes to the global CustomizationLayerValues.xml file, you must restart JDeveloper.

Configuring Workspace-Level Layer Values from the Studio Developer Role

When configuring layer values for an application, you can use either the **Studio Developer** role or the **Customization Developer** role. Note that when you configure an application-specific CustomizationLayerValues.xml file, you can create and modify layer values, but you cannot create additional customization layers. It is not necessary to restart JDeveloper to pick up changes made to the application-specific layer values.

When you create an application-specific CustomizationLayerValues.xml file, JDeveloper stores it in an application-level directory (for example, *workspace-directory*\.mds\dt\customizationLayerValues\CustomizationLayerValues.xml). You can access this file in the Application Resources panel of the Applications window, under the **MDS DT** node.

The following procedure describes how to configure the CustomizationLayerValues.xml file for a specific application from the **Studio Developer** role. This procedure can also be used from the **Customization Developer** role.

Before you begin:

It may be helpful to have an understanding of layers and layer values. For more information, see How to Configure Customization Layers.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes, as described in Creating a Customization Class.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.
- Launch JDeveloper using the **Studio Developer** role, and open the application that you want to customize.

To configure design time customization layer values at the workspace level from the Studio Developer role:

1. In the Application Resources panel, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click **adf-config.xml**.
2. In the overview editor, click the **MDS Configuration** navigation tab.

3. On the MDS Configuration page, below the table of customization classes, click the **Configure Design Time Customization Layer Values** link to open the workspace-level `CustomizationLayerValues.xml` file.

   When you click the link, the file opens in the source editor. If the override file doesn't already exist, JDeveloper displays a confirmation dialog. Click **Yes** to create and open a copy of the global file.

4. In the file, specify layer values as necessary, as described in How to Configure Customization Layers.
5. Save your changes.

Configuring Workspace-Level Layer Values from the Customization Developer Role

You can also configure layer values for an application from the **Customization Developer** role. Note that when you configure an application-specific `CustomizationLayerValues.xml` file, you can create and modify layer values, but you cannot create additional customization layers. It is not necessary to restart JDeveloper to pick up changes made to the application-specific layer values.

When you create an application-specific `CustomizationLayerValues.xml` file, JDeveloper stores it in an application-level directory (for example, `*workspace-directory*\.mds\dt\customizationLayerValues\CustomizationLayerValues.xml`). You can access this file in the Application Resources panel of the Applications window, under the **MDS DT** node.

The following procedure describes how to configure the `CustomizationLayerValues.xml` file for a specific application from the **Customization Developer** role.

Before you begin:

It may be helpful to have an understanding of layers and layer values. For more information, see How to Configure Customization Layers.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes, as described in Creating a Customization Class.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

To configure design time customization layer values at the workspace level from the Customization Developer role:

1. In the Customization Context window, click the **Configure application layer values** link.

When you click the link, the `CustomizationLayerValues.xml` file opens in the source editor. If the override file doesn't already exist, JDeveloper displays a confirmation dialog. Click **Yes** to create and open a copy of the global file.

2. Specify layer values as necessary, as described in How to Configure Customization Layers.
3. Save your changes.

   After you make changes to the application-specific `CustomizationLayerValues.xml` file while you are in the **Customization Developer** role, any tip layer you have selected in the Customization Context window is deselected. You can then select the desired tip layer.

How to Customize Metadata in JDeveloper

You use the same development procedures and techniques to customize metadata that you use when developing the base application. To implement customizations, however, you must be working in the **Customization Developer** role and specify the customization context by selecting a tip layer and layer value before editing the metadata. For an application to be customizable, customizations must be enabled in your project. For more information, see Developing a Customizable Application.

Before you begin:

It may be helpful to have an understanding of how customization works. For more information, see Customization and Layers: Use Cases and Examples, and Customizing an Application.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

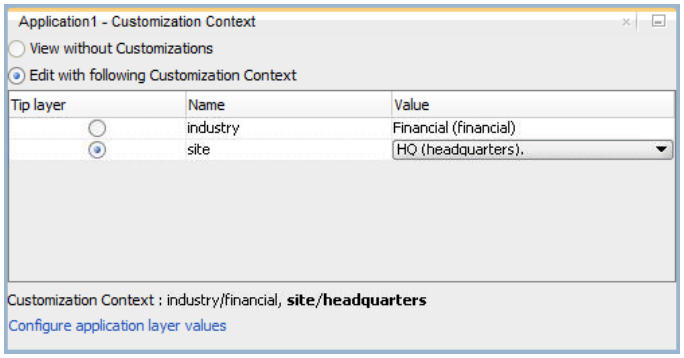
- Create your customization classes, as described in Creating a Customization Class.
- Create a JAR using the procedure described in Adding Customization Classes into a JAR.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.
- Update the `adf-config.xml` file, as described in How to Configure the adf-config.xml File .
- Enable seeded customizations in your application, as described in How to Enable Seeded Customizations for User Interface Projects, and How to Enable Seeded Customizations in Existing Pages.
- Configure the applications customization layers, as described in How to Configure Customization Layers.
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

To customize metadata in JDeveloper:

1. In the Customization Context window, select the layer and value for which you want to implement customizations.

The **Customization Context** (displayed at the bottom of the Customization Context window) changes to reflect your selection, as shown in Figure 51-4.

Figure 51-4 Customization Context Window with site/headquarters Selected as the Tip Layer



Application1 - Customization Context

○ View without Customizations

● Edit with following Customization Context

Tip layer	Name	Value
○	industry	Financial (financial)
●	site	HQ (headquarters).

Customization Context : industry/financial, **site/headquarters**

Configure application layer values

> **Note:**
>
> The selection you make in the Customization Context window indicates the context for the customizations that you will implement in JDeveloper. This selection does not directly impact the runtime for the application. At runtime, the customization context is returned from your customization classes. For more information, see How to Create Customization Classes.

2. Edit the metadata as you typically would during development. For example, double-click an entity object. Then edit the object using the overview editor.

   While you use the same techniques for editing metadata during customization that you would during development, certain restrictions apply. For example, some string properties, such as button labels, cannot be edited directly in the Properties window: they must be edited using the Select Text Resource dialog or the Expression Builder. For more information about restrictions to editing during customization, see Introducing the Customization Developer Role. For information about using the Expression Builder, see Opening the Expression Builder from the Properties Window.

   Even though you use the overview editor to implement customizations, you do not make changes to the base metadata file. Your changes are stored separately in a customization metadata file.

   > **Note:**
   >
   > To see the uncustomized base metadata, you can select **View without Customizations** in the Customization Context window.

3. You can optionally choose **Remove Customization** from the dropdown menu for a property (in the Properties window) to clear the existing customization.

> **Note:**
>
> In the Properties window, tip layer customizations are indicated by an orange icon, while properties that are not customized in the current tip layer are indicated by a green icon. A customization can only be removed in the context in which it was added. So you can remove only those customizations that have an orange indicator in the Properties window.

4. From the main menu, choose **File > Save** to save your changes.

After you have completed your customizations, you can run and test the customized application.

What Happens When You Customize an Application

When you implement customizations in an application, JDeveloper creates a metadata file for the customizations and a subpackage to store them in.

The metadata file contains the customizations for the customized object, which are applied over the base metadata at runtime. The new metadata file is named the same as the base file for the object with an additional `.xml` extension. For example, if you implement customizations for the `browseOrders.jsff` page, the customization metadata file is named `browseOrders.jsff.xml`. Or if you implement customizations on the `OrderItems` entity object, the base metadata file is named `OrderItems.xml` and the customization metadata file is named `OrderItems.xml.xml`.

The customization metadata files are stored in a subpackage hierarchy that is created at the same level as the object you customize. The first-level package is named `mdssys`, and it contains a package named `cust`. The `cust` package contains a package for each customization layer for which you have implemented customizations.

For example, say you have a base application that has a package called `oracle.summit.model.entities` containing your entity objects, and you have a customization layer named `site` with two layer values: `headquarters` and `remoteoffices`. Then you implement customizations for the `OrderItems` entity object at the `headquarters` layer value. When you implement these customizations, JDeveloper creates the subpackage hierarchy `oracle.summit.model.entities.mdssys.cust.site.headquarters` and stores the customization metadata files there.

Similarly, for pages in your user interface project, JDeveloper creates a directory structure to store the customization metadata files. For example, if you customize the `BrowseOrders.jsff` page in the Web Content node of your user interface project, JDeveloper creates the directory structure `mdssys/cust/site/headquarters` under Web Content and stores the customization metadata file there.

How to Customize ADF Library Artifacts in JDeveloper

In the **Customization Developer** role, you can use JDeveloper to customize artifacts in an ADF library. This need can arise when, for example, one development team produces task flows as part of a framework service and makes them available to other teams as an ADF library. Then another development team uses one of the task flows in a consuming application, and needs to fine-tune it to fit the requirements of the application.

Customizing an ADF Library Artifact

You can add an ADF library to your project in the **Customization Developer** role just as you would add it in the **Studio Developer** role. However, in the **Customization Developer** role, content from an ADF library appears as editable to allow you to implement customizations, whereas in the **Studio Developer** role it is read-only. For more information about working with ADF libraries, see Reusing Application Components .

Before you begin:

It may be helpful to have an understanding of how customization works. For more information, see Customization and Layers: Use Cases and Examples, and Customizing an Application.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes, as described in Creating a Customization Class.
- Create a JAR using the procedure described in Adding Customization Classes into a JAR.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.
- Update the `adf-config.xml` file, as described in How to Configure the adf-config.xml File .
- Enable seeded customizations in your application, as described in How to Enable Seeded Customizations for User Interface Projects, and How to Enable Seeded Customizations in Existing Pages.
- Configure the applications customization layers, as described in How to Configure Customization Layers.
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

To customize an ADF library artifact:

1. In the Applications window, click the **Applications Window Options** icon and choose **Show Libraries**.

   This displays the libraries in the Applications window, so that you can explore them and access their artifacts.

2. Add the desired library to your project if it is not already shown among the libraries in the Applications window.

   For information about how to do this, see Adding ADF Library Components into Projects.

3. Customize the artifacts just as you would customize other content in your project.

For example, you can drag and drop taskflows from a library to `.jspx` or `.jsff` pages in a consuming project, drag and drop taskflows from a library to a page or fragment in another library, drag and drop library content or taskflows from the Resource catalog, drag and drop data controls from Data Controls panel to `.jspx` or `.jsff` pages in a library, edit business components, and drag and drop a data control from a library to the Data Controls panel and then drop to a page in another palette. All of these actions result in customizations of the library.

Specifying a Location for ADF Library Customizations

The location where ADF library customizations are stored is *`project-dir`*`\libraryCustomizations` by default. If your workspace contains multiple projects, you should change this to a workspace-level location for each project (for example, *`workspace-dir`*`\.mds\ADFLibraryCustomizations`).

You can change the location of ADF library customizations on the **Project Source Paths > ADF Library Customizations** page of the Project Properties dialog. If you change this location after you have implemented customizations on an ADF library, you must move the customization metadata files to the new location. To do this, use the file system to move the customization metadata (XML) files from the old directory to the new one.

If you have more than one project in the workspace with existing ADF library customizations that need to be moved to the common location, move the customizations to the new location one project at a time. For each project, change the location of ADF library customizations in the Project Properties dialog, and then move the customization metadata files from the old location to the new location. To mitigate conflicts where an ADF library artifact has customizations in more than one project, you have following options:

- From both projects, open the ADF Library artifact for which there are conflicting customizations, and decide upon which customizations you want. Preserve the customizations you want to keep and delete the others.
- If both customizations are important, open the ADF library artifact from the first project and implement the customizations that were previously done in second project. Then save the customizations in the first project and remove the customizations from the second project.

Do not open ADF library customization metadata files from multiple projects in a text editor and merge their contents. This can corrupt the customization metadata file.

Additionally, the location where ADF library customizations are stored is automatically included when you create a MAR deployment profile. If you change this location after you have created a MAR profile, you must also change the corresponding entry in the contributors list on the User Metadata file group page of the Edit MAR Deployment Profile Properties dialog before packaging. Alternatively, you can re-create the MAR profile to pick up this change. For more information about creating a MAR deployment profile, see How to Create Deployment Profiles.

How to View ADF Library Runtime Customizations from Exported JARs

When working in the JDeveloper Customization Developer role, you can view runtime customizations implemented on ADF library artifacts contained in an exported JAR.

Before you begin:

It may be helpful to have an understanding of how customization works. See Customization and Layers: Use Cases and Examples, and Customizing an Application.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customizable application, as described in Developing a Customizable Application.
- Deploy the application and implement runtime customizations on it, then export the runtime customizations to a JAR file.
- Launch JDeveloper using the **Customization Developer** role, and open the customizable application.

To make runtime customizations viewable from JDeveloper:

1. From the Applications window context menu, choose **Application Properties**.
2. In the Application Properties dialog, select **Customization Libraries**.
3. Click **Browse**, and navigate to the location of the exported JAR file.
4. Select the JAR file and click **Select**.
5. Click **OK**.

Now the JAR is available so that JDeveloper can look up customizations on ADF library artifacts. When you open an object that contains ADF library artifacts, JDeveloper looks for customizations in this JAR file and displays them if appropriate. JDeveloper decides what to display for a given artifact in a given customization context as follows:

- If the artifact has *neither* runtime customizations *nor* seeded customizations associated with it, the artifact from the ADF library is displayed.
- If the artifact has only *either* runtime customizations *or* seeded customizations associated with it (but not both), the customized artifact is displayed.
- If the artifact has *both* runtime customizations *and* seeded customizations associated with it, the seeded customization takes precedence and is displayed.

Additionally, when you run the application locally from JDeveloper, the runtime customizations are displayed. However, the runtime customizations are not included in any packaging of the application for deployment.

What Happens When You Customize ADF Library Artifacts

During the development of enterprise applications, there might be artifacts (such as task flows) that can be reused in multiple applications. To facilitate reuse of these common artifacts, they can be packaged into an ADF library and distributed. This allows you to add the ADF library to the list of libraries that the consuming application depends on. Then when the application is packaged, the customizations from all such ADF libraries are included in the MAR, which is later deployed to the MDS repository. Note, however, that ADF library customizations are added to the MAR deployment profile when you create the profile, which is not automatically updated when customizations are implemented after creating the profile. To pick up these subsequent customizations, use the **Update Profile** button on the MAR Options page of the Edit MAR Deployment Profile Properties dialog.

> **Note:**
>
> The ADF library provider should take care to ensure that no name conflicts arise due to customizations in the library. In the event that name conflicts arise between customizations packaged in an ADF library and the customizations from the consuming project, the customizations from the ADF library are ignored.

When you implement customizations on objects from an ADF library, the customization metadata is stored by default in a subdirectory of the project called `libraryCustomizations`. And although you create ADF library customizations at the project level, they are merged together during packaging to be available at the application level at runtime. Essentially, ADF libraries are JARs that are added at the project level, which map to library customizations being created at the project level. However, although projects map to web applications at runtime, the MAR (which contains the library customizations) is at the EAR level, so the library customizations are seen from all web applications.

Therefore, you can customize an ADF library artifact in only one place in an application for a given customization context (customization layer and layer value). Customizing the same library content in different projects for the same customization context would result in duplication in MAR packaging. To avoid duplicates that would cause packaging to fail, implement customizations for a given library in only one project in your application.

> **Note:**
>
> Using the same location for ADF library customizations for all of the projects in your application can help to avoid duplicate customization. For more information, see Specifying a Location for ADF Library Customizations.

For example, say the ADF library you are using contains a page fragment `text.jsff`. In the consuming application, customize this library page in only one project. By doing so, customizations are available for all projects in the application that consume this library at runtime.

You are also restricted from customizing an object from an ADF library when your project already contains an object with the same name. In case of duplication, you must fix the projects by deleting one of the duplicate documents or deleting one and manually merging the differences into the other.

Similarly, if the ADF library contains seeded customizations for an artifact within a given customization context (customization layer and layer value), you cannot implement customizations for that artifact within the same customization context. In this situation, the ADF library artifact is read-only. You can, however, implement customizations for the artifact within other customization contexts.

For example, say the ADF library you are using contains seeded customizations for the `Headquarters` layer value in the `Site` layer. When you select this as your tip layer in the Customization Context window, the customized objects in that ADF library are read-only. However, if you select `Site/Remote Site 1` as your tip layer, then the objects are customizable.

> **Note:**
>
> When the consuming application implements customizations on content from an ADF library, the customizations are written to the local project directories, but they are not automatically injected with the `web-app-root` during packaging. For more information, see Creating a MAR Deployment Profile.

What Happens at Runtime: How Customizations are Applied

At runtime, the application applies the customization metadata files over the base application in the order of precedence defined in the `cust-config` section of the `adf-config.xml` file.

The layer value is retrieved from the customization class at runtime and evaluated in the context the application is running, and the appropriate customizations for that layer value are applied.

What You May Need to Know About Customized Applications

When you are customizing an application, you might be using integrated source control or customizing resource strings. When you use these features, there is additional information you need to know.

Customization and Integrated Source Control

When working in the **Customization Developer** role, your source control integration complements the process of customization. If JDeveloper is configured to automatically check out and add new files to source control and you attempt to customize a base document that is available from a source control system, JDeveloper behaves in the following way:

- If the corresponding customization file is not already available, then a new customization file is created in source control and the customizations are written to it.
- If the corresponding customization file exists, it is checked out and customizations are written to it.
- If the corresponding customization file exists and it is already checked out or not yet in version control, customizations are written to it without any further version control operation.

Since the base document is not modified in the **Customization Developer** role, the base document is not checked out.

If JDeveloper is not configured to automatically check out or add new files to source control, you must manually make the customization files editable and check in newly created customization files to source control. For more information about using source control in JDeveloper, see section Using a Source Control System.

Editing Resource Bundles in Customized Applications

During the course of customizing your application, you might want to customize the content to use different resource bundle keys or define and use new resource keys.

You can open a customizable application in the **Customization Developer** role and use the Properties window to customize the usages of resource bundle strings. You can change a document to use another already existing resource key in a resource bundle, or create a new resource. For more information about resource bundles, see Working with Resource Bundles.

New resource keys (created in the **Customization Developer** role) are saved to an application-level override bundle (in XLIFF format), and JDeveloper adds an entry to the `adf-config.xml` file like the one shown in the following example to configure the application-level override bundle.

You must also configure the `adf-config.xml` file to support the overriding of the base resource bundle. As the following example shows, you must tag the `bundleId` element with `override="true"` to make it overrideable. After it is marked as overridden, customizations of that bundle are stored in the application's override bundle.

```
<adf-resourcebundle-config xmlns="http://xmlns.oracle.com/adf/resourcebundle/
config">
  <applicationBundleName>
    path-to-resource-bundle/bundle-name
  </applicationBundleName>
  <bundleList>
    <bundleId override="true">
      package.BundleID
    </bundleId>
  </bundleList>
</adf-resourcebundle-config>
```

> **Note:**
>
> If an application is not configured for customization, you can open it in the **Customization Developer** role and define new resource keys by choosing **Application > Edit Resource Bundles** from the main menu. However, you cannot change a document to use the new resource keys if it is not configured for customization.

How to Package and Deploy Customized Applications

You need to deploy your ADF application after you have made the necessary customizations. The customized metadata is packaged into a MAR file and made ready for deployment.

After you customize the application, you will want to deploy it. Before you deploy the customized application, you must follow the configuration procedures for setting up your MDS repository, as described in Managing the MDS Repository of the *Administering Oracle Fusion Middleware*.

An enterprise application can contain model and user interface projects, and both types of projects can contain customized metadata. The customized metadata is packaged into a MAR for deployment. By default, the customizations from both types of projects are added to a single MAR. For information about how to create a MAR profile, see Creating a MAR Deployment Profile.

Implicitly Creating a MAR Profile

When you use JDeveloper to package a Fusion web application, JDeveloper creates an auto-generated MAR profile that includes default metadata (such as customizations), when *either* of the following conditions are met.

- The **Enable User Customizations > Across Sessions using MDS** checkbox is selected on the ADF View settings page of the Project Properties dialog for the user interface project.
- The MDS configuration section of the `adf-config.xml` file contains a `<metadata-store-usage>` element that is marked as `deploy-target="true"`, as shown in the following example.

```
< . . . >
  <persistence-config>
    <metadata-namespaces>
      <namespace path="/oracle/apps" metadata-store-usage="repos1"/>
    </metadata-namespaces>
    <metadata-store-usages>
      <metadata-store-usage id="repos1" deploy-target="true">
      . . .
      </metadata-store-usage>
    </metadata-store-usages>
  </persistence-config>
< . . . >
```

Explicitly Creating a MAR Profile

For customizations created in JDeveloper to take effect in the application when it is deployed, these customizations need to be made available to the application at runtime. There are two techniques you can use to accomplish this:

- Package the customizations along with the application using a MAR profile.

  Create a MAR profile that includes the customization metadata. The MAR profile should be included in the deployed EAR file to ensure that the customizations are available at runtime. Your customization classes must be packaged in the EAR file such that they are in the application-level class loader.

> **Note:**
>
> If you have only seeded customizations, you do not need to create a MAR profile to import them into the MDS repository unless you also want to support runtime customizations. If you have seeded customizations and do not have cross-session persistence enabled, the seeded customizations will be packaged in the EAR file by default and loaded from the class path.

- Import the customizations to the runtime repository used by the application.

  You typically use this approach if customizations to library metadata need to be applied to an application that is deployed separately. Using this approach, you package the customizations into a JAR file and then use the command `importMetadata` with Oracle WebLogic Scripting Tool (WLST) to import them to the MDS runtime repository. For more information about this and other WLST commands, see the *WLST Command Reference for Infrastructure Components*.

If your application has customizations on objects from an ADF library, the customization metadata is implicitly included when you create the MAR profile. If you change the location of ADF library customizations in the Project Properties dialog, you must re-create the MAR profile before packaging.

If you plan to use design time at runtime capabilities to add or edit resource keys in the override bundle at runtime, the override bundle must be packaged as part of the MAR profile. By default, the override bundle is packaged as part of the auto-generated MAR profile if the application contains seeded customizations. However, if the application doesn't contain seeded customizations, you must explicitly create the MAR deployment profile to package the override bundle. When the MAR profile is created explicitly, the override bundle is added and included by default as part of the user metadata.

When you package and deploy the completed customized application, you should do so from the **Studio Developer** role, rather than from the **Customization Developer** role. For information about how to create a MAR profile, see How to Create Deployment Profiles.

Extended Metadata Properties

Extended metadata provides additional settings for customization of the Fusion web application. You can edit the extended metadata properties and identify who and which parts of metadata can be customized at runtime.

Extended metadata is data that describes the metadata content. The extended metadata file contains additional information about the metadata file. One use of this extended information is to identify which parts of the metadata can be customized at runtime (design time at runtime customizations) and who can customize them. For information about this use of extended metadata properties, see How to Enable Customization for Design Time at Runtime.

You can open a metadata file (such as a `.jspx` file) in JDeveloper and use the Properties window to view and edit its extended metadata properties. When you open a metadata file, its extended metadata properties are displayed in the Properties window. These properties can be edited to add metadata information at either of the following levels:

- File-level: These properties are displayed in the Properties window when the root element is selected in the Structure window.
- Element-level: These properties are displayed in the Properties window when an element is selected in the Structure window. The selected element should have a non-null identifier.

Extended metadata properties are supported for file types that support customizations and can be packaged in a MAR, such as `.jsff` and `.jspx` files.

Extended metadata for a metadata document is stored in an associated resource description framework (RDF) file. RDF is a W3C standard used to define an XML framework for defining metadata. The RDF file associated with the metadata document is created when the first property value is specified using the Properties window. Extended metadata properties are editable only when JDeveloper is in the **Studio Developer** role. RDF files are read-only in the **Customization Developer** role.

The RDF file is stored in the `mdssys` directory. For example, if the metadata being described is stored in the file system as `/myapp/data/page1.jspx`, the corresponding extended metadata document would be stored as `/myapp/data/mdssys/mdx/page1.jspx.rdf`. The extended metadata document must then be packaged with the corresponding metadata base file and added to the same deployment profile. For information about creating a MAR deployment profile, see How to Create Deployment Profiles.

> **Note:**
>
> Don't edit the extended metadata documents directly. Use the Properties window.

How to Edit Extended Metadata Properties

You can use extended metadata properties to provide additional metadata information that is not covered in the metadata file (such as a `.jspx` file). When you open the metadata file in JDeveloper, extended metadata properties are displayed in the Properties window, which you can use to edit these properties when you are using JDeveloper in the **Studio Developer** role.

For example, suppose you want to deliver a metadata file in some form to external customers. Along with metadata file, you need to provide additional information about the file, such as the creator, subject, description, format, and rights. You can accomplish this by creating an extended metadata property file for your metadata file.

Before you begin:

It may be helpful to have an understanding of how extended metadata is used. For more information, see Extended Metadata Properties.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete this task:

- Launch JDeveloper using the **Studio Developer** role, and open the application.

To edit extended metadata properties:

1. In the Applications window, select the object for which you want to edit extended metadata properties.
2. In the Structure window, select the appropriate element (typically the root element).
3. In the Properties window, expand the appropriate node to edit the properties.

To display the Properties window with the values for the selected component, choose **Window > Properties** from the main menu.

4. Edit the value for the desired property and press Enter.
5. From the main menu, choose **File > Save** to save your changes.

If you have edited extended metadata properties for a metadata file, you must package your extended metadata (or RDF) files with the metadata files when you deploy the application.

How to Enable Customization for Design Time at Runtime

You can also use extended metadata properties to provide information about which parts of the metadata can be customized at runtime and who can customize the metadata content.

By default, all components that you can add to a `.jspx` page are preconfigured to allow runtime customization to support implicit user personalization (such as changing the order of columns in a table).

Components that are preconfigured to allow customization need no further modification to enable design time at runtime customizations. If you use them in a `.jspx` page, then they are customizable by default.

Depending on the requirements of your application, you will need to modify customization properties in the following situations:

- For components that are configured to allow customization, you can override the default settings to disallow customization.
- For components that are not configured to allow customization and metadata objects (such as `.jspx` pages), you can override the settings to allow customization.
- For components that are configured to allow customization, you can optionally restrict who is allowed to perform customizations at runtime.

If you edit customization properties, you must package your extended metadata (RDF) files with the metadata files when you deploy the application.

Additionally, you can restrict customizations on a entire subtree of components by marking the root of the subtree to disallow customizations. You can then mark individual components of that subtree as customizable to allow customizations for those specific components.

Editing Customization Properties in the Properties window

In the Customization group in the Properties window, there are two properties that allow you to specify whether customizations for an object are permitted at runtime and who is permitted to do them. The **CustomizationAllowed** property can be set on any element to specify whether or not it can be customized. The **CustomizationAllowedBy** property controls which users can customize the element. These settings are not enforced when you are implementing seeded customizations using JDeveloper, but are instead enforced when the application is customized at runtime (design time at runtime customizations).

For example, say you have a `.jspx` page with a form that contains two panels, and you need to allow runtime customization for content in Panel1, but not Panel2.

You would set **CustomizationAllowed** to `true` for Panel1, and set it to `false` for Panel2. If you need to allow runtime customization on an entire page, you would set **CustomizationAllowed** to `true` for the `.jspx` page root.

Before you begin:

It may be helpful to have an understanding of how extended metadata is used. For more information, see Extended Metadata Properties.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customizable application, as described in Developing a Customizable Application.
- Launch JDeveloper using the **Studio Developer** role, and open the application.

To edit customization properties:

1. In the Applications window, select the object for which you want to edit customization properties.
2. In the Structure window, select the appropriate element.
3. In the Properties window, expand the **Customization** node to edit the customization properties.

   To display the Properties window with the values for the selected component, choose **Window > Properties** from the main menu.
4. Edit the property value and press Enter.

   For example, to allow runtime customizations on a `.jspx` file, select the file and set the **CustomizationAllowed** property to `true`.
5. From the main menu, choose **File > Save** to save your changes.

Using a Standalone Annotations File to Specify Type-Level Customization Properties

You can optionally use a standalone annotations file to specify whether or not customizations are allowed for a given type of component. This file allows you to set customization properties on element types, rather than on instances. You can override the setting for a given type by explicitly setting `true` or `false` on a specific instance. The following example shows the contents of a sample standalone annotations file.

```
<?xml version="1.0" encoding="UTF-8"?>
<grammarMetadata xmlns="http://xmlns.oracle.com/bali/xml/metadata"
                 xmlns:md="http://xmlns.oracle.com/bali/xml/metadata"
                 xmlns:mmd="http://xmlns.oracle.com/bali/xml/metadata/model"
                 xmlns:mds="http://xmlns.oracle.com/mds"
                 namespace="http://www.oracle.com/mds/restrictCustomizations">
  <elementMetadata elementName="orderDetail">
    <attributeMetadata attributeName="itemTypeRef">
      <mds:customizationAllowedBy>sales admin</mds:customizationAllowedBy>
    </attributeMetadata>
    <attributeMetadata attributeName="description">
      <mds:customizationAllowed>true</mds:customizationAllowed>
      <mds:customizationAllowedBy>hr</mds:customizationAllowedBy>
    </attributeMetadata>
    <attributeMetadata attributeName="title">
      <mds:customizationAllowed>true</mds:customizationAllowed>
    </attributeMetadata>
  </elementMetadata>

  <elementMetadata elementName="bankTransfer">
    <mds:customizationAllowed>false</mds:customizationAllowed>
  </elementMetadata>

  <elementMetadata elementName="order">
    <mds:customizationAllowed>true</mds:customizationAllowed>
    <attributeMetadata attributeName="paymentRef">
      <mds:customizationAllowedBy>sales</mds:customizationAllowedBy>
    </attributeMetadata>
    <elementMetadata elementName="itemDetail">
      <attributeMetadata attributeName="itemsRef">
        <mds:customizationAllowedBy>hr</mds:customizationAllowedBy>
      </attributeMetadata>
    </elementMetadata>
  </elementMetadata>

</grammarMetadata>
```

If you use a standalone annotations file, you must register it with MDS in the `adf-config.xml` file. Create a `mdsc:standalone-definitions` section in the `mdsc:type-config` section of the `adf-config.xml` file, as shown in the following example.

```
<?xml version="1.0"?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
            xmlns:mdsc="http://xmlns.oracle.com/mds/config">
 <mdsdata>
  <mdsc:mds-config version="11.1.1.000" >
   <mdsc:type-config>
     <mdsc:type-definitions>

       <mdsc:url>jar:file:/c:/jdev/lib/oafwk.jar!/oracle/apps/schemas/oa.xsd</mdsc:url>

       <mdsc:mds>/oracle/mds/TypeSeven.xml</mdsc:mds>
       <mdsc:mds>/oracle/mds/TypeEight.xml</mdsc:mds>
       <mdsc:file>typefile7.xsd</mdsc:file>
       <mdsc:file>typefile8.xsd</mdsc:file>
      </mdsc:type-definitions>
     <mdsc:standalone-definitions>

       <mdsc:url>jar:file:/c:/jdev/lib/oafwk.jar!/oracle/apps/schemas/
oa.xsd</mdsc:url>

       <mdsc:mds>/oracle/mds/standAloneSeven.xml</mdsc:mds>
       <mdsc:mds>/oracle/mds/standAloneEight.xml</mdsc:mds>
       <mdsc:file>standAloneFile7.xsd</mdsc:file>
       <mdsc:file>standAloneFile8.xsd</mdsc:file>
     </mdsc:standalone-definitions>
    </mdsc:type-config>
     ....
  </mdsc:mds-config>
 </mdsdata>
</adf-config>
```

Enabling Runtime Modification of Customization Configuration

For a given session, you can make modifications to the customized configuration at runtime.

You can prepare your customized application to accept overrides to the customization configuration (the `cust-config` section of the `adf-config.xml` file) at runtime on a per-session basis, thus allowing the user to change the way customizations are applied for a given session (or web request).

Consider a scenario where an application is configured with a `site` layer and a `user` layer and you want to make design time at runtime customizations to the `site` layer. If you use the application's customization configuration (defined in the `adf-config.xml` file), any customizations that you implement are applied to the `user` layer. So, you need to be able to adjust the customization configuration for a given session to allow your customizations to be applied to the `site` layer.

Or perhaps you have a requirement that an administrator wants to see the base metadata document with the `site` layer customizations alone. For cases like this, you need to specify a modified customization configuration, other than what was originally specified in application's `adf-config.xml` file.

For each web request, Oracle ADF creates an MDS session. For any MDS customization configuration modifications that apply to a session (web request), the user could programmatically provide modified MDS session options with a new customization configuration to Oracle ADF that would be applied on top of the original MDS configuration while creating a MDS session.

To implement this functionality, use the following ADF interfaces for `sessionOptionsFactory`:

- `oracle.adf.share.mds.SessionOptionsFactory` is the interface you use to specify modified MDS session options for a web request in a Fusion web application.

  ```
  SessionOptionsFactory :: oracle.mds.core.SessionOptions
  createSessionOptions(oracle.mds.core.SessionOptions defaultOptions)
  ```

  You implement this method to return the modified MDS `sessionOptions` to ADF.
- `oracle.adf.share.config.ConfigUtils` is the public class you can use to register your session options factory with ADF.

  ```
  ConfigUtils :: public static void setSessionOptionsFactory(ADFContext
  context, SessionOptionsFactory factory)
  ```

See your ADF API documentation for further detail on these interfaces.

You register your `sessionOptionsFactory` with Oracle ADF so that ADF can get modified session options from your implementation before the MDS session is created in request lifecycle.

The following example shows how you can implement `sessionOptionsFactory`. This example sets a modified customization configuration for the session to use the `site` customization layer alone regardless of the customization configuration specified in the `adf-config.xml` file. See the Javadoc for `oracle.mds` for more information.

```
package mycompany;

import oracle.adf.share.mds.SessionOptionsFactory;
import oracle.mds.config.CustClassListMapping;
import oracle.mds.config.CustConfig;
import oracle.mds.config.MDSConfigurationException;
import oracle.mds.core.SessionOptions;
import oracle.mds.cust.CustClassList;
import oracle.mds.cust.CustomizationClass;

public class MySessionOptionsFactory implements SessionOptionsFactory {
  public MySessionOptionsFactory() {
    super();
  }
  /**
   * Called to allow the application code to create a new SessionOptions object.
   * The application code should make sure to read the values from the
   * defaultOptions object as part of contruction of their new object and make
   * sure they only override the intended values.
   * @param defaultOptions
   * @return modified MDS session options
   */
  public SessionOptions createSessionOptions(SessionOptions defaultOptions) {
    // create new mds Customization configuration
    CustConfig custconfig = null;

    // create customization class array. Just put SiteCC implementation as we
    // wish to apply site customizations alone.
    CustomizationClass[] custclassarray = new CustomizationClass[] {new
SiteCC()};

    CustClassList custclasslist = new CustClassList(custclassarray);

    // specify the base metdata package namespace mapping on which site
    // customizations would apply
    CustClassListMapping[] mappings =
        new CustClassListMapping[] {new CustClassListMapping("mycompany/package",
                                                 null, null, custclasslist)};
    // create new customization configuration
    try{
      custconfig = new CustConfig(mappings);
    }
    catch (Exception ex){
      //do nothing
    }

    // now return modified sessionOptions to ADF with new mds customization
    // configuration. Only use newly created customization configuration in here.
    // For rest of option, use whatever available in defaultOptions.
    return new SessionOptions(defaultOptions.getIsolationLevel(),
                              defaultOptions.getLocale(),
                              custconfig,
                              defaultOptions.getVersionContext(),
                              defaultOptions.getVersionCreatorName(),
                              defaultOptions.getCustomizationPolicy(),
                              defaultOptions.getServletContextAsObject());
  }
}
```

52
Allowing User Customizations at Runtime

This chapter describes how to use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime.
This chapter includes the following sections:

About User Customizations

JDeveloper allows you to save the attributes of ADF Faces components based on your specific requirements.

Certain ADF Faces components have attributes that can be saved for a specific user. For example, the value of the `disclosed` attribute on a `panelBox` component can be saved for a specific user during the current session. Say the `myOrders` page in an application contains four `panelBox` components that display order information. By default, they are expanded, as shown in Figure 52-1.

Figure 52-1 panelBox Components Are Expanded by Default

Because this application is configured to allow user customizations, then during the user's session, anytime that user returns to the page, the Payment Information box remains collapsed. You need only to enable user customizations for the project in order for these changes to be persisted to the user's session.

> **Note:**
>
> The user session begins when the user logs in to the application, and ends when the user leaves the application. It is possible that while using an application, the user could navigate across application boundaries (for example, to a peer application) and thereby leave the application, at which point the user session would end.

Table 52-1 shows the attribute value changes persisted by an ADF Faces application, after you configure the application to allow user customizations.

Table 52-1 Implicitly Persisted Attribute Values

Component	Attribute	Affect at Runtime

`panelBox`
`showDetail`
`showDetailHeader`
`showDetailItem`
	`disclosed`	Users can display or hide content using an icon in the header. Detail content will either display or be hidden, based on the last action of the user.

`showDetailItem` (used in a `panelAccordion` component)	`flex`	The heights of multiple `showDetailItem` components are determined by their relative value of the flex attribute. The `showDetailItem` components with larger flex values will be taller than those with smaller values. Users can change these proportions, and the new values will be persisted.
`showDetailItem` (used in a `panelAccordion` component)	`inflexibleHeight`	Users can change the size of a panel, and that size will remain.
`panelSplitter`	`collapsed`	Users can collapse either side of the splitter. The collapsed state will remain as last configured by the user.
`panelSplitter`	`splitterPosition`	The position of the splitter in the panel will remain where last moved by user.
`richTextEditor`	`editMode`	The editor will display using the mode (either WYSIWYG or source) last selected by the user.
`calendar`	`activeDay`	The day considered active in the current display will remain the active day.
`calendar`	`view`	The view (day, week, month, or list) that currently displays activities will be retained.
`panelWindow` `dialog`	`contentHeight`	Users can change the height of a `panelWindow` or `dialog` popup component, and that height will remain.
`panelWindow` `dialog`	`contentWidth`	Users can change the width of a `panelWindow` or `dialog` popup component, and that width will remain.

`button`
`link`
`commandMenuItem`
`commandNavigationItem`
	`windowHeight`	When users change the `contentHeight` attribute value of a `panelWindow` or `dialog` component, any associated `windowHeight` value on a command component is also changed and will remain.

Table 52-1 (Cont.) Implicitly Persisted Attribute Values

Component	Attribute	Affect at Runtime
button link commandMenuItem commandNavigationItem	windowWidth	When users change the contentWidth attribute value of a panelWindow or dialog component, any associated windowWidth value on a command component is also changed and will remain.
column	displayIndex	ADF Faces columns can be reordered by the user at runtime. The displayIndex attribute determines the order of the columns. (By default, the value is set to -1 for each column, which means the columns will display in the same order as the data source). When a user moves a column, the value on each column is changed to reflect the new order. These new values will be persisted.
column	frozen	ADF Faces columns can be frozen so that they will not scroll. When a column's frozen attribute is set to true, all columns before that column (based on the displayIndex value) will not scroll. When you use the table with a panelCollection component, you can configure the table so that a button appears that allows the user to freeze a column.
column	noWrap	The content of the column will either wrap or not. You need to create code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from true to false.
column	selected	The selected column is based on the column last selected by the user.
column	visible	The column will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from true to false.
column	width	The width of the column will remain the same size as the user last set it.

Table 52-1 (Cont.) Implicitly Persisted Attribute Values

Component	Attribute	Affect at Runtime
`table`	`filterVisible`	ADF Faces tables can contain a component that allows users to filter the table rows by an attribute value. For a table that is configured to use a filter, the filter will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a button that allows a user to toggle the value from `true` to `false`.

`dvt:areaGraph`
`dvt:barGraph`
`dvt:bubbleGraph`
`dvt:comboGraph`
`dvt:horizontalBarGraph`
`dvt:lineGraph`
`dvt:scatterGraph`
	`timeRangeMode`	The time range for the data displayed on a graph time axis can be specified for all data visualization graph components. By default, all data is displayed. The time range can also be set for a relative time range from the last or first data point, or an explicit time range. You will need to write code that allows the user to change this attribute value. For example, you might create a dropdown list to choose the time range for a graph.

`dvt:ganttLegend`	`visible`	The legend for data visualization project, resource utilization, and scheduling Gantt chart components will either be visible or not inside the information panel. You will need to write code that allows the user to change this attribute value, for example, a hide and show button to display the legend.
`dvt:hierarchyViewer`	`layout`	The data visualization hierarchy viewer component supports nine hierarchy layout options including a top-to-bottom vertical, tree, circle, radial, and so on. Users can change the layout in the map control panel and the last selected layout will be retained.
`dvt:map`	`mapZoom`	This data visualization geographic map component attribute specifies the beginning zoom level of the map. The zoom levels are defined in the map cache instance as part of the base map. You will need to write code that allows the user to change this attribute value.

Table 52-1 (Cont.) Implicitly Persisted Attribute Values

Component	Attribute	Affect at Runtime
`dvt:map`	`srid`	This data visualization geographic map component attribute specifies the srid (spatial reference id) of all the coordinates of the map, which includes the center of the map, defined by startingX and startingY, and all the points in the point theme. You will need to write code that allows the user to change this attribute value.
`dvt:map`	`startingX`, `startingY`	This data visualization geographic map component attribute specifies the X and Y coordinate of the center of the map. The srid for the coordinate is specified in the srid attribute. If the srid attribute is not specified, this attribute assumes that its value is the longitude of the center of the map. You will need to write code that allows the user to change this attribute value.

`dvt:projectGantt`
`dvt:resourceUtilizationGantt`
`dvt:schedulingGantt`
	`splitterPosition`	The position of the splitter in the panel will remain where last moved by user.

`dvt:timeAxis`	`scale`	Data visualization components for project, resource utilization, and scheduling Gantt charts use this facet to specify the major and minor time axes in the Gantt chart. The time scale (`twoyears`, `year`, `halfyears`, `quarters`, `twomonths`, `months`, `weeks`, `twoweeks`, `days`, `sixhours`, `threehours`, `hours`, `halfhours`, `quarterhours`) can be set by the user using the menu bar **View** menu and the selection will be retained. Note that a custom time scale can also be named for this component value.
`dvt:timeSelector`	`explicitStart`, `explicitEnd`	Data visualization area, bar, combo, line, scatter, and bubble graph components use this child tag attribute to specify the explicit start and end dates for the time selector. Only value-binding is supported for this attribute. You will need to write code that allows the user to change this attribute value.

Runtime User Customization Use Cases and Examples

You can configure an application so that the value of the attributes listed in Table 52-1 can be persisted across sessions using the MDS repository. For example, if an application allowed persistence to the MDS repository, then a user could collapse the Payment Information box, as shown in Figure 52-2, and it would be collapsed the next time that user entered the application.

> **Note:**
>
> Before you can enable persistence to the repository, you must first follow all MDS configuration procedures as documented in Managing the MDS Repository of the *Administering Oracle Fusion Middleware*.

Along with the automatic persistence available through ADF Faces, you can create your own custom user customization capabilities for the following types of changes:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

If you want to create these types of custom user customizations, you need to add code (for example, in an event handler) that will call the APIs to handle the persistence.

Enabling an application to use the change persistence framework requires that you first enable your application to allow user customizations. Part of this process is determining where those changes should be persisted, either to the session or the MDS repository.

If you choose to persist changes to the session, by default all values as shown in Table 52-1 will be saved for the user's session. However if you choose to persist changes to a repository, you must explicitly configure which of these attribute values will be persisted to the repository. Instead of persisting all these attribute values, you can restrict changes so that only certain attribute value changes for a component are persisted, or so that only specific instances of the components persist changes.

> **Note:**
>
> You cannot persist changes to a component that is contained inside (anywhere in the subtree) of `af:forEach` or `af:iterator` tags using the `addComponentChange()` method. While such structure results in multiple copies of a component in the view tree, each component has only a single representation in the JSP document. However, the `addDocumentChange()` method does allow persistence for such components. See the discussion of the `DocumentChange` and `ComponentChange` classes in What You May Need to Know About the Change Persistence Framework API.

For any applications that persist changes to an MDS repository, when you deploy your application, you must create a metadata archive (MAR) profile in the application's EAR assembly. See How to Create Deployment Profiles.

Additional Functionality for Runtime User Customization

You may find it helpful to understand other features before you start working with user customizations. Following are links to other functionality that may be of interest.

- For information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see Managing the MDS Repository in *Administering Oracle Fusion Middleware*.
- The MDS framework allows you to create customizable applications that can be customized and subsequently deployed by a customer. See Customizing Applications with MDS .

Enabling Runtime User Customizations for a Fusion Web Application

In order to enable an ADF application to use the change persistence framework, you need to edit the web.xml and adf-config.xml files.

Enabling an application to allow user customizations (whether for the default changes that some ADF Faces components provide, or for custom capabilities that you create) requires that you configure your application to use the change persistence framework and that you also determine where those changes should be persisted (either the session or the MDS repository).

> **Note:**
>
> If you are planning on persisting changes to the MDS repository, before configuring an ADF Faces application to use change persistence, you must first follow all MDS configuration procedures as documented in Managing the MDS Repository of the *Administering Oracle Fusion Middleware*.

How to Enable User Customizations

You enable your application to use the change persistence framework by editing the `web.xml` and `adf-config.xml` files.

Before you begin:

It may be helpful to have an understanding of the features of runtime user customization. For more information, see Enabling Runtime User Customizations for a Fusion Web Application.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the **Studio Developer** role, and open (or create) the application in which you want to enable runtime user customization.

To enable user customizations:

1. In the Applications window, double-click the web project in your application.
2. In the Project Properties dialog, select the **ADF View** node.
3. On the ADF View page, select the **Enable User Customizations** checkbox. If you want the changes to be persisted to only the session, select the **For Duration of Session** radio button. If you want the changes to persist to the MDS repository, select **Across Sessions Using MDS**.
4. If you choose to persist to the repository, you now need to declare each component tag and associated attribute values that you want persisted to the repository (if you choose to persist only to the session, all values will be persisted).

   For procedures to accomplish this task, see Configuring User Customizations. Once that configuration is complete, you can override those settings on a per component instance basis. For procedures, see Controlling User Customizations in Individual JSF Pages.

   > **Note:**
   >
   > If you have created custom user customization capabilities as documented in Implementing Custom User Customizations, then you also need to declare those attribute values or operations.

What Happens When You Enable User Customizations

When you elect to save changes only to the session, JDeveloper adds the CHANGE_PERSISTENCE context parameter to the web.xml file, and sets the value to session. This context parameter registers the ChangeManager class that will be used to handle persistence. If you instead elect to save the changes to the MDS repository, the value is set to oracle.adf.view.rich.change.FilteredPersistenceChangeManager, as shown in the following example.

```
<context-param>
  <param-name>org.apache.myfaces.trinidad.CHANGE_PERSISTENCE</param-name>
  <param-value>
    oracle.adf.view.rich.change.FilteredPersistenceChangeManager
  </param-value>
</context-param>
```

> **Tip:**
>
> If needed, you can manually set this value to oracle.adf.view.rich.change.MDSDocumentChangeManager if you do not want any customizations to be restricted based on configurations in the adf-config.xml file or on the individual JSF pages, and you always want the changes to be persisted to the MDS repository and not the session.

When you elect to persist to the repository, JDeveloper also does the following:

- Adds the following JARs to the class path if they don't exist:
  - `javatools-nodep.jar`
  - `facesconfigmodel.jar`
  - `taglib.jar`
- Adds another context parameter to `web.xml` to register the `MDSJSPProviderHelper` class to handle merging MDS customization documents with the base JSP document, as shown in the following example.

  ```
  <context-param>
    <param-name>oracle.adf.jsp.provider.0</param-name>
    <param-value>oracle.mds.jsp.MDSJSPProviderHelper</param-value>
  </context-param>
  ```

- Adds the ADF Faces Change Manager Runtime 11 library to the project.
- In the `adf-config.xml` descriptor file, sets the `persistent-change-manager` element to the `MDSDocumentChangeManager`, which is the class that will be used to persist the changes. The following example shows the configuration for persisting to the MDS repository.

  ```
  <persistent-change-manager>
    <persistent-change-manager-class>
      oracle.adf.view.rich.change.MDSDocumentChangeManager
    </persistent-change-manager-class>
  </persistent-change-manager>
  ```

- Creates JSF JSP pages as XML documents. See Controlling User Customizations in Individual JSF Pages.

Additionally, when you elect to save the changes to the MDS repository, and you include facelets in your application, JDeveloper adds the `faceletCache` context parameter to the `web.xml` file. The value of this parameter is set to `oracle.adfinternal.view.faces.facelets.rich.MDSFaceletCache`, as shown in the following example.

```
<context-param>
  <param-name>com.sun.faces.faceletCache</param-name>

  <param-value>oracle.adfinternal.view.faces.facelets.rich.MDSFaceletCache</param-value>

</context-param>
```

The facelets cache enhances the performance of your application and the cache capacity can be configured in MDS on the server. See Managing the MDS Repository in *Administering Oracle Fusion Middleware*.

Configuring User Customizations

You can configure your ADF application to use any type of change persistence (the session or a repository). By default, the attribute values are persisted to the user's session. You must declare the attributes values if you choose to persist the changes to the repository.

If you choose to persist changes to an MDS repository, you must decide which of the attribute values that are by default persisted to the session (as shown in Table 52-1) should also be persisted to the repository. Alternatively, you can configure which changes you do not want persisted.

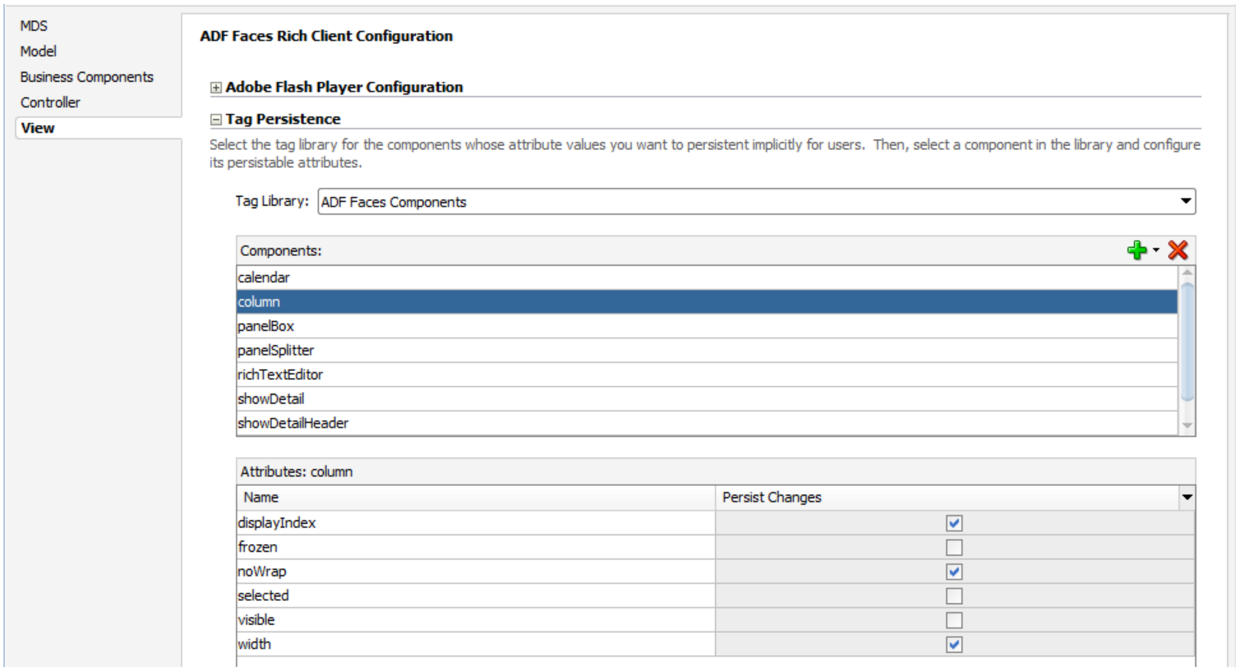
> **Tip:**
>
> Often, a system administrator is the one to set the configurations in the `adf-config.xml`. The `persist` and `dontPersist` attributes on a component allow page authors to override that setting as needed.

For example, suppose you decide that you don't want the value for the `width` attribute on columns to be persisted to the repository, but you do want all other default attribute changes for columns to be persisted. You must explicitly set the other default column values that you want to be persisted, and you also must explicitly configure the application to NOT persist the `width` attribute.

> **Note:**
>
> If you have created custom user customization capabilities as documented in Implementing Custom User Customizations, then you must explicitly declare those attribute values or operations as well.

You set (and unset) these values using the overview editor for the `adf-config.xml` file. Figure 52-3 shows the overview editor where only certain attribute values for the `column` component will be persisted.

Figure 52-3 Overview Editor for the adf-config.xml File



ADF Faces Rich Client Configuration

⊞ **Adobe Flash Player Configuration**

⊟ **Tag Persistence**

Select the tag library for the components whose attribute values you want to persistent implicitly for users. Then, select a component in the library and configure its persistable attributes.

Tag Library: ADF Faces Components

Components:
calendar
column
panelBox
panelSplitter
richTextEditor
showDetail
showDetailHeader

Attributes: column

Name	Persist Changes
displayIndex	☑
frozen	☐
noWrap	☑
selected	☐
visible	☐
width	☑

Once set, you can override persistence for a specific component on a page. For example, suppose you want to disallow change on the `width` attribute on only one table's columns. You want the rest of the tables in the application to persist changes to that attribute. You would configure the columns to globally persist changes to the `width` attribute, but then for that one table, you would override the global configuration directly on the JSF page. For more information, see Controlling User Customizations in Individual JSF Pages.

> **Note:**
>
> If you've enabled just session persistence, then all attribute values shown in Table 52-1 will be persisted to the session. There is no way to override this either globally or on an instance.

How to Configure Change Persistence

By default, when you configure your application to use any type of change persistence (that is, to either the session or a repository), the values of all attributes shown in Table 52-1 will always be persisted to the user's session. If you configured your changes to be persisted to a repository, then you must declare the attributes whose values should be persisted to that repository. If there are any values that you don't want persisted, then you need to configure those values as well.

Before you begin:

It may be helpful to have an understanding of how runtime user customization are persisted. For more information, see Configuring User Customizations.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the **Studio Developer** role, and open (or create) the application in which you want to enable runtime user customization.

To declare attribute value persistence to a repository:

1. In the Application Resources panel, expand the **Descriptors** and **ADF META-INF** nodes, and then double-click **adf-config.xml**.
2. In the overview editor, click the **View** navigation tab.
3. In the View page, in the **Tag Persistence** section, in the **Components** table, select the component whose changes you want to persist (or not persist) to the repository.

   If the component does not appear in the table, click the **Add** icon to select and add it.

> **Note:**
>
> The filter rules specified in the `adf-config.xml` file are applicable only when you have chosen to persist to the MDS repository (see How to Enable User Customizations). These rules do not apply for persistence within session scope.
>
> If persistence fails for any reason (for example if one of the filter rules fails or there are MDS repository errors), then the values will be stored only within the session scope.

The **Attributes** table displays all the attributes for the selected component whose values can be persisted.

4. In the **Attributes** table, select **Persist Changes** for each of the attributes whose values you want persisted. Deselect any if you do not want the values persisted.

> **Note:**
>
> If you are implementing custom user customizations (see Implementing Custom User Customizations), then you will need to edit the `adf-config.xml` manually to add the configuration. See What Happens When You Configure Change Persistence for an example on how to configure user customizations.

What Happens When You Configure Change Persistence

When you select the component tags and attribute values to be persisted in the `adf-config.xml` file, JDeveloper enters tag library information for the components and attributes that are to be persisted. The following example shows the entry for persisting the value of the `disclosed` attribute on the `panelBox` component.

```
<taglib-config>
  <taglib uri="http://xmlns.oracle.com/adf/faces/rich">
    <tag name="panelBox">
      <attribute name="disclosed">
        <persist-changes>
          true
        </persist-changes>
      </attribute>
...
    </tag>
  </taglib>
</taglib-config>
```

Controlling User Customizations in Individual JSF Pages

Using an ADF Faces component’s persist and dontPersist attributes, you can override any globally set persistence configuration for a component.

Once you have enabled your application to allow user customizations, you can control user customizations for specific components on the page.

By default, the framework persists changes for all component instances, based on the configuration in the `adf-config.xml` file. You can override this default behavior by explicitly setting what should be persisted and what should not be persisted on each component instance using the `persist` and `dontPersist` attributes.

> **Note:**
>
> The filter rules specified using the `persist` and `dontPersist` attributes are applicable only when you have chosen to persist to the MDS repository (see How to Enable User Customizations). These rules do not apply for persistence within session scope.
>
> If persistence fails for any reason (for example if one of the filter rules fails or there are MDS repository errors), then the values will be stored only within the session scope.

The following components support the `persist` and `dontPersist` attributes:

- `panelBox`
- `showDetail`
- `showDetailHeader`
- `showDetailItem`
- `column`
- `tree`
- `treeTable`
- `panelSplitter`
- `calendar`
- `dvt:projectGantt`
- `dvt:resourceUtilizationGantt`
- `dvt:schedulingGantt`
- `dvt:ganttLegend`
- `dvt:hierarchyViewer`
- `dvt:timeAxis`

How to Control User Customizations on a JSF Page

You can override any globally set persistence configuration for a component using its `persist` and `dontPersist` attributes.

> **Tip:**
>
> Often, a system administrator is the one to set the configurations in the `adf-config.xml`. The `persist` and `dontPersist` attributes allow page authors to override that setting as needed.

Before you begin:

It may be helpful to have an understanding of how runtime user customizations can be restricted on an individual page. For more information, see Controlling User Customizations in Individual JSF Pages.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the **Studio Developer** role, open the application, and open the page for which you want to modify user customization behavior.

To implement user customizations on a JSF Page:

1. In the Applications window, double-click the page that contains components that will be persisting changes.
2. If you want to persist all persistable attributes for a component:
   a. In the Properties window, expand the **Advanced** section.
   b. From the dropdown list for the **Persist** field, select **All Available**.
3. If you do not want to persist any attributes, repeat Step 2 for the **Don'tPersist** field.
4. If more than one attribute can be persisted for the component, and you do not want to persist all of them:
   a. In the Properties window, from the dropdown menu to the right of the **Persist** field, choose **Edit**.
   b. In the Edit Property dialog, shuttle any attributes to be persisted from **Available** to **Selected**.
5. If you do not want to persist an attribute value, repeat Step 4 for the **Don't Persist** field.

Note:

The filter rules specified using the `persist` and `dontPersist` attributes take precedence over any `adf-config.xml` configuration set for global component-level restrictions.

Values specified for the `dontPersist` attribute take precedence over values specified for the `persist` attribute. For example, if for a `panelBox` component you set `disclosed` as the value for both the `persist` and `dontPersist` attributes, the value of the `disclosed` attribute will not be persisted.

If you set the value of the `persist` or `dontPersist` attribute to `All Available`, then any values entered as choices using the Edit dialog and the shuttle will be ignored and all available attribute values will be persisted or not persisted.

What Happens at Runtime: How Changes are Persisted

When an application is configured to persist changes to the session, any changes made during the session are recorded in a session variable in a data structure that is indexed according to the view ID and the component's ID attribute value. Every time the page is requested, in the subsequent create View or Restore View phase, all changes are applied in the same order as they were added. This means that the changes registered through the session will be applied only during subsequent requests in the same session.

When an application is configured to persist changes to the MDS repository, any changes made during the session are recorded by mutating the Document Object Model that MDS maintains for the JSP document behind the view. A JSF phase listener registered by ADF controller triggers a commit on the MDS session during the appropriate lifecycle phase, resulting in the change document being persisted in the MDS store. Every time the page is requested, Oracle's JSP engine seeks the JSP document from an MDS JSP provider, which provides a flattened document after merging the stored changes to the base document. MDS records the change against the unique value of the component's ID attribute.

Tip:

If changes are applied in response to a partial submit of the page (for example, a `button` with the `partialSubmit` attribute set to `true`), the component for which changes are applied must be set as the value for the `partialTarget` attribute.

Additionally, be aware that when you run the application from JDeveloper in the Integrated WebLogic Server, MDS creates a local file-based repository to persist metadata customizations. In contrast, when the application is deployed to a test or production environment, customizations are persisted to the configured MDS repository. For more information about MDS repository configuration, see the *Administering Oracle Fusion Middleware*. For more information about deploying an application, see Deploying the Application.

What You May Need to Know About Using Change Persistence on Templates and Regions

How changes are persisted for components on templates or regions is handled differently, depending on whether the changes are persisted to the session or to the MDS repository. With session persistence, changes are recorded and restored on components against the `viewId` for the given session. As a result, when the change is applied on a component that belongs to a region or page template, that change is applicable only in scope of the page that uses the region or template. It does not span all pages that consume the region or template.For example, suppose you have `pageOne.jspx` and `pageTwo.jspx`, and they both contain the region defined in `region.jsff`, which in turn contains a `showDetail` component. When `pageOne.jspx` is rendered and the `disclosed` attribute on the `showDetail` component changes, the implicit attribute change is recorded and will be applied only for `pageOne.jspx`. If the user navigates to `pageTwo.jspx`, no attribute change is applied.

When you persist changes to the MDS repository, MDS records and restores customizations for a document identified by a combination of the JSP page path and customization name/value configuration setting as set on the customization class (for more information, see Customization Classes). As a result, for a given page that is rendered, when MDS applies a change on a component within a region or template, it is applicable for all pages that consume the region or template and that have the same customization name and value as the source page.

In the previous example, assume that the `showDetail` component uses the ID of `myShowDetail`. When `pageOne.jspx` is rendered and the `disclosed` attribute on the `showDetail` component changes, the attribute change is recorded for `region.jsff` (and not the page that consumes it). This change is applied when any page that contains the region is rendered, as long as the ID remains the same.

Implementing Custom User Customizations

Apart from the in-built user customization capabilities present in specific ADF Faces components, the change persistence framework allows you to create your own custom user customization capabilities.

In addition to the user customization capabilities built in to certain ADF Faces components, you can create your own custom user customization capabilities. The change persistence framework supports the following types of user customizations:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

To create custom user customizations, you must create a customization class for each type of user customization and then configure your application to use that class. You also need to set up the layers of customization for your application. For more information about both of these procedures, see Developing a Customizable Application.

Once those prerequisites are satisfied, you add logic that calls methods on the ADF Faces classes that handle persisting change either to the session or the MDS repository. To handle the change, you create code that uses the APIs from one of the ADF Faces specialized component change classes. For most cases, you add this code to the event handler method on a managed bean associated with the page the persisting component is on. If you want all instances of a component to persist the same change, you need to add this code for each page on which that component appears.

If you are creating a custom component, you can implement user customizations for the component by adding code directly to the custom component class. In that case, you will need to add the code only to the component class, and not once for each instance of the component. See Creating Implicit Change Persistence in Custom Components.

What You May Need to Know About the Change Persistence Framework API

To better understand what you need to do to create custom user customizations, it may help to have a deeper understanding of the change persistence and MDS frameworks. When you elect to persist changes to the MDS repository, the change persistence framework works in conjunction with the MDS framework. Where and how the customizations are saved are determined by how you set up your MDS repository, your customization layers, and your customization classes. Details about the MDS framework and the repository and how to use it are covered in Customizing Applications with MDS .

The change persistence framework uses the underlying change manager classes from Apache MyFaces Trinidad (in the `org.apache.myfaces.trinidad.change` package) along with a few ADF Faces-specific classes (in the `oracle.adf.view.rich.change` package). The instance of the registered `ChangeManager` class is accessible through the `RequestContext` object. It is responsible for gathering changes as they are created and added during a request, and then persisting them. The `SessionChangeManager` class is an implementation of `ChangeManager` which handles persistence within a session only, while the `MDSDocumentChangeManager` class is an implementation that persists to the MDS repository only. The `FilteredPersistenceChangeManager` class is an implementation of `ChangeManager` that stores the changes that pass the filter rules into the repository using the registered persistence change manager. Any change that does not get persisted to the repository will be persisted to the session when `FilteredPersistenceChangeManager` is used.

Additional classes are used to describe the changes to a component. You use these APIs to handle persisting any changes to components other than the implicit value changes the ADF Faces framework provides (as shown in Table 52-1). `ComponentChange` is the base class for all classes used to implement specific changes that act on the JSF component hierarchy, such as adding or removing a facet or a child component. These changes are automatically applied during subsequent creation of the view, in the same order in which they were added. Classes that extend the `ComponentChange` class and that also implement the `DocumentChange` interface can directly persist changes to the MDS repository. Classes that do not implement the `DocumentChange` interface can persist changes only to the session.

Table 52-2 describes the specialized classes that handle specific customizations. If "yes" appears in the Repository column, then the class implements the `DocumentChange` interface and it can persist changes to the MDS repository.

Table 52-2 Classes Used to Handle Change Persistence

Class Name	Repository	Description
`AddChildDocumentChange` `AddComplexChildDocumentChange`	Yes Yes	Adds a child or complex child (`dvt:`) component using document mark up. While applying this change, the child or complex child component is created and added to the document.
`AddComplexChildAttributeChange`	Yes	Adds a complex child (`dvt:`) component attribute.
`AttributeComponentChange` `ComplexAttributeComponentChange`	No Yes	Changes the value of an attribute.
`AttributeDocumentChange` `ComplexAttributeDocumentChange`	Yes Yes	Changes the value of a facet attribute.
`MoveChildComponentChange`	Yes	Moves a child from one container to another.
`RemoveChildComponentChange`	Yes	Removes a child component.
`RemoveComplexChildAttributeComponentChange` `RemoveComplexChildAttributeDocumentChange`	Yes Yes	Removes a complex child (`dvt:`) component attribute.
`SetFacetChildComponentChange`	No	Adds a child component to the facet using a document markup. While applying this change, the markup will be added to the document.
`SetFacetChildDocumentChange`	Yes	Adds a child component to a facet. While applying this change, the DOM element corresponding to the child component is added to the document. If the facet doesn't exist, it will be created. If the facet does exist, all of its content will be removed and the new content added.
`RemoveFacetComponentChange`	Yes	Removes a facet.
`ReorderChildrenComponentChange`	Yes	Reorders children of a component.

Aside from a ChangeManager class, you may also need to implement and register the `DocumentChangeFactory` interface with the `ChangeManager` class. If the `DocumentChangeFactory` implementation can provide an equivalent `DocumentChange` for a `ComponentChange`, the `ChangeManager` will use it to persist the `DocumentChange` to the repository.

How to Create Code for Custom User Customizations

You need to add code to handle any explicit changes you want to create, and to configure the components on the JSF page to handle customization. As with the default user customizations, you also must register the custom changes in the `adf-config.xml` file.

> **Note:**
>
> When the changes are expressible in more than one form, the change must be recorded in the form with highest precedence. For example:
>
> - Attribute change for a component: The attribute can be specified on the component tag or it can be expressed using the `<f:attribute>` tag. In a JSF JSP document, `<f:attribute>` takes lesser precedence over the attribute specified on the component tag. Therefore, the attribute change on the component tag will be recorded for customization.
> - Column header text in a column component: The header text for the column can be specified using either the `headerText` attribute or using header facet. In this case, the facet component will have precedence.

Before you begin:

It may be helpful to have an understanding of the features of custom runtime user customization. For more information, see Implementing Custom User Customizations.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the **Studio Developer** role, open the application, and open the page for which you want to modify user customization behavior.

To create custom user customizations:

1. Create a managed bean for the page that contains the component, as described in Using a Managed Bean in a Fusion Web Application.

   For more information regarding managed beans and how they are used as backing beans for JSF pages, see the "Creating and Using Managed Beans" section in *Developing Web User Interfaces with Oracle ADF Faces*.

2. Add code to the event handler method for the component that will be used to make the change. This code should obtain the component that contains the change. It should then use the component and the appropriate APIs to create, record, and persist the change.

   The following example shows the code on the action event handler for a command button for a change that will be persisted to the MDS repository. When a user clicks the button, that source graphic file changes. The event handler method accesses the component and changes the source attribute for the graphic. It then calls the private `addAttributeChange` method, which first uses the component API to record the change, and then uses the `AttributeComponentChange` class to set the new source attribute value.

   ```
   public void modifyObjectImage(ActionEvent event) {
          UIComponent uic = event.getComponent().findComponent("oi1");
          String source = "/images/mediumAd.gif";
          uic.getAttributes().put("source", source);
          _addAttributeChange(uic, "source", source);
       }
   . . .
   private static void _addAttributeChange(UIComponent uic, String attribName,
   ```

```
                                                     Object attribValue) {
        FacesContext fc = FacesContext.getCurrentInstance();
        ChangeManager cm =
             RequestContext.getCurrentInstance().getChangeManager();
        ComponentChange cc =
             new AttributeComponentChange(attribName, attribValue);
        cm.addComponentChange(fc, uic, cc);
     }
```

> **Note:**
>
> When you persist changes, in addition to explicitly recording a change on the component (which is done in the example above using `uic.getAttributes().put("source", source)` method), you must also directly apply the change using the component API, as was done using the private `_addAttributeChange(uic, "source", source)` method. Applying the change in this way allows the user to see the change in response to the same request. If the change is recorded on the component, then the change will not be seen until a subsequent request.
>
> Additionally, if you know that the component will always persist to the repository regardless of any restricted change persistence settings, you can instead call the `AdfFacesContext.getCurrentInstance().getPersistentChangeManager()` method.

3. The `ChangeManager` class provides support for automatically converting an `AttributeComponentChange` into an `AttributeDocumentChange`, thereby allowing persistence to a repository. However, if you need to convert another type of change and you use a specialized change manager class that does not implement the `DocumentChange` class, you need to create a custom `DocumentFactory` implementation that converts the component change to a document change.

> **Note:**
>
> Automatic conversion of `AttributeComponentChange` into an `AttributeDocumentChange` assumes that the component attribute is represented as an attribute of the same name on the associated element in the JSPX document.
>
> Only those attribute values that are expressible in the JSPX document can be persisted using `AttributeDocumentChange`. In other words, `CharSequence`, `Number`, `Boolean` and `ValueExpression` are the only supported data types.
>
> Only values that implement `java.io.Serializable` can be persisted using `AttributeComponentChange`.

4. If you create a custom `DocumentFactory` implementation, you need to register it with the appropriate change manager class using the following method in your bean:

```
public static void registerDocumentFactory(String targetClassName,
                                           String converterClassName)
```

Where targetClassName is the name of the ComponentChange class and converterClassName is the name of your DocumentChangeFactory extension that is capable of converting the target ComponentChange into a DocumentChange. The semantics of name for these classes is same as that of getName() in the java.lang.Class class.

5. If the class you use to create the component change adds a child that has a subtree of components, and you want to persist the changes to the repository, you must create a DocumentFragment to represent the change.

   The following example shows how to use the AddComponentDocumentChange specialized class to create a DocumentChange object and use a DocumentFragment to represent the change.

```
public void appendChildToDocument(ActionEvent event)
{
  UIComponent eventSource = event.getComponent();
  UIComponent uic = eventSource.findComponent("pg1");
  // only allow the image to be added once
  if (_findChildById(uic,"oi3") != null)
    return;
  FacesContext fc = FacesContext.getCurrentInstance();
  DocumentFragment imageFragment = _createDocumentFragment(_IMAGE_MARK_UP);
  DocumentChange change = new AddChildDocumentChange(imageFragment);
  ChangeManager apm = RequestContext.getCurrentInstance().getChangeManager();
  apm.addDocumentChange(fc, uic, change);
}
 private static final String _IMAGE_MARK_UP =
 "<af:objectImage id='oi3' height='100' width='120' " +
     "source='http://www.somewhere.com/someimage.jpg' " +
     "xmlns:af='http://xmlns.oracle.com/adf/faces'/>";

private static DocumentFragment _createDocumentFragment(
    String markUp)
{
 // prepend XML declaration
  markUp = "<?xml version = '1.0' encoding = 'ISO-8859-1'?>" + markUp;
  DocumentBuilderFactory factory = DocumentBuilderFactory.newInstance();
  factory.setNamespaceAware(true);
  factory.setValidating(false);
  DocumentBuilder builder;
  try
  {
    builder = factory.newDocumentBuilder();
  }
  catch (ParserConfigurationException pce)
  {
    _LOG.log(Level.WARNING, "Unable to get XML Parser:", pce);
     return null;
  }
  try
  {
    // use a version explicitly with ISO-8859-1 instead
    byte[] markupBytes = markUp.getBytes();
    Document newDoc = builder.parse(new ByteArrayInputStream(markupBytes));
    DocumentFragment fragment = newDoc.createDocumentFragment();
    // add the document's root element to the fragment
    fragment.appendChild(newDoc.getDocumentElement());
    return fragment;
  }
  catch (SAXException se)
  {
    _LOG.log(Level.WARNING, "Unable to parse markup:" + markUp, se);
    return null;
  }
  catch (IOException ioe)
  {
    _LOG.log(Level.WARNING, "IO Problem with markup:" + markUp, ioe);
    return null;
  }
}
```

6. Register the user customizations in the `adf-config.xml` file, as documented in Configuring User Customizations. If the custom changes are of any type other than `AttributeDocumentChange`, you will need to manually edit the `adf-config.xml` file and indicate that all changes are allowed for the component, as shown in the following example.

   ```
   <tag name="inputText">
     <attribute name="label">
       <persist-changes>true</persist-changes>
     </attribute>
     <persist-operations>ALL</persist-operations>
   </tag>
   ```

Creating Implicit Change Persistence in Custom Components

Changes are persisted as component changes in the session. Attribute changes are handled by ADF Faces runtime code. Implicit change persistence applies to component specific list of attributes.

When you create a custom component, you may decide that you want certain attribute values on that component to be persisted whenever change persistence is enabled in an application. Setting implicit change on a custom component is similar to setting explicit change persistence on existing components. You add code that executes the actual persistence, but instead of you placing that code on a managed bean, that code can be handled directly by the component class. If your component's attribute values are synchronized with the server using events, then you can use the broadcast method to persist the changes. If the attribute value that you want to persist does not use events, then you need to add code in the renderer and component class.

How to Set Implicit Change Persistence For Attribute Values that Use Events

When an attribute value uses events, you need to add code to the component class.

Before you begin:

It may be helpful to have an understanding of how persistence is implemented in custom components. For more information, see Creating Implicit Change Persistence in Custom Components.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the **Studio Developer** role, and open the application.

To set implicit change persistence for attribute values that use events:

1. In the Applications window, double-click the custom component class Java file.
2. Add code to the broadcast method that will use the specialized class to create a new ComponentChange object and then call the ChangeManager to add the change.

   The following example shows the code added to the UIXShowDetail class that persists a change to the disclosed attribute. In this case, the AttributeComponentChange class is used.

```
public class UIXShowDetail extends UIXComponentBase
{
  ...
  public void broadcast(FacesEvent event) throws AbortProcessingException
  {
    super.broadcast(event);
    ...
    if (event instanceof DisclosureEvent)
    {
      boolean isDisclosed = ((DisclosureEvent) event).isExpanded();
      setDisclosed(isDisclosed);
      //Record a Change for 'disclosed' attribute
      AttributeComponentChange aa =
       new AttributeComponentChange('disclosed', isDisclosed ?
Boolean.TRUE : Boolean.FALSE);
      AdfFacesContext adfContext = AdfFacesContext.getCurrentInstance();
      adfContext.getChangeManager().addComponentChange(getFacesContext(),
this, aa);
      ...
    }
  }
  ...
```

How to Set Implicit Change Persistence For Other Attribute Values

When an attribute does not use events, you need to place code in the component's renderer class.

Before you begin:

It may be helpful to have an understanding of how persistence is implemented in custom components. For more information, see Creating Implicit Change Persistence in Custom Components.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the **Studio Developer** role, and open the application.

To set implicit change persistence for other attribute values:

1. In the Applications window, double-click the custom component's render class Java file.

2. Use the `findTypeConstants` method, which takes a `ClientMetadata` instance and use the `addPersistedProperty` method to mark certain properties as persisted. The following example shows code from the renderer class used for the ADF Faces `PanelSplitter` component, which implicitly persists the `splitterPosition` attribute value.

```
// Code from PanelSplitterRenderer.java
protected void findTypeConstants(
    FacesBean.Type type,
    ClientMetadata metadata)
  {
    super.findTypeConstants(type, metadata);
    metadata.addRequiredProperty(
      _orientationKey = type.findKey("orientation"));
    metadata.addRequiredProperty(
      _positionedFromEndKey = type.findKey("positionedFromEnd"));
    metadata.addRequiredProperty(
      _disabledKey = type.findKey("disabled"));
    metadata.addRequiredProperty(
      _splitterPositionKey = type.findKey("splitterPosition"));
    metadata.addPersistedProperty(_splitterPositionKey);
  }
```

3. In the JavaScript component peer class, define the attribute value to be persisted, using the `setProperty` function. This function needs to be invoked with the attribute name (as defined in the renderer in the previous step), the value, and "`true`", meaning the value of the attribute will be set. The following example shows code from the `panelSplitter` class that sets the splitter position.

```
// Code from AdfDhtmlPanelSplitterPeer.js file where we set the
   splitter position

  var component = this.getComponent();
 component.setProperty("splitterPosition",position, true);
// position is the value to be set
```

53 Using the Active Data Service

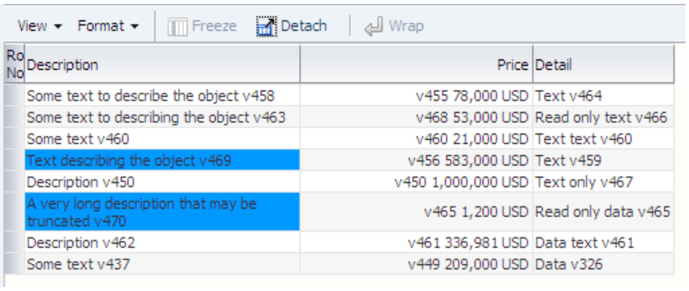
This chapter describes how to work with the ADF Model layer and Active Data Service (ADS) to provide real-time updates to ADF Faces components.
This chapter includes the following sections:

About the Active Data Service

ADF Faces provides a mechanism called Active Data Service (ADS) that allows us push changes from the server to the client. Through ADS, you can inform the browser about the fact that changes are available.

The Fusion technology stack includes Active Data Service (ADS), which is a server-side push framework that allows you to provide real-time data updates for ADF Faces components. You bind ADF Faces components to a data source and ADS pushes the data updates to the browser client without requiring the browser client to explicitly request it. For example, you may have a table bound to attributes of an ADF data control whose values change on the server periodically, and you want the updated values to display in the table. You can configure your application and the component so that whenever the data changes on the server, the ADF Model layer notifies the component and the component rerenders the changed data with the new value highlighted, as shown in Figure 53-1.

Figure 53-1 Table Displays Updated Data as Highlighted



Ro No	Description	Price	Detail
	Some text to describe the object v458	v455 78,000 USD	Text v464
	Some text to describing the object v463	v468 53,000 USD	Read only text v466
	Some text v460	v460 21,000 USD	Text text v460
	Text describing the object v469	v456 583,000 USD	Text v459
	Description v450	v450 1,000,000 USD	Text only v467
	A very long description that may be truncated v470	v465 1,200 USD	Read only data v465
	Description v462	v461 336,981 USD	Data text v461
	Some text v437	v449 209,000 USD	Data v326

Active Data Service Use Cases and Examples

Using ADS is an alternative to using automatic partial page rendering (PPR) to rerender data that changes on the backend as a result of business logic associated with the ADF data control bound to the ADF Faces component. Whereas automatic PPR requires sending a request to the server (typically initiated by the user), ADS enables changed data to be pushed from the data store as the data arrives on the server. Also, in contrast to PPR, ADS makes it possible for the component to rerender only the changed data instead of the entire component. This makes ADS ideal for situations where the application needs to react to data that changes periodically.

To use this functionality, you must configure the application to use ADS. If your application services do not support ADS, then you also need to create a proxy of the service so that the components can display the data as it updates in the source.

Any ADF Faces page can use ADS. However, you can configure only the following ADF Faces components and ADF Data Visualization (DVT) components to work with active data:

- `activeImage`
- `activeOutputText`
- `chart` (all types)
- `gauge` (all types)
- `pivotTable`
- `tree`
- `treeTable`
- `geoMap` (`mapPointTheme` only)
- `sunburst`
- `treemap`

For specific information about ADS support for DVT components, see Active Data Support in *Developing Web User Interfaces with Oracle ADF Faces*.

Additionally, note that collection-based components (such as `table`, `tree`, and `pivotTable`) support ADS only when the `outputText` component or `sparkChart` is configured to display the active data; other components are not supported inside the collection-based component.

Limitations of the Active Data Service Framework

The framework for ADS has the following limitations.

- ADS does not support active data on ADF Faces table components with filtering enabled. Once a table is filtered at runtime, active data cannot be displayed.
- ADS does not time out from user inactivity by default. To ensure that an active session is not maintained indefinitely, you can configure the `web.xml` context-parameter `oracle.adf.view.rich.poll.TIMEOUT` to specify how long ADS should run before it times out from user inactivity. For more information, see How to Configure Session Timeout for Active Data Service.

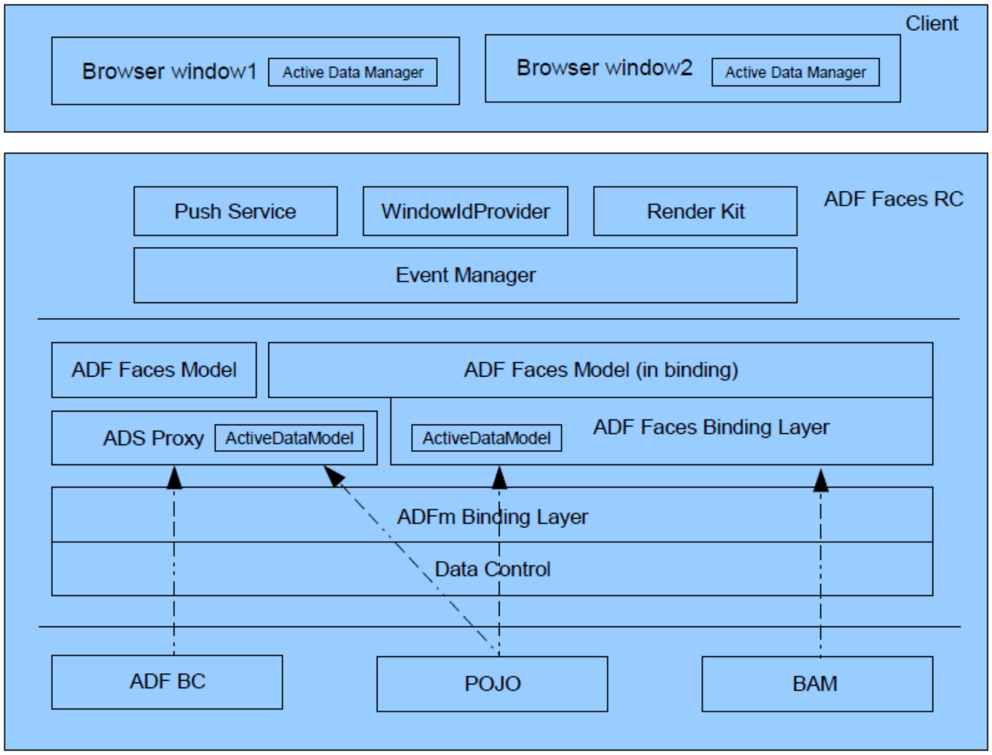
- ADS does not restart if the user attempts to navigate away from the browser page and then chooses to stay on the page by canceling the exit action in the browser-displayed warning dialog. To workaround this limitation, ADF Faces provides client listener support to handle `beforeunload` events for browsers that support displaying a Confirm on Page Exit dialog. The ADF document that handles this event will allow the user to cancel the exit before ADS stops processing.
  For more information, see What You May Need to Know About Navigating Away From the ADS Enabled Page in *Developing Web User Interfaces with Oracle ADF Faces*.
- ADS executes on a non-request thread and does not support the forced execution of component-level EL expressions. Therefore EL expressions on ADF Faces components that you may use to calculate component properties (such as fill color in a chart configured to use active data) will not be executed when the component value is updated by ADS. To execute EL in this scenario, you should calculate the property value in the model and use EL to bind the component property to the model. Alternatively, your page may apply JavaScript inline to apply the property value change after the active data update occurs. This latter solution effectively forces ADF Faces to rerender the component.

> **Note:**
>
> The ADF DVT components may impose additional limitations. For details, see Active Data Support in *Developing Web User Interfaces with Oracle ADF Faces*.

Active Data Service Framework

The framework for ADS contains a number of components that work together to send the active data from the source to the UI component. When a data event occurs, if the associated ADF Model layer binding is configured for active data, the Active Data model delivers the data to the Event Manager. The Event Manager then retrieves the data and invokes the Push Service, which delivers the data to the correct component, based on how the service is configured (for more information, see Data Transport Modes). The component then applies the new data pushed from the server. Figure 53-2 shows the ADS framework.

Figure 53-2 Active Data Service Framework



In order to use the Active Data Service, you need to have a data store that publishes events when data is changed, and you need to create business services that react to those events. By default, **ADF Business Components** does not react to data events. The Active Data Proxy framework allows all types of data sources, including ADF Business Components, to work with ADS. It combines the `ActiveDataModel` with the JSF model, so that you need to override functionality only on this proxy rather than on both the `ActiveDataModel` and the JSF model.

The following comprise the ADS framework:

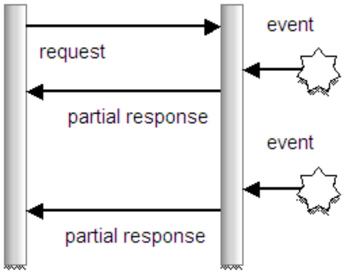
- `ActiveDataModel` interface: Abstraction of the active data model. Its responsibilities include:
  - Starting and stopping active data
  - Keeping track of the current active data event ID
  - Letting the renderer know whether the model needs active data or not.
- Event Manager: A server-side component that works with the ADF Model layer. It is responsible for the following:
  - Listening to binding events
  - Retrieving active data
  - Managing active data encoding
  - Invoking the Push service to send the encoded active data

- Push service: A delivery channel that interacts with the Event Manager on the server side and with the Active Data Manager on the client side. It provides the following:
  - Establishing and maintaining the connection between the server and the client
  - Transmitting the active data over this connection from the server to the client
  - Ensuring that active data gets delivered within desired parameters and forcing component update if not
- Active Data Manager: A client-side component that distributes the active data to the correct component. Specifically, it is responsible for the following;
  - Delivering events from the server side that are coming through the channel, using an event delivery service
  - Handling multiple browser windows through a shared channel
  - Dispatching active data events to rich client components, so that the components can render the change accordingly
- Active Data Proxy: A proxy that allows all types of data sources to enable push functionality. Specifically, the proxy is responsible for the following:
  - Implementing and delegating `ActiveDataModel` functionality
  - Delegating to JSF models
  - Listening to data change events from the data source
  - Generating active data events based on the data change events

Data Transport Modes

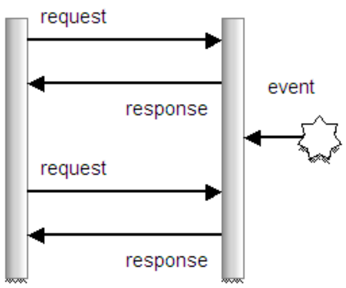
Active data is sent to the client using data streaming (push) or one of two types of data polling. With data streaming, there is only one request, which stays open. When a data change event occurs, a partial response is sent (the response is not closed), the client is notified, and the associated component is updated to show the new data, as shown in Figure 53-3.

Figure 53-3 Streaming Mode



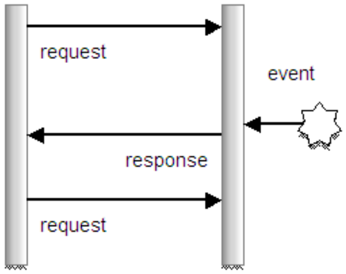
With data polling, the application is configured to poll the data source at specified intervals, as shown in Figure 53-4. With each request, a response is sent and closed, whether or not a data change event has occurred. If the data has changed, then the client is notified and the component is updated.

Figure 53-4   Poll Mode



Long polling is similar to streaming. When the page is rendered, a request is sent to the active channel. However, a response is not returned until there is a data change event. At that point, the connection is closed. As soon as the connection is closed, a new connection is initiated, which results in the connection being active most of the time: there are no specific intervals. Long polling results in the majority of data change events being received when they occur, because the connection is already established and ready to send a response to the client, as shown in Figure 53-5. See What You May Need to Know About Configuring an ADS Transport Mode.

Figure 53-5   Long Polling Mode



To use ADS, you need to configure your application to determine the method of data transport, as well as other performance options.You also need to configure the bindings for your components so that they can use ADS. If you are using ADF Business Components, you need to modify your model to implement the `ActiveModel` interface to register itself as the listener for active data events using the Active Data Proxy.

Configuring the Active Data Service

The adf-config.xml file is used to configure ADS. You can configure your ADF application and the component so that whenever the data changes on the server, the component is notified and rerenders with the new value highlighted. ADS can use any of the three modes to determine active data to the component: streaming, polling, or long polling.

You need to configure ADS to determine the data transport mode, as well as to set other configurations, such as a latency threshold and reconnect information.

> **Note:**
>
> If you enable ADS but do not configure it, the ADS framework will use the default values shown in Table 53-1.

How to Configure the Active Data Service

Configuration for running the Fusion web application with ADS in JDeveloper and Integrated WebLogic Server is done in the `adf-config.xml` file. For information about the `adf-config.xml` file, including how to create one if you need to, see the Configuration in adf-config.xml section of *Developing Web User Interfaces with Oracle ADF Faces*.

> **Note:**
>
> To support automatic replication and failover for web applications within a clustered environment, Oracle WebLogic Server supports mechanisms for replicating HTTP session state across clusters. You can configure **Oracle Application Development Framework** (Oracle ADF) to ensure the Fusion web application's state can be restored from any server in the cluster. To support failover for pages configured to display active data, it is necessary to enable failover for the ADF Business Components **application module** and to enable ADF Controller to track changes to the ADF memory scopes. With these ADF settings configured, when failover occurs, the ADF server will detect the failover and request all pages configured to display active data to refresh themselves, after that ADS restarts and data is pushed to the client. For details about how to enable failover for the Fusion web application in a high availability environment, see Configuring Oracle ADF for High Availability.

Before you begin:

It may be helpful to have an understanding of the ADS configuration choices. See Configuring the Active Data Service and What You May Need to Know About Configuring an ADS Transport Mode.

You may also find it helpful to understand functionality that can be added using other **Oracle ADF** features. See About the Active Data Service.

To configure the Active Data Service:

1. In the Application Resources panel, expand the **Descriptors** and **ADF Meta-INF** nodes, and then double-click **adf-config.xml**.
2. Click the **Source** tab to open the file in the source editor, and create an entry for each of the elements shown in Table 53-1.

Table 53-1 ADS Configuration Elements in adf-config.xml

Element	Description	Default Value (in milliseconds)	Minimum Value (in milliseconds)
`<transport>`	The method by which data will be delivered to the client. Value values are: • `streaming` (default) • `polling` • `long-polling`		
`<latency threshold>`	Latency threshold in milliseconds. Active data messages with network delays greater than this threshold will be treated as late.	10000	1000
`<keep-alive-interval>`	Frequency in milliseconds for sending keep-alive messages when no events are generated.	10000	5000
`<polling-interval>`	When `<transport>` set to `polling`, frequency in milliseconds of the poll request.	5000	1000
`<max-reconnect-attempt-time>`	Maximum period of time in milliseconds a client will attempt to reconnect the push channel to the server upon getting disconnected.	1800000 (30 minutes)	0
`<reconnect-wait-time>`	Time interval in milliseconds to wait between reconnect attempts.	10000	1000

Performance Tip:

Keep the following in mind when configuring the ADS.

- Set the latency threshold to more than 1000 to avoid frequent component refreshing.
- Set the keep-alive interval and reconnect wait time to be less than the browser's keep-alive timeout.
- Set the max reconnect time to be less than your web server's session timeout.

The following example shows a sample configuration that has content pushed to the client.

```
<?xml version="1.0" encoding="utf-8" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
            xmlns:ads="http://xmlns.oracle.com/adf/activedata/config">
```

```
    <ads:adf-activedata-config xmlns=
                          "http://xmlns.oracle.com/adf/activedata/config">
      <transport>streaming</transport>
      <latency-threshold>5000</latency-threshold>
      <keep-alive-interval>10000</keep-alive-interval>
      <max-reconnect-attempt-time>90000</max-reconnect-attempt-time>
      <reconnect-wait-time>8000</reconnect-wait-time>
    </ads:adf-activedata-config>
  </adf-config>
```

3. Synchronize the clocks on the data server and on the application server. If these are not synchronized, then events may appear to ADS to have occurred in the future.

What You May Need to Know About Configuring an ADS Transport Mode

ADS can use one of three transport modes to deliver active data to the component: streaming, polling, or long polling.

When you configure ADS to use the streaming mode, data is pushed to the client whenever a change event is raised by the data. On the client side, after the push channel is established, if there is no activity within the time of the value for the `latency-threshold` element plus the `keep-alive-interval`, an `establish-channel-request` will be sent out repeatedly based on the value of the `reconnect-wait-time` element, until the amount of time passed reaches the value of the `max-reconnect-attempt-time` element. After that, the connection will be considered disconnected. For example, given the values shown in How to Configure the Active Data Service, if there is no activity in 15,000 milliseconds, an establish channel request will be sent out every 8,000 milliseconds for up to 90,000 milliseconds. After that, the connection will be considered disconnected.

On the server side, the server disconnects the push channel and starts a timer to clean up with a `cleanup-delay-time` when there is an empty active data message or when it fails to send out an active data message. The `cleanup-delay-time` is calculated as `max-reconnect-attempt-time` + 30 * 1000 ms. Its default value is 30 minutes.

When you configure ADS to use the polling mode, on the client side the polling request is scheduled to be sent out repeatedly after the value of the `polling-interval` element has been reached. If no response is received after the value of the `max-reconnect-attempt-time` has elapsed, the connection is treated as disconnected and no more requests will be sent. After receiving a polling response, if the time the response has taken is greater than the `polling-interval` element, the service sends the next request out right away. If it is less, the next request will be sent as scheduled.

For the server side, the session ends after the polling response is returned. At that point, a timer with a `cleanup-delay-time` is set up to trigger cleanup. If a new request comes in before the timer fires, the old timer is canceled, and new timer is created.

When you configure ADS to use the long polling mode, requests are made as they are in streaming mode; however, as soon as the connection is treated as disconnected, a new connection is initiated. The result is a significant reduction in latency.

Table 53-2 compares the three different modes.

Table 53-2 Comparison of Streaming, Polling, and Long-Polling Modes

Comparison Benchmark	Streaming	Polling	Long-Polling
Latency	Very good. Directly after an event occurs on the server side, a partial response is sent to the client. If there is another event, immediately, it is also sent as a partial response. There is almost no latency with this approach.	Poor, depending on the polling interval. If the polling interval is short (for example, 0.5 seconds), it will slow down the network because the connections are repeatedly opened. It is also expensive on the client- and server-side resources.	Good. However, when there is a new event immediately after a response has been closed, there is some latency until the new data appears on the client side. On average, this is not a problem.
HTTP Proxy	Poor. For some older servers, because the response is never released, when a proxy is sitting between client and server, it is possible that the proxy will buffer responses. This is an unfortunate optimization that prevents real-time data from flowing into the browser. Long polling should be used if a proxy is used.	Good.	Good.
Number of live connections	Poor. Many concurrent connections, as the stream is always live.	Good. Connections are live only during the actual poll. Note however that if there is a high polling rate then the number of concurrent connections will also be high.	Poor. Many concurrent connections, as the stream is almost always live.
Communication channel	`HTTP GET` This can result in the display of a "busy" cursor or the animation of a browser's "throbber" icon.	`XMLHttpRequest` (XHR) `HTTP GET`	`XMLHttpRequest` (XHR) `HTTP GET`

How to Configure Session Timeout for Active Data Service

By default, applications that you configure to use ADS will not time out. In polling mode, the client periodically sends polling request to server. In long polling mode, the client sends a new polling request immediately after a polling request is returned from the server. In steaming mode, the server holds the GET request response and will indefinitely write active data to it. Due to the behavior of each data transport mode, ADS will maintain the application session active whether or not the user interacts with the application.

To prevent this situation of maintaining an active session indefinitely due to ADS, the `web.xml` configuration file contains the `oracle.adf.view.rich.poll.TIMEOUT` context-parameter, which specifies how long ADS should run before it times out from user inactivity. The ADS client is considered eligible to time out if there is no keyboard or mouse activity. The default timeout period is set at ten minutes. So if the user remains inactive for ten minutes, that is, does not use the keyboard or mouse, then ADS will stop polling or will abort its connection with server, and from that point on, the application participates in the standard server-side session timeout. For example, if the server-side session timeout is 65 minutes, and the polling timeout parameter is set to 15 minutes, then it is expected that the session should expire when the user is inactive for more than 80 minutes.

You can override this timeout setting for a specific web page using the ADF Faces poll component `timeout` attribute. The poll component allows you to deliver a heartbeat to the server to prevent users from being timed out of their session for specific pages. For more information about the `oracle.adf.view.rich.poll.TIMEOUT` context-parameter and individual web pages, see the Using Polling Events to Update Pages section of *Developing Web User Interfaces with Oracle ADF Faces*.

Before you begin:

It may be helpful to have an understanding of the ADS configuration choices. For more information, see Configuring the Active Data Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see About the Active Data Service.

To configure the Active Data Service to timeout after session becomes inactive:

1. In the Applications window, in the user interface project, expand the **Web Content** and **WEB-INF** nodes, and then double-click **web.xml**.
2. In the overview editor for the `web.xml` file, click the **Application** navigation tab and in the Context Initialization Parameters section, click the **Create** icon to add the polling timeout parameter as follows:

   Name: Enter the context parameter `oracle.adf.view.rich.poll.TIMEOUT`.

   Value: Enter the amount of time in milliseconds after which all pages configured to use active data will time out and ADS will stop. To disable ADF time out due to user inactivity, enter `-1`. The default value for ADS to timeout is `600000` milliseconds (ten minutes).

Configuring Components to Use the Active Data Service

The process of configuring components to use Active Data Service (ADS) is dependent on the usage of the Active Data proxy. You can configure components to use ADS with or without the proxy.

How you configure components to use ADS depends on whether or not you must use the Active Data proxy. If your application uses a data store that publishes events when data is changed, and your business services react to those events (for example, if your application uses BAM), then you do not need to use the Active Data proxy.

If your business services do not react to those events (for example, if your application uses ADF Business Components), then you must use the Active Data proxy and follow different procedures for configuring your components.

> **Note:**
>
> If your business service requires the use of the Active Data proxy, then you can only use the following components with active data:
>
> - `table`
> - `tree`
> - `treeTable`
> - ADF Data Visualization `chart`, `gauge`, `mapPointTheme`, `pivotTable`, `pivotFilterBar`, `sunburst`, and `treemap` components

How to Configure Components to Use the Active Data Service Without the Active Data Proxy

To use ADS without the proxy, you need to set a value on the binding element in the corresponding page definition file.

Before you begin:

It may be helpful to have an understanding of the ADS configuration choices. For more information, see Configuring Components to Use the Active Data Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see About the Active Data Service.

To configure a component to display active data without the Active Data proxy:

1. From the Data Controls panel, drag and drop a collection onto a JSF page, and from the context menu, choose the desired component.
2. If you are dropping the collection as an ADF bound tree or tree table, you need to ensure the following:
   - That the binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
   - That the binding rule contains a single attribute.
   - That the table does not use filtering.
   - That the tree component's `nodeStamp` facet contains a single `outputText` tag and contains no other tags, as described in What You May Need to Know About Displaying Active Data in ADF Trees.
3. From the Application window, right-click the page and choose **Go to Page Definition**.

   The editor for the page definition file opens for the selected page.

4. In the Structure window, select the node that represents the attribute binding for the component.
5. In the Properties window, expand the **Advanced** section, and select **Push** from the **ChangeEventPolicy** dropdown menu.

> **Tip:**
>
> You can use the `statusIndicator` component to indicate the server state. For more information, see the Displaying Application Status Using Icons section of *Developing Web User Interfaces with Oracle ADF Faces*.

How to Configure Components to Use the Active Data Service with the Active Data Proxy

To use ADS with the proxy, you need bind the value of your component to decorator class that will use the proxy. For more information about this class, see Using the Active Data Proxy to set a value on the binding element in the corresponding page definition file.

Before you begin:

It may be helpful to have an understanding of the ADS configuration choices. For more information, see Configuring Components to Use the Active Data Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see About the Active Data Service.

To configure a component to display active data with the Active Data proxy:

1. From the Data Controls panel, drag and drop a collection onto a JSF page, and from the context menu, choose the desired component.
2. If you are using an ADF bound tree or tree table, you need to ensure the following:
   - That the binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
   - That the binding rule contains a single attribute.
   - That the table does not use filtering.
   - That the tree component's `nodeStamp` facet contains a single `outputText` tag and contains no other tags, as described in What You May Need to Know About Displaying Active Data in ADF Trees.
3. From the Application window, right-click the page and choose **Go to Page Definition**.

   The editor for the page definition file opens for the selected page.
4. In the Structure window, select the node that represents the attribute binding for the component.
5. In the Properties window, change the value attribute to be bound to a decorator class that you will create for use with the proxy.

   For more information, see Using the Active Data Proxy.

What You May Need to Know About Displaying Active Data in ADF Trees

When you create an ADF Faces tree (or tree table) component, you configure a nodeStamp facet, which is a holder for the component used to display the data for each node of the tree. Each node is rendered (stamped) once, repeatedly for all nodes.

Because of this stamping behavior, only certain types of components are supported as children inside an ADF Faces tree component. When the tree component is not bound to an active data source, all components that have no behavior are supported. However, when you configure the tree to use ADS, only the outputText component is supported inside of the nodeStamp facet, as shown in the following example. The nodeStamp facet must not contain any other tags. So, for example, active data will not work if you add panelGroupLayout tags to the nodeStamp facets of a tree configured to use ADS.

```
<f:facet name="nodeStamp">
  <af:outputText value="#{row.str2}"/>
</f:facet>
```

What Happens at Runtime: How Components Render When Bound to Active Data

After you configure your application and the component for ADS, whenever the data changes on the server, the component is notified and rerenders with only the changed data. In contrast, a component not configured for either active data or automatic PPR will need to be explicitly refreshed after a data change occurs. The explicit refresh will refetch all data that is visible on the client, including data that has not changed. Consequently, this will force the entire component to rerender. Additionally, when the component is bound to an active data source (with active data policy "Push"), the component rerenders with the new value highlighted.

What You May Need to Know About Running ADS in a Google Chrome Browser

When the Fusion web application runs in the Google Chrome web browser and a user presses Ctrl+N (or Ctrl+T) to open a new window (or tab) and then copies the URL from the original window into the new window, active data in the original window will stop streaming. According to the Google Chrome process model, the new browser window will be created in a separate process and both windows will share the same HTTP session. However, because browser windows that are created in two separate processes cannot communicate with each other, ADS will become out of sync between the client and server and will stop streaming. As a workaround, to allow active data in multiple Google Chrome windows, before copying the URL from the original window into the new window users must press Ctrl-Shift-N to open the browser window in incognito mode (private browsing). Because Ctrl-Shift-N opens the window in a separate process and a separate HTTP session, ADS will not attempt to synchronize between the windows and streaming will be unaffected.

Using the Active Data Proxy

In order to make business services react to events, you need to use the Active Data proxy in the ADF application. Certain procedures must be followed to configure components.

You use the active data proxy when your business services do not react to data events. If you want your components to update based on events passed into ADF Business Components, then you need to use the Active Data Proxy.

> **Tip:**
>
> If your application uses BAM for the business service, then you do not need to use the Active Data Proxy.

> **Note:**
>
> If your business service requires the use of the Active Data Proxy, then you can only use the following components with active data:
>
> - `table`
> - `tree`
> - `treeTable`
> - ADF Data Visualization `mapPointTheme`, `pivotTable`, `pivotFilterBar`, `sunburst`, and `treemap` components

How to Use the Active Data Proxy

You will create a Java class that subclasses one of the following decorator classes:

- `ActiveCollectionModelDecorator` class
- `ActiveGeoMapDataModelDecorator` class

These classes are wrapper classes that delegate the active data functionality to a default implementation of `ActiveDataModel`. The `ActiveDataModel` class listens for data change events and interacts with the Event Manager. Specifically, it does the following:

- Starts and stops the active data and the `ActiveDataModel` object, and registers and unregisters listeners to the data source.
- Wraps the JSF model interface. For example, the `ActiveCollectionModelDecorator` class wraps the `CollectionModel` class.
- Generates active data events based on data change events from the data source.
- Manages listeners from the Event Manager and pushes active data events to the Event Manager.

You need to implement methods on this Java class that registers itself as the listener of the active data source and gets the model to which the data is being sent.

Note:

The Active Data framework does not support complicated business logic or transformations that require the ADF runtime context, such as a user profile or security. For example, the framework cannot convert an ADF context locale-dependent value and return a locale-specific value.

As an example of complicated business logic, say you have logic that allows a user to move an order from `open` status to `pending`. This change results in an `update` event, which should cause the order to be removed from a data object called "Open Orders." The framework cannot handle this event type transformation based on business logic. Instead, you need to have your data source handle this before publishing the data change event.

Before you begin:

It may be helpful to have an understanding of the active data proxy. For more information, see Using the Active Data Proxy.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see About the Active Data Service.

You will need to complete this task:

Implement the logic to fire the active data events asynchronously from the data source. For example, this logic might be a business process that updates the database, or a JMS client that gets notified from JMS.

To use the active data service:

1. Create a Java class that extends the decorator class appropriate for your component. The following example shows a class created for a table.

```
package view;

import oracle.adf.view.rich.model.ActiveCollectionModelDecorator;
import oracle.adf.view.rich.activedata.ActiveDataEventUtil;
import oracle.adf.view.rich.activedata.JboActiveDataEventUtil;

/**
 * This code wraps the existing collection model in the page and implements
the
   ActiveDataModel interface to enable ADS for the existing page.
 */
public class DeptModel
  extends ActiveCollectionModelDecorator
{
}
```

2. Implement the method that returns the model. The following example shows an implementation of the `getCollectionModel()` method that relies on expression language (EL) to avoid needing to typecast to an internal class. The method returns the `DepartmentsView1` collection from the binding container.

```
public CollectionModel getCollectionModel()
{
   if (_model == null)
   {
       FacesContext fc = FacesContext.getCurrentInstance();
       Application app = fc.getApplication();
       ExpressionFactory elFactory = app.getExpressionFactory();
       ELContext el = fc.getELContext();

       // This is EL to avoid typecasting to an Internal class.
       ValueExpression ve = elFactory.createValueExpression(el,
                    "#{bindings.DepartmentsView1.collectionModel}",
Object.class);

       // Now GET the collectionModel
       _model = (CollectionModel)ve.getValue(el);
   }
   return _model;
}
```

3. Create an inner class that is your own implementation of an `ActiveDataModel` class, which the decorator can use to start and stop the active data and connect and disconnect from the data source. This class should also use the `changeCount` API to maintain data read consistency, as shown in the following example. For more information, see What You May Need to Know About Maintaining Read Consistency.

```
public class MyActiveDataModel extends BaseActiveDataModel
{
    protected void startActiveData(Collection<Object> rowKeys,
                                   int startChangeCount)
    {
      _listenerCount.incrementAndGet();
      if (_listenerCount.get() == 1)
      {
        System.out.println("start up");

        Runnable dataChanger = new Runnable()
        {
          public void run()
          {
            System.out.println("MyThread starting.");
            try
            {
              Thread.sleep(2000);
              System.out.println("thread running");
              triggerDataChange(MyActiveDataModel.this);
            }
            catch (Exception exc)
            {
              System.out.println("MyThread exceptioned out.");
            }
            System.out.println("MyThread terminating.");
          }
        };
        Thread newThrd = new Thread(dataChanger);
        newThrd.start();
      }
    }

    protected void stopActiveData(Collection<Object> rowKeys)
```

```
        {
          _listenerCount.decrementAndGet();
          if (_listenerCount.get() == 0)
          {
            System.out.println("tear down");
          }
        }

        public int getCurrentChangeCount()
        {
          return _currEventId.get();
        }

        public void bumpChangeCount()
        {
          _currEventId.incrementAndGet();
        }

        public void dataChanged(ActiveDataUpdateEvent event)
        {
          fireActiveDataUpdate(event);
        }

        private final AtomicInteger _listenerCount = new AtomicInteger(0);
        private final AtomicInteger _currEventId = new AtomicInteger();
    }
```

4. Implement the method that will return the `ActiveDataModel` class, as shown in the following example.

```
public ActiveDataModel getActiveDataModel()
  {
    return _activeDataModel;
  }
```

5. Create a method that creates application-specific events that can be used to insert or update data on the active model.

   The following example shows the `triggerDataChange()` method, which uses the active model (an instance of `MyActiveDataModel`) to create `ActiveDataUpdateEvent` objects to insert and update data. You will need to import `oracle.adf.view.rich.activedata.ActiveDataEventUtil` and `oracle.adf.view.rich.activedata.JboActiveDataEventUtil` to implement this method.

```
public void triggerDataChange(MyActiveDataModel l)
  throws Exception
  {

    // do an update on dept 1
      l.bumpChangeCount();
      ActiveDataUpdateEvent event =
        ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.UPDATE,
                                     l.getCurrentChangeCount(),
                                     JboActiveDataEventUtil.convertKeyPath(new Key
                                            (new Object[]{ new Long(1), new Integer(0) })),
                                     null,
                                     new String[] { "name" },
                                     new Object[] { "Name Pushed" });

      l.dataChanged(event);
```

```
        try
        {
          Thread.sleep(2000);
        }
        catch (InterruptedException ie)
        {
          ie.printStackTrace();
        }
        // insert dept 99

          l.bumpChangeCount();
           event =

    ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.INSERT_AFTER,
                                         l.getCurrentChangeCount(),
                                         JboActiveDataEventUtil.convertKeyPath(new Key
                                               (new Object[]{ new Long(99), new Integer(0) })),
                                         JboActiveDataEventUtil.convertKeyPath(null),
                                         new String[]{ "addr1", "name" },
                                         new Object[]{ "Addr Inserted", "Name Inserted" });

          l.dataChanged(event);

        try
        {
          Thread.sleep(2000);
        }
        catch (InterruptedException ie)
        {
          ie.printStackTrace();
        }

        // delete dept 10

          l.bumpChangeCount();
           event =
            ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REMOVE,
                                         l.getCurrentChangeCount(),
                                         JboActiveDataEventUtil.convertKeyPath(new Key
                                               (new Object[]{ new Long(9), new Integer(0) })),
                                         null, null, null);

          l.dataChanged(event);

        try
        {
          Thread.sleep(2000);
        }
        catch (InterruptedException ie)
        {
          ie.printStackTrace();
        }

        // refresh the entire table

          l.bumpChangeCount();
           event =
            ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REFRESH,
                                             l.getCurrentChangeCount(),
                                             null, null, null, null);

          l.dataChanged(event);
        }

      private MyActiveDataModel _activeDataModel = new MyActiveDataModel();

      private CollectionModel _model = null;

    }
```

What You May Need to Know About Maintaining Read Consistency

Read consistency guarantees a consistent view of the data in ADF application runtime. In order to use active data, your application must maintain read consistency.

Using active data means that your component has two sources of data: the active data feed and the standard data fetch. Because of this, you must make sure your application maintains read consistency.

For example, say your page contains a table and that table has active data enabled. The table has two methods of delivery from which it updates its data: normal table data fetch and active data push. Say the back end data changes from `foo` to `bar` to `fred`. For each of these changes, an active data event is fired. If the table is refreshed *before* those events hit the browser, the table will display `fred` because standard data fetch will always get the latest data. But then, because the active data event might take longer, some time *after* the refresh the data change event would cause `foo` to arrive at the browser, and so the table would update to display `foo` instead of `fred` for a period of time. Therefore, you must implement a way to maintain the read consistency.

To achieve read consistency, the `ActiveDataModel` has the concept of a change count, which effectively timestamps the data. Both data fetch and active data push need to maintain this `changeCount` object by monotonically increasing the count, so that if any data returned has a lower `changeCount`, the active data event can throw it away. For an example of an implementation of the `ActiveDataModel` class that maintains read consistency, see How to Use the Active Data Proxy.

Using the Active Data with a Scalar Model

ADS is very much model driven and requires no extra setups in the declarative view. It supports ADF components such as activeCommandToolbarButton, activeImage, activeOutputText, table, tree, and DVT components. Let’s take a look on how to use activeOutputText with a Java Bean, as you may not have a model.

ADF components that display collection-based data can be configured to work with ADS and require no extra setup in the view layer. However, imagine that your JSPX page uses an `activeOutputText` component to display new counts based on a Java timer. In this case, you will replace the model layer with scalar or "flat" data that you display from a Java Bean.

How to Use the Active Data with a Scalar Model

To implement the scalar model, follow these basic steps (as illustrated in the following example):

1. Use the `ActiveModelContext` API to register the bean with ADS so the bean (a scalar model) imitates an actual model.

   Add the registration code to the active attribute's getter method. Adding the registration code to the bean's constructor can cause ADS to fail.

2. Implement a custom mechanism to push the data to the view layer, as shown in the following example.

```
package oracle.adfdemo.view.feature.rich;

import java.util.Collection;
import java.util.Timer;
import java.util.TimerTask;
import java.util.concurrent.atomic.AtomicInteger;

import oracle.adf.view.rich.activedata.ActiveModelContext;
import oracle.adf.view.rich.activedata.BaseActiveDataModel;
import oracle.adf.view.rich.activedata.ActiveDataEventUtil;
import oracle.adf.view.rich.event.ActiveDataEntry;
import oracle.adf.view.rich.event.ActiveDataUpdateEvent;

public class CounterBean extends BaseActiveDataModel
// Example using a Java timer to create new counts
{
  public CounterBean()
  {
    timer.schedule(new UpdateTask(), 2000, 2000);
  }

  public String getState()
  {
    // 1. Use the ActiveModelContext API to register the scalar model key path
for
    //    the "state" attribute.
    ActiveModelContext context = ActiveModelContext.getActiveModelContext();
    Object[] keyPath = new String[0];
    context.addActiveModelInfo(this, keyPath, "state");

    return String.valueOf(counter);
  }

  // Not needed. We do not need to connect to a (real) active data scource.
  protected void startActiveData(Collection<Object> rowKeys, int
          startChangeCount) {}

  // Not needed. We do not need to connect to a (real) active data scource.

  protected void stopActiveData(Collection<Object> rowKeys) {}

  public int getCurrentChangeCount()
  {
    return counter.get();
  }
  protected class UpdateTask extends TimerTask
  {
    public void run()
    {
      counter.incrementAndGet();

      // 2. Use ActiveDataEventUtil to create an event object to update the
model.
      ActiveDataUpdateEvent event =
        ActiveDataEventUtil.buildActiveDataUpdateEvent(
          ActiveDataEntry.ChangeType.UPDATE,
          counter.get(),
          new String[0],
          null,
          new String[] { "state" },
          new Object[] { counter.get() });
      fireActiveDataUpdate(event);
    }
  }

  private static final Timer timer = new Timer();
  private final AtomicInteger counter = new AtomicInteger(0);
}
```

After you create the bean, register the bean as a managed bean in the faces-config.xml file, as the following example for counterBean illustrates:

```
...
<managed-bean>
  <managed-bean-name>counterBean</managed-bean-name>
  <managed-bean-class>
      oracle.adfdemo.view.feature.rich.CounterBean
  </managed-bean-class>
  <managed-bean-scope>session</managed-bean-scope>
</managed-bean>
```

Once the bean is registered, you can use ADS to stream the data to the view layer. Your ADF Faces component use expression language to receive the pushed data, as illustrated by the activeOutputText component value attribute in the following example:

```
...
<f:view>
   <af:document title="Active Data Visual Design Demo"
                  binding="#{templateBindings.documentComponent}"
                 smallIconSource="#{aboutBean.smallIconSource}"
                 largeIconSource="#{aboutBean.largeIconSource}" theme="dark"
                  id="d1">
      <af:pageTemplate id="dmoTpl" viewId="#{templates.componentTemplate}">
        <f:attribute name="tagName" value="Active Data Visual Design"/>
        <f:attribute name="demoKind" value="visualDesign"/>
        <f:attribute name="customEditorPresent" value="true"/>
        <f:facet name="center">
          <af:panelGroupLayout layout="scroll">
             <af:activeOutputText
                value="#{counterBean.state}"
                inlineStyle=
                   "color:brown;
                    font-size:100px;
                    font-weight:bold;
                    text-align:center;"
              />
          </af:panelGroupLayout>
        </f:facet>
      </af:pageTemplate>
   </af:document>
</f:view>
```

54

Configuring High Availability for Fusion Web Applications

This chapter describes considerations for developing Fusion web applications that you intend to deploy to a high availability, clustered server environment.
This chapter includes the following topics:

- About Oracle ADF High Availability
- Configuring Oracle ADF for High Availability
- Troubleshooting Fusion Web Applications for High Availability

About Oracle ADF High Availability

Oracle ADF is used to build large enterprise applications. And if you want to have your application run on high availability servers, then you should understand what is high availability. High availability for a Fusion web application refers to the ability of users to access a system without loss of service.

High availability for the Fusion web application is the ability of the application to be available when it is needed.

A high availability environment ensures that users can access the application without loss of service. Deploying the Fusion web application to a high availability environment minimizes the time when the application is down, or unavailable, and maximizes the time when it is running, or available.

High availability comes from redundant systems and components. You can categorize high availability solutions by their level of redundancy into active-active solutions and active-passive solutions.

An **active-active solution** deploys two or more active servers and can be used to improve scalability and provide high availability. In active-active deployments, all instances handle requests concurrently. Oracle recommends active-active solutions for all single-site middleware deployments. **Active-passive solutions** deploy an active instance that handles requests and a passive instance that is on standby.

For information about high availability environments, see What is High Availability in *High Availability Guide*.

Oracle ADF Scope and Session State Considerations

At runtime, ADF objects such as the binding container and managed beans are instantiated. Each of these objects has a defined life span set by its scope attribute.

For more information about the life span of ADF objects, see About Object Scope Lifecycles.

Oracle ADF Failover and Expected Behavior Considerations

An Oracle WebLogic cluster provides application high availability. If one member of the cluster is unavailable, any other available member of the cluster is able to handle the request. You should familiarize yourself with failover requirements and the expected behavior of an application in the event of a failover.

Session Failover Requirements

For seamless failover of a Fusion web application, the application must meet the following conditions:

- The application is in a cluster and at least one member of the application cluster is available to serve the request.
- For stateful applications, state replication is configured correctly, as described in Configuring Oracle ADF for High Availability.
- If you use Oracle HTTP Server, the server is configured with the WebLogicCluster directive to balance among all available application instances.
- If you use a hardware load balancer, the load balancer is:
  - Routing traffic to all available instances
  - Configured correctly with a health monitor to mark unavailable instances
  - Configured to support persistence of session state

Expected Behavior for Application Failover

If the environment is configured correctly, application users do not notice when an application instance in a cluster becomes unavailable. The sequence of events in an application failover is, for example, as follows:

1. A user makes a request and is routed by a hardware load balancer to Instance A of the application.
2. Instance A of the application becomes unavailable because of node failure, process failure, or network failure.
3. The hardware load balancer marks Instance A as unavailable.
4. The user makes a subsequent request. The request is routed to Instance B.
5. Instance B is configured as a replication partner of Instance A and has the user's session state.
6. The application resumes using the session state on Instance B and the user continues working without interruption.

ADF Application Module for Oracle RAC Considerations

When you configure the ADF application module to access a highly available database system, such as redundant databases or Oracle Real Application Clusters (Oracle RAC) as the backend, the data source must be container-defined. In this scenario, you must use a GridLink data source or a multi data source. However, from the standpoint of the application module configuration, the naming convention for the multi data source or GridLink data source is the same as it is for a non-multi data source or

GridLink data source. This naming convention ensures that the correct data source is used at runtime.

To more information about configuring GridLink data sources or multi data sources for high availability applications, see the Database Considerations chapter of the *High Availability Guide*.

For information about high availability considerations related to modifying the mdsDS data source URL post deployment of the Fusion web application, see the Configuring High Availability for Other Components chapter of the *High Availability Guide*.

Configuring Oracle ADF for High Availability

When a failover happens in the cluster environment, the ADF application state must be saved in a shared location either in a file system or database or in memory and this should be available to all the nodes in the cluster to replicate the state of the session. Most of the configurations for a high availability will be done in the application metadata files and the development needs to be done keeping in mind that code should support high availability for any kind of J2EE applications.

To support automatic replication and failover for web applications in a clustered environment, Oracle WebLogic Server supports mechanisms for replicating HTTP session state across clusters. You can configure Oracle ADF to ensure the Fusion web application's state can be restored from any server in the cluster.

How to Configure Application Modules for High Availability

An **application module** is the transactional component that the Fusion web application uses to work with application data. It defines an updateable data model and top-level procedures and functions, called *service methods*, related to a logical unit of work related to an end-user task. An application module supports *passivating*, or storing, its transaction state as a snapshot in the database. It also supports the reverse operation of activating the transaction state from one of these saved snapshots.

For more information on application module state management, see About Fusion Web Application State Management.

To enable support for ADF Business Components failover, set the `jbo.dofailover` parameter to `true` so that the application module state is saved on release. This enables Oracle ADF to restore the application module state from a snapshot saved from a previous check in. By contrast, when the failover feature is disabled, which it is by default, then application module state is saved only when the application is reused by a subsequent user session and only when the application module pool cannot find an unused application module.

You can set this parameter in your application module configuration on the **Pooling and Scalability** tab of the overview editor for application module configurations (on the `bc4j.xcfg` file).

To configure application modules for high availability:

1. Launch JDeveloper and open the application.
2. In the Applications window, expand the project that contains the data model and double-click the application module.

3. In the overview editor for the application module, select the **Configurations** navigation tab and click the configuration hyperlink for the configuration you want to configure for high availablity.
4. In the overview editor for application module configurations (on the `bc4j.xcfg` file), click the **Database and Scalability** tab.
5. Select the **Failover Transaction State Upon Managed Release** checkbox and save the change.

How to Enable Support for Replicating HTTP Session State

To enable support for replicating HTTP session state, you must assign a value to the `persistent-store-type` element in the Oracle WebLogic Server `weblogic.xml` file. The value `replicated_if_clustered` ensures that the in-effect persistent store type will be replicated so that sessions on the clustered environment are stored in accordance with the value set for the cluster of servers to which this server belongs.

> **Note:**
>
> Oracle ADF applications such as the Oracle WebCenter Portal Suite are preconfigured and do not need additional configuration.

To configure the weblogic.xml file for high availability:

1. Launch JDeveloper and open the application.
2. In the Applications window, expand the project that contains the web application and expand the **WEB-INF** folder.
3. Double-click the **weblogic.xml** file, and click the **Source** tab to edit the file.
4. In the file, add the `persistent-store-type` definition to the `session-descriptor` element:

```
<weblogic-web-app>
 <session-descriptor>
   <persistent-store-type>
     replicated_if_clustered
   </persistent-store-type>
 </session-descriptor>
</weblogic-web-app>
```

How to Ensure Oracle ADF Receives Notifications From Managed Bean Changes

When you design an application to run in a clustered environment, you must ensure that Oracle ADF is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

When a value within a managed bean in either view scope or page flow scope is modified, the application must notify Oracle ADF so that it can ensure the bean's new value is replicated.

To enable ADF Controller to track changes to ADF memory scopes and replicate the page flow scope and view scope within the server cluster, you must set the ADF Controller parameter `<adf-scope-ha-support>` in the application's `adf-config.xml` file to `true`. For example, when set to `true` for an application and that application adds or removes a bean from a page flow scope during a request, the change will automatically replicated within a cluster.

The `adf-config.xml` file is the central configuration file for all ADF components. The file contains sections to configure the runtime behavior for ADF components, including, ADF Controller.

> **Note:**
>
> If your application uses MDS and will use an Oracle database that supports failover, Oracle recommends enabling MDS retry on failover. To do this, add the following `retry-connection` entry to the MDS configuration section of adf-config.xml.
>
> ```
> <persistence-config>
>       <metadata-namespaces>...
>       <metadata-store-usages>...
>       <external-change-detection enabled="false" />
>       <read-only-mode enabled="true"/>
>       <retry-connection enabled="true"/>
> </persistence-config>
> ```

To configure the adf-config.xml file for high availability:

1. In the Application window, expand the **Application Resources**.
2. Select **Descriptors**, and then select the **ADF META-INF** node.
3. Double-click the **adf-config.xml** file, and click the **Source** tab to edit the file.
4. Add the following to the file:

```
<adf-controller-config xmlns="http://xmlns.example.com/adf/controller/
config">
 <adf-scope-ha-support>true</adf-scope-ha-support>
</adf-controller-config>
```

For more information about using the `adf-config.xml` file to configure ADF, see adfc-config.xml.

What You May Need to Know About Using Application Scoped Managed Beans in a Clustered Environment

JSF Application Scope beans are backed by a servlet context which can only have one instance per cluster node. Therefore, for each design time configured bean, there will be a runtime instance of the bean for each node in a cluster. Because there is no synchronization across nodes, each instance of the application running on different nodes will have separate instances of that bean with separate values. Therefore, application scoped managed beans should not be used to carry application-wide values that can be updated to be shared across all nodes in a cluster. They can, however, be used to carry constants, read-only values, or values to reflect the state of a single node within the cluster (such as the number of users on a node).

How to Disable Design Time Optimizations

The `org.apache.myfaces.trinidad.CHECK_FILE_MODIFICATION` context parameter provides optimization for developing and testing the Fusion web application in the JDeveloper. Leaving this parameter set to `true` when the application runs in a high availability environment can lead to errors after failover occurs. Note that this limitation should not affect your work because you typically use this parameter in a development environment only, not a high availability environment.

To configure the CHECK_FILE_MODIFICATION parameter for high availability:

1. In the Applications window, expand the user interface project and expand the **WEB-INF** folder.
2. Double-click the **web.xml** file and click the **Application** navigation tab.
3. In the overview editor, expand the **Context Initialization Parameters** section and confirm that the `org.apache.myfaces.trinidata.CHECK_MODIFICATION` parameter definition is set to `false`.

   The `web.xml` file definition will be:

```
<web-app>
 ...
  <context-param>
    <param-name>org.apache.myfaces.trinidad.CHECK_FILE_
                                                         MODIFICATION</param-name>
    <param-value>false</param-value>
  </context-param>
</web-app>
```

Troubleshooting Fusion Web Applications for High Availability

There are procedures to troubleshoot common issues with Fusion web applications at design time and also after deployment.

This section describes procedures for troubleshooting possible issues with Fusion web applications at design time and after deployment.

How to Test the Fusion Web Application With Failover Mode Enabled

When running or debugging an application that uses failover support (`jbo.dofailover` is enabled) within the JDeveloper environment, you are frequently starting and stopping the application server. The ADF failover mechanism has no way of knowing whether you stopped the server to simulate an application server failure, or whether you stopped it because you want to retest something from scratch in a fresh server instance. If you intend to do the latter, exit out of your browser before restarting the application on the server. This eliminates the chance that you will be confused by the correct functioning of the failover mechanism when you didn't intend to be testing that aspect of your application.

How to Troubleshoot High Availability Issues at Design Time

When you develop the Fusion web application in Oracle JDeveloper, the integrated development environment provides support for detecting potential high availability issues. The warnings that JDeveloper provides are generated by the audit framework and are triggered to appear in the JDeveloper source editors. The warnings the editors show are based on the audit rules for high availability applications.

The high availability audit rules that JDeveloper enables by default are:

- **ADF Controller Configuration - High Availability for ADF Scopes is not Enabled** warns the developer that the `adf-scope-ha-support` flag in the `adf-config.xml` file is set is not set to `true`. This audit rule fires only when the `<adf-controller-config>` element is in the ADF application-level configuration file (`adf-config.xml`).
- **ADF Page Flows - Bean in Scope Map is Modified** warns the developer when the some code calls a setter method on a bean to indicate that the code did not subsequently call the `ControllerContext.markScopeDirty()` method. This audit rule fire only when the `adf-scope-ha-support` flag in the `adf-config.xml` file is set to true.
- **ADF Page Flows - EL Bean is Modified** warns the developer when some code evaluates an EL expression that mutates a bean to indicate that the code did not subsequently call the `ControllerContext.markScopeDirty()` method. This audit rule fire only when the `adf-scope-ha-support` flag in the `adf-config.xml` file is set to true.
- **ADF Page Flows - Managed Bean Class Not Serializable** warns the developer that a managed bean has a non-serializable class defined in `viewScope`, `pageFlowScope`, or `sessionScope`. This audit rule fire only when the `adf-scope-ha-support` flag in the `adf-config.xml` file is set to `true`.

You can modify the high availability audit rule settings using the Preference dialog in JDeveloper. From the JDeveloper toolbar, choose **Tools - Preferences**, under **Audit - Profiles** expand **ADF Controller Configuration** or **ADF Pages Flows** and make the desired audit rule selections.

You can also trigger the audit by choosing **Build - Audit *project.jpr*** from the JDeveloper toolbar.

How to Troubleshoot High Availability Issues After Deployment

There are two actions to take if you encounter Fusion web application deployment issues: verify the JRF Runtime and verify the status of application deployments.

Verifying the JRF Runtime Installation

The first step to troubleshooting an Fusion web application deployment is to verify that the JRF Runtime is installed on the WebLogic Server domain. ADF applications require the JRF and ADF runtime. You cannot run ADF applications with a standalone WebLogic Server domain or just the WebLogic Server portion of the Application Development product; you must extend it with the JRF extension template.

For more information on the JRF Template, see Oracle JRF and ADF Templates in *Domain Template Reference*.

Verifying the Success of All Application Deployments

Fusion web applications deploy when the Managed Server first starts. Use the Administration Console to check that all application deployments were successful:

1. Click **Deployments** in the left hand pane. The right hand pane shows the application deployments and their status. The state of all applications, assuming all the servers are running, should be ACTIVE.
2. If an application deployment has failed, the server logs may provide some indication of why the application was not deployed successfully. The server logs are located in the `DOMAIN_HOME/servers/server_name/logs` directory. Common issues include:

- Unavailability of external resources, such as database resources. Examine the error, fix it, and attempt to redeploy the application.
- The appropriate applications or libraries are not targeted correctly to the right Managed Server or Cluster.

How to Troubleshoot Oracle ADF Replication and Failover Issues

State Replication is most prominent in failover scenarios. A user working on one server may discover that, upon failover:

- Windows may close or the state might reset.
- Screens may require a reset.
- The application may redirect to the logon screen.

To diagnose and troubleshoot state replication issues.

1. Confirm that this is not a known replication issue.

   See Oracle ADF Failover and Expected Behavior Considerations for possible expected behaviors. Before proceeding to further diagnose the issue, first confirm that the failover behavior is not an expected behavior.
2. Check load balancer settings.

   For replication and failover to function correctly, the load balancer must be configured with the appropriate persistence settings. For more details on configuring Hardware Load Balancers for Oracle WebLogic Server, see Load Balancing in a Cluster in *Administering Clusters for Oracle WebLogic Server*.
3. Check the cluster status.

   Replication occurs within the context of a cluster. For failover to be successful, there must be at least one other healthy member of the cluster available. You can check cluster status in one of two ways:

   - Check the cluster status using the Oracle WebLogic Server Administration Console - In the Left-hand pane, click on **Servers**. Verify the state of all servers in the cluster.
   - Check the cluster status using the `weblogic.Admin` utility. You can use the `weblogic.Admin` utility to query the state of all servers in a specific cluster. For example:

```
$ java weblogic.Admin -url Adminhost:7001 -username <username> -password
 <password> CLUSTERSTATE -clustername Spaces_Cluster
```

This example returns:

```
There are 2 server(s) in cluster: Spaces_Cluster
The alive servers and their respective states are listed below:
Application Server---RUNNING
Managed Server---RUNNING
```

4. Check cluster communications.

   Even if all cluster members are running, there may be communication issues which prevent them from communicating replication information to each other. There are two types of cluster communication configurations. Troubleshooting depends on the cluster type:

   - Checking Unicast cluster communications - For Unicast clusters, Managed Servers must be able to access each other's hosts and each other's default listening port.

     Ensure that all individual Managed Servers have their Listen Address set correctly. You can find this setting by selecting **Configuration**, **General** for each Managed Server.

   - Checking Multicast cluster communications - For multicast clusters, servers must be able to intercept the same multicast traffic. Ensure that multicast is configured correctly by running the WebLogic utility `utils.MulticastTest` on each machine. For example:

     ```
     $ java utils.MulticastTest -H
     ```

5. Confirm Oracle WebLogic Server application configuration.

   Oracle WebLogic Server is not configured by default for failover. In-memory replication takes place only with the proper setting in the `weblogic.xml` file:

   ```
   <session-descriptor>
   <persistent-store-type>replicated_if_clustered</persistent-store-type>
   </session-descriptor>
   ```

   A persistent-store-type of replicated is also acceptable. This setting can be made in JDeveloper, as described in How to Enable Support for Replicating HTTP Session State .

6. Confirm Oracle ADF Business Components configuration.

   Oracle ADF is not configured by default for failover. Failover is supported only with the proper setting in the ADF Business Components configuration file (`bc4j.xcfg`):

   ```
   <AppModuleConfig ...
    <AM-Pooling jbo.dofailover="true"/>
   </AppModuleConfig>
   ```

   This setting is made in JDeveloper through the Edit Business Components Configuration dialog, as described in How to Configure Application Modules for High Availability.

7. Confirm Oracle WebLogic Server connection pool parameter.

   Set an appropriate value for the `weblogic-application.xml` deployment descriptor parameter `inactive-connection-timeout-seconds` on the element `<connection-check-params>` `pool-params`.

When enabling application module state passivation, a failure can occur when Oracle WebLogic Server is configured to forcibly release connections back into the pool. The failure creates an exception "`Connection has already been closed`" that gets saved to the server log. The user interface does not show this exception.

Set `inactive-connection-timeout-seconds` to several minutes. In most cases, this setting avoids forcing the inactive connection timeout and passivation failure. Adjust the setting as needed for your environment.

8. Confirm ADF Controller configuration.

   Oracle ADF is not configured by default to replicate changes to ADF objects in ADF memory scopes. ADF object replication is supported only with the proper setting in the ADF application-level configuration file (`adf-config.xml`):

   ```
   <adfc:adf-controller-config>
    <adfc:adf-scope-ha-support>true</adfc:adf-scope-ha-support>
   </adfc:adf-controller-config>
   ```

   This setting is made in JDeveloper through the source editor. See How to Configure Application Modules for High Availability.

9. Check default logger messages.

   By default the ADF log shows high-level messages (`INFO` level). The default logging often reports problems with serialization and replication without the need to enable more detailed log messages.

10. Enable log messages for ADF high availability applications.

    Configure the ADF logger to output runtime messages for high availability. By default the ADF log shows high-level messages (`INFO` level). You enable high availability diagnostics for ADF Controller by setting the logging level in Fusion Middleware Control to `FINE`.

    When enabled, the logger outputs a warning if the `adfc:adf-scope-ha-support` setting in the `adf-config.xml` file is not set.

11. Enable debug.

    Check the server logs for any unusual messages on Managed Server startup. In particular, if the Managed Server is unable to locate other members of the cluster. The server logs are located in the `*DOMAIN_HOME*/servers/*SERVER_NAME*/logs` directory.

    For further debugging, enable the flags `DebugCluster`, `DebugClusterAnnouncements`, `DebugFailOver`, `DebugReplication`, and `DebugReplicationDetails`. You can enable each flag with the `weblogic.Admin` utility:

    ```
    $ java weblogic.Admin -url Adminhost:7001 -username <username> -password
     <password> SET -type ServerDebug -property DebugCluster true
    ```

12. Enable component state serialization checking.

    Enable server checking to ensure no unserializable state content on session attributes is detected. This check is disabled by default to reduce runtime overhead. Serialization checking is supported by the Java server system property `org.apache.myfaces.trinidad.CHECK_STATE_SERIALIZATION`.

    Table 54-1 shows the options you can use with the property. Use commas to delimit the options.

Table 54-1 CHECK_STATE_SERIALIZATION Options

Option	Description
tree	Checks whether the entire component tree is serializable. This is the fastest component check. Most testing should be performed with this flag enabled.
component	Checks each component individually for serializability. This option is much slower than "tree." It is typically turned on only after testing with "tree" reports an error. This option narrows down the problematic component.
property	Checks each component attribute individually for serializability. This is slower than "component" and narrows down the specific problematic component attribute after a failure has been detected in the "tree" or "component" modes.
session	Checks that all attributes in the JSF Session Map that are marked as Serializable are serializable.
application	Checks that all attributes in the JSF Application Map that are marked as Serializable are serializable.
beans	Checks that any serializable object in the appropriate map has been marked as dirty if the serializable content of the object changes during the request.
all	Checks everything.

For high availability testing, start off by validating that the Session and JSF state is serializable by launching the application server with the system property:

```
-Dorg.apache.myfaces.trinidad.CHECK_STATE_SERIALIZATION=session,tree
```

Add the `beans` option to check that any serializable object in the appropriate map has been marked as dirty if the serialized content of the object has changed during the request:

```
-Dorg.apache.myfaces.trinidad.CHECK_STATE_SERIALIZATION=session,tree,beans
```

If a JSF state serialization failure is detected, relaunch the application server with the system property to enable component and property flags and rerun the test:

```
-Dorg.apache.myfaces.trinidad.CHECK_STATE_SERIALIZATION=all
```

These are Java system properties and you must specify them when you start the application server.

55
Deploying Fusion Web Applications

This chapter describes how to deploy Oracle ADF applications to a target application server. It describes how to create deployment profiles, how to create deployment descriptors, and how to load ADF runtime libraries. It includes instructions for running an application in the Integrated WebLogic Server as well as deploying to a standalone Oracle WebLogic Server.
This chapter includes the following sections:

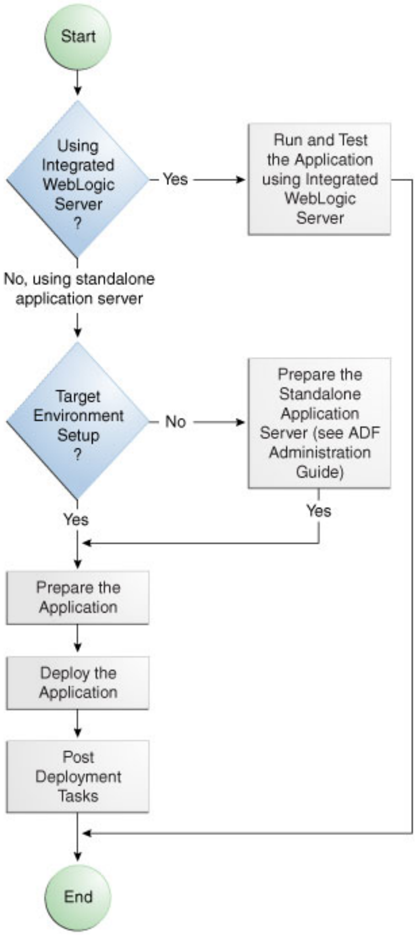
About Deploying Fusion Web Applications

In order to run a web application, it needs to be deployed to a web server. Using JDeveloper, you can directly deploy an Oracle ADF application to an integrated application server or deploy to any standalone application server.

Deployment is the process of packaging application files as an archive file and transferring that file to a target application server. You can use JDeveloper to deploy **Oracle ADF** applications directly to the application server (such as Oracle WebLogic Server), or indirectly to an archive file as the deployment target, and then install this archive file to the target server. For application development, you can also use JDeveloper to run an application in Integrated WebLogic Server. JDeveloper supports deploying to server clusters, but you cannot use JDeveloper to deploy to individual Managed Servers that are members of a cluster.

Figure 55-1 shows the flow diagram that describes the overall deployment process. Note that preparing the target application server for deployment by installing the ADF runtime is described in Deploying ADF Applications in *Administering Oracle ADF Applications*.

Figure 55-1 Deployment Overview Flow Diagram



Start
Using Integrated WebLogic Server ?
Yes
Run and Test the Application using Integrated WebLogic Server
No, using standalone application server
Target Environment Setup ?
No
Prepare the Standalone Application Server (see ADF Administration Guide)
Yes
Yes
Prepare the Application
Deploy the Application
Post Deployment Tasks
End

Note:

Normally, you use JDeveloper to deploy applications for development and testing purposes. If you are deploying Oracle ADF applications for production purposes, you can use Enterprise Manager or scripts to deploy to production-level application servers.

For more information about deployment to later-stage testing or production environments, see Deploying Using Oracle Enterprise Manager Fusion Middleware Control in *Administering Oracle ADF Applications*.

ADF Java EE applications are based on standardized, modular components and can be deployed to the following application server:

- Oracle WebLogic Server

  Oracle WebLogic Server provides a complete set of services for those modules and handles many details of application behavior automatically, without requiring programming. For information about which versions of Oracle WebLogic Server are compatible with JDeveloper, see the certification information website at http://www.oracle.com/technetwork/developer-tools/jdev/documentation/index.html.

Deploying a Fusion web application is slightly different from deploying a standard Java EE application. JSF applications that contain ADF Faces components have a few additional deployment requirements:

- ADF Faces requires Sun's JSF Reference Implementation 1.2 and MyFaces 1.0.8 (or later).

You can use JDeveloper to:

- Run applications in Integrated WebLogic Server

  You can run and debug applications using Integrated WebLogic Server and then deploy to standalone WebLogic Server.
- Deploy directly to the standalone application server

  You can deploy applications directly to the standalone application server by creating a connection to the server and choosing the name of that server as the deployment target.
- Deploy to an archive file

  You can deploy applications indirectly by choosing an EAR file as the deployment target. The archive file can subsequently be installed on a target application server.

The Summit sample application for Oracle ADF demonstrates the use of the Fusion web application technology stack to create transaction-based web applications. You can run the Summit sample application in JDeveloper using Integrated WebLogic Server. For more information about the Summit ADF sample applications, see Introduction to the ADF Sample Application.

Developing Applications with Integrated WebLogic Server

If you are developing an application in JDeveloper and you want to run the application in Integrated WebLogic Server, you do not need to perform the tasks required for deploying directly to Oracle WebLogic Server or to an archive file. JDeveloper has a default connection to Integrated WebLogic Server and does not require any deployment profiles or descriptors. Integrated WebLogic Server has a preconfigured domain that includes the ADF libraries, as well as the `-Djps.app.credential.overwrite.allowed=true` setting, that are required to run Oracle ADF applications. You can run an application by choosing **Run** from the JDeveloper main menu.

You debug the application using the features described in Testing and Debugging ADF Components.

Developing Applications to Deploy to Standalone Application Server

Typically, for deployment to standalone application servers, you test and develop your application by running it in Integrated WebLogic Server. You can then test the application further by deploying it to standalone Oracle WebLogic Server in development mode to more closely simulate the production environment.

In general, you use JDeveloper to prepare the application or project for deployment by:

- Creating a connection to the target application server

- Creating deployment profiles (if necessary)
- Creating deployment descriptors (if necessary, and that are specific to the target application server)
- Updating `application.xml` and `web.xml` to be compatible with the application server (if required)
- Enabling the application for Real User Experience Insight (RUEI) in `web.xml` (if desired)
- Migrating application level security policy data to a domain-level security policy store
- Configuring the Oracle Single Sign-On (Oracle SSO) service and properties in the domain `jps-config.xml` file when you intend the web application to run using Oracle SSO

You must already have an installed application server. For Oracle WebLogic Server, you can use the Oracle 12**c** Installer or the Oracle Fusion Middleware 12**c** Application Developer Installer to install one. For other application servers, follow the instructions in the applications server documentation to obtain and install the server.

You must also prepare the application server for Fusion web application deployment. See Preparing the Standalone Application Server for Deployment in *Administering Oracle ADF Applications*.

- Extending Oracle WebLogic Server domains to be ADF-compatible using the ADF runtime
- For WebLogic, setting the Oracle WebLogic Server credential store overwrite setting as required (`-Djps.app.credential.overwrite.allowed=true` setting).
- Creating a global JDBC data source for applications that require a connection to a data source

After the application and application server have been prepared, you can:

- Use JDeveloper to:
  - Directly deploy to the application server using the deployment profile and the application server connection.
  - Deploy to an EAR file using the deployment profile. For Oracle ADF applications, WAR and MAR files can be deployed only as part of an EAR file.
- Use Enterprise Manager, scripts, or the application server's administration tools to deploy the EAR file created in JDeveloper. See Deploying Using Oracle Enterprise Manager Fusion Middleware Control in *Administering Oracle ADF Applications*.

Running a Fusion Web Application in Integrated WebLogic Server

In order to test run an ADF application during development, you can use JDeveloper to run an application in Integrated WebLogic Server. You do not have to manually complete many of the steps that are necessary for deployment to a standalone server.

JDeveloper is installed with Integrated WebLogic Server which you can use to test and develop your application. For most development purposes, Integrated WebLogic

Server will suffice. When your application is ready to be tested, you can select the run target and then choose the **Run** command from the main menu.

> **Note:**
>
> The first time you run an application in Integrated WebLogic Server, the Create Default Domain dialog appears for you to define an administrative password for the new domain.

When you run the application target, JDeveloper detects the type of Java EE module to deploy based on artifacts in the projects and workspace. JDeveloper then creates an in-memory deployment profile for deploying the application to Integrated WebLogic Server. JDeveloper copies project and application workspace files to an "exploded EAR" directory structure. This file structure closely resembles the EAR file structure that you would have if you were to deploy the application to an EAR file. JDeveloper then follows the standard deployment procedures to register and deploy the "exploded EAR" files into Integrated WebLogic Server. The "exploded EAR" strategy reduces the performance overhead of packaging and unpackaging an actual EAR file.

In summary, when you select the run target and run the application in Integrated WebLogic Server, JDeveloper:

- Detects the type of Java EE module to deploy based on the artifacts in the project and application
- Creates a deployment profile in memory
- Copies project and application files into a working directory with a file structure that would simulate the "exploded EAR" file of the application.
- Performs the deployment tasks to register and deploy the simulated EAR into Integrated WebLogic Server
- Automatically migrates identities, credentials, and policies

  Later on, if you plan to deploy the application to a standalone WebLogic Server instance, you will need to migrate this security information. See How to Deploy Applications with ADF Security Enabled.

> **Note:**
>
> JDeveloper ignores the deployment profiles that were created for the application when you run the application in Integrated WebLogic Server.

The application will run in the base domain in Integrated WebLogic Server. This base domain has the same configuration as a base domain in a standalone WebLogic Server instance. In other words, this base domain will be the same as if you had used the Oracle Fusion Middleware Configuration Wizard to create a base domain with the default options in a standalone WebLogic Server instance.

JDeveloper will extend this base domain with the necessary domain extension templates, based on the JDeveloper technology extensions. For example, if you have installed JDeveloper Studio, JDeveloper will automatically configure the Integrated

WebLogic Server environment with the ADF runtime template (JRF Fusion Middleware runtime domain extension template).

You can explicitly create a default domain for Integrated WebLogic Server. You can use the default domains to run and test your applications. Open the Application Servers window, right-click **IntegratedWebLogicServer** and choose **Create Default Domain**.

How to Run an Application in Integrated WebLogic Server

You can test an application by running it in Integrated WebLogic Server. You can also set breakpoints and then run the application within the ADF Declarative Debugger.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you run an application in the Integrated WebLogic Server. For more information, see Running a Fusion Web Application in Integrated WebLogic Server.

To run an application in Integrated WebLogic Server:

1. In the Applications window, select the project, unbounded task flow, JSF page, or file as the run target.
2. Right-click the run target and choose **Run** or **Debug**.

   The Create Default Domain dialog appears for the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

How to Run an Application with Metadata in Integrated WebLogic Server

When an application is running in Integrated WebLogic Server, the MAR (Metadata Archive) profile itself will not be deployed to a repository, but a simulated MDS repository will be configured for the application that reflects the metadata information contained in the MAR. This metadata information is simulated, and the application runs based on this location in source control.

Any customizations or documents created by the application that are not configured to be stored in other MDS repositories are written to this simulated MDS repository directory. For example, if you customize an object, the customization is written to the simulated MDS repository. If you execute code that creates a new metadata object, then this new metadata object is also written to the same location in the simulated MDS repository. You can keep the default location for this directory (`ORACLE_HOME\jdeveloper\`**systemXX.XX**`\o.mds.dt\adrs\`**Application**`\AutoGeneratedMar\mds_adrs_writedir`), or you can set it to a different directory. You also have the option to preserve this directory across different application runs, or to delete this directory before each application run.

If your workspace has different working sets, only the metadata from the projects defined in the working set and their dependent projects will be included in the MAR. You can view and change a project's dependencies by right-clicking the project in the Applications window, choosing **Project Properties**, and then selecting **Dependencies**. For instance, an application may have several projects but `workingsetA` is defined to be `viewcontroller2` and `viewcontroller5`; and `viewcontroller5` has a dependency on `modelproject1`. When you run or debug `workingsetA`, only the metadata for `viewcontroller2`, `viewcontroller5`, and `modelproject1` will be included in the MAR for deployment.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you run an application with metadata in the Integrated WebLogic Server. For more information, see Running a Fusion Web Application in Integrated WebLogic Server.

You will need to complete this task:

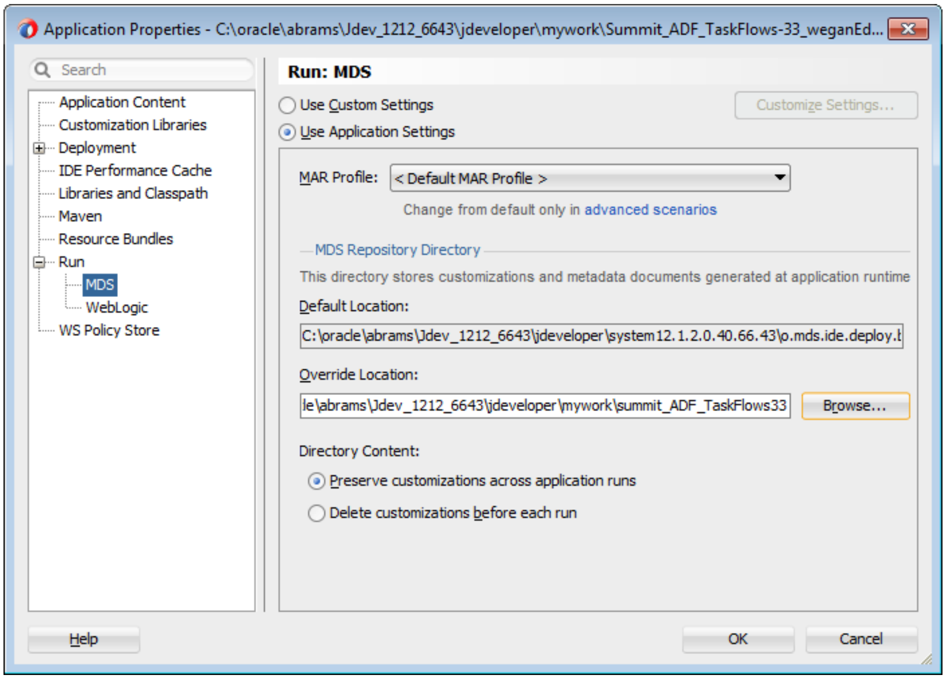
Created a MAR profile, either manually or automatically by JDeveloper.

To deploy the MAR profile to Integrated WebLogic Server:

1. In the Applications window, right-click the application and choose **Application Properties**.
2. In the Application Properties dialog, expand **Run** and choose **MDS**.
3. On the Run MDS page:
   - Select the MAR profile from the **MAR Profile** dropdown list
   - Enter a directory path in **Override Location** if you want to customize the location of the simulated MDS repository.
   - Select the **Directory Content** option. You can chose to preserve the customizations across application runs or delete customizations before each run.

   Select the MAR profile from the **MAR Profile** dropdown list. Figure 55-2 shows **Demometadata1** selected as the MAR profile.

Figure 55-2 Setting the Run MDS Options



Application Properties - C:\oracle\abrams\Jdev_1212_6643\jdeveloper\mywork\Summit_ADF_TaskFlows-33_weganEd...

Run: MDS

○ Use Custom Settings

● Use Application Settings

MAR Profile: < Default MAR Profile >

Change from default only in advanced scenarios

MDS Repository Directory

This directory stores customizations and metadata documents generated at application runtime

Default Location: C:\oracle\abrams\Jdev_1212_6643\jdeveloper\system12.1.2.0.40.66.43\o.mds.ide.deploy.t

Override Location: le\abrams\Jdev_1212_6643\jdeveloper\mywork\summit_ADF_TaskFlows33

Directory Content:

● Preserve customizations across application runs

○ Delete customizations before each run

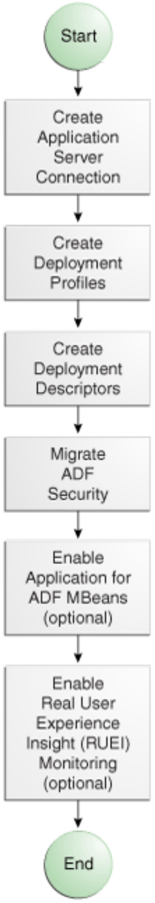
Preparing the Application

Once your application is developed, you must perform some essential tasks to deploy the Fusion web application to an integrated or standalone WebLogic Server.

Before you deploy a Fusion web application to a standalone application server, you must perform prerequisite tasks within JDeveloper to prepare the application for deployment.

Figure 55-3 show the process flow to prepare the application for deployment. After the application has been prepared and the application server has been prepared as described in Preparing the Standalone Application Server for Deployment in *Administering Oracle ADF Applications*, you can proceed to deploy the application as described in Deploying the Application.

Figure 55-3 Preparing the Application for Deployment Flow Diagram



Start
Create Application Server Connection
Create Deployment Profiles
Create Deployment Descriptors
Migrate ADF Security
Enable Application for ADF MBeans (optional)
Enable Real User Experience Insight (RUEI) Monitoring (optional)
End

How to Create a Connection to the Target Application Server

You can deploy applications to the application server via JDeveloper application server connections.

If your application involves customization using MDS, you should register your MDS repository with the application server:

- WebLogic: register the MDS into the WebLogic Domain

  For information about registering MDS in WebLogic, see Registering and Deregistering a Database-Based MDS Repository in *Administering Oracle Fusion Middleware*.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you prepare an application for deployment. See Preparing the Application.

You will need to complete this task:

Installed an application server.

To create a connection to an application server:

1. Launch the Application Server Connection wizard.

   You can:

   - In the Applications Servers window, right-click **Application Servers** and choose **New Application Server**.
   - In the New Gallery, expand **General**, select **Connections** and then **Application Server Connection**, and click **OK**.
   - In the Resources window, choose **New** > **IDE Connections > Application Server**.
2. In the Create Application Server Connection dialog, on the Usage page, select **Standalone Server** and click **Next**.
3. On the Name and Type page, enter a connection name.
4. In the **Connection Type** dropdown list, choose:
   - **WebLogic** to create a connection to Oracle WebLogic Server
5. Click **Next**.
6. On the Authentication page, enter a user name and password for the administrative user authorized to access the application server.
7. Click **Next**.
8. On the Configuration page, enter the information for your server:

   For WebLogic:

   - The Oracle WebLogic host name is the name of the WebLogic Server instance containing the TCP/IP DNS where your application (`.jar`, `.war`, `.ear`) will be deployed.
   - In the **Port** field, enter a port number for the WebLogic Server instance on which your application (`.jar`, `.war`, `.ear`) will be deployed.

     If you don't specify a port, the port number defaults to 7001.
   - In the **SSL Port** field, enter an SSL port number for the WebLogic Server instance on which your application (`.jar`, `.war`, `.ear`) will be deployed.

     Specifying an SSL port is optional. It is required only if you want to ensure a secure connection for deployment.

  If you don't specify an SSL port, the port number defaults to 7002.

  - Select **Always Use SSL** to connect to the WebLogic Server instance using the SSL port.
  - Optionally enter a **WebLogic Domain** only if WebLogic Server is configured to distinguish non-administrative server nodes by name.

9. Click **Next**.
10. Click **Next**.
11. If the SSl Signer Exchange Prompt dialog appears, click **Y**.
12. On the Test page, click **Test Connection** to test the connection.

    JDeveloper performs several types of connections tests. The JSR-88 test must pass for the application to be deployable. If the test fails, return to the previous pages of the wizard to fix the configuration.
13. Click **Finish**.

How to Create Deployment Profiles

A **deployment profile** defines the way the application is packaged into the archive that will be deployed to the target environment. The deployment profile:

- Specifies the format and contents of the archive file that will be created
- Lists the source files, deployment descriptors, and other auxiliary files that will be packaged
- Describes the type and name of the archive file to be created
- Highlights dependency information, platform-specific instructions, and other information

You need a WAR deployment profile for each web user interface project that you want to deploy in your application. If you want to package seeded customizations or place base metadata in the MDS repository, you need an application level metadata archive (MAR) deployment profile as well. For more information about seeded customizations, see Customizing Applications with MDS . If the application has customization classes, you need a JAR file for those classes and you need to add that JAR when you create the EAR file. Finally, you need an application level EAR deployment profile and you must select the projects (such as WAR and MAR profiles and customization classes JAR files) to include from a list. When the application is deployed, the EAR file will include all the projects that were selected in the deployment profile.

> **Note:**
>
> If you create your project or application using the ADF Fusion Web Application template, JDeveloper automatically creates default WAR, EAR, MAR, and JAR deployment profiles. Typically, you would not need to edit or create deployment profiles manually.

For Oracle ADF applications, you can deploy the application only as an EAR file. The WAR and MAR files that are part of the application should be included in the EAR file when you create the deployment profile.

> **Note:**
>
> If your Fusion web application has business services that you want to deploy, you will need to create a Business Component Service Interface deployment profile and deploy it. For more information about business services, see How to Deploy Web Services to Oracle WebLogic Server.

Creating a WAR Deployment Profile

You will need to create a WAR deployment profile for each web-based project you want to package into the application. Typically, the WAR profile will include the dependent data model projects it requires.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a WAR deployment profile. For more information, see Preparing the Application.

You will need to complete this task:

Create web-based projects. If you used the ADF Fusion Web Application template, you should already have a default WAR deployment profile.

To create WAR deployment profiles for an application:

1. In the Applications window, right-click the web project that you want to deploy and choose **New > From Gallery**.

   You will create a WAR profile for each web project.

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **WAR File**, and click **OK**.

   If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Features** tab.

3. In the Create Deployment Profile -- WAR File dialog, enter a name for the project deployment profile and click **OK**.

4. In the Edit WAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

   - If you have customization classes in your application, they must be loaded from the EAR-level application class loader and not from the WAR. You will later add these customization classes to the EAR.

     By default, customization classes that are implemented in the data model project are added to the data model project's WAR class path. So for each WAR, you must exclude the customization classes.

     If you created your customization classes in an extension project of the application and included them using the **Libraries and Classpath** page of the Application Properties dialog, they will be packaged at the EAR level by default. No further action is necessary to remove them from the WAR profile.

     However, if you created your customization classes in the data model project of the application, they must be removed from the WAR profile. Deselect any customization classes in the Edit WAR Deployment Profiles Properties dialog Filters page for each user interface project. If you are using a `customization.properties` file, it should also be deselected.

- You might also want to change the Java EE web context root setting. To do so, choose **General** in the left pane.

  By default, when **Use Project's Java EE Web Context Root** is selected, the associated value is set to the project name, for example, `Application1-Project1-context-root`. You need to change this if you want users to use a different name to access the application.

  If you are using custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

5. Click **OK** to exit the Deployment Profile Properties dialog.
6. Click **OK** again to exit the Project Properties dialog.
7. Repeat Steps 1 through 7 for all web projects that you want to deploy.

Creating a MAR Deployment Profile

If you have seeded customizations or base metadata that you want to place in the MDS repository, you need to create a MAR deployment profile.

The namespace configuration under `<mds-config>` for MAR content in the `adf-config.xml` file is generated based on your selections in the MAR Deployment Profile Properties dialog.

Although uncommon, an enterprise application (packaged in an EAR) can contain multiple web application projects (packaged in multiple WARs), but the metadata for all these web applications will be packaged into a single metadata archive (MAR). The metadata contributed by each of these individual web applications can be global (available for all the web applications) or local to that particular web application.

To avoid name conflicts for metadata with global scope, make sure that all metadata objects and elements have unique names across all the web application projects that forms part of the enterprise application.

JDeveloper creates an auto-generated MAR when the **Enable User Customizations** and **Across Sessions using MDS** options are selected in the ADF View page of the Project Properties dialog or when you explicitly specify the deployment target directory in the `adf-config.xml` file.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a MAR deployment profile. See Preparing the Application.

You will need to complete this task:

> Create an MDS repository for your customization requirements to deploy metadata using the MAR deployment profile. For more information, see the section about managing the MDS repository in Managing the MDS Repository in *Administering Oracle Fusion Middleware*. If you used the ADF Fusion Web Application template, you should already have a default MAR deployment profile.

To create a MAR deployment profile:

1. In the Applications window, right-click the application in which you want to create a MAR profile and choose **New > From Gallery**.

   You will create a MAR profile if you want to include customizations.

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **MAR File,** and click **OK**.

   If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Features** tab.

3. In the Create Deployment Profile -- MAR File dialog, enter a name for the MAR deployment profile and click **OK**.

4. In the Edit MAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane.

   Figure 55-4 shows a sample **User Metadata** directory tree.

Note the following important points:

- To include all customizations, you need only create a file group with the desired directories.
- ADF Model and ADF view directories are added by default. No further action is required to package the ADF Model and ADF view customizations into the MAR. ADF view content is added to **HTML Root dir**, while ADF Model and Business Components content is added to **User Metadata**.
- To include the base metadata in the MDS repository, you need to explicitly select these directories in the dialog.

  When you select the base document to be included in the MAR, you also select specific packages. When you select one package, all the documents (including subpackages) under that package will be used. When you select a package, you cannot deselect individual items under that package.

- To include files from other than ADF Model and ADF view, users should create a new file group under **User Metadata** with the desired directories and explicitly select the required content in the Directories page.
- If a dependent ADF library JAR for the project contains seeded customizations, they will automatically be added to the MAR during MAR packaging. They will not appear in the MAR profile.
- If ADF Library customizations were created in the context of the consuming project, those customizations would appear in the MAR profile dialog by default.

5. Click **OK** to exit the Deployment Profile Properties dialog.
6. Click **OK** again to exit the Application Properties dialog.

Creating an Application Level EAR Deployment Profile

The EAR file contains all the necessary application artifacts for the application to run in the application server. If you used the ADF Fusion Web Application template, you should already have a default EAR deployment profile. For more information about the EAR file, see What You May Need to Know About EAR Files and Packaging.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an EAR deployment profile. For more information, see Preparing the Application.

You will need to complete these tasks:

1. Add classes into a JAR file, as described in Adding Customization Classes into a JAR.
2. Create the WAR deployment profiles, as described in Creating a WAR Deployment Profile.

To create an EAR deployment profile for an application:

1. In the Applications window, right-click the application and choose **New > From Gallery**.

   You will create an EAR profile for the application.

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **EAR File,** and click **OK**.

   If you don't see **Deployment Profiles** in the Categories tree, click the **All Features** tab.

3. In the Create Deployment Profile -- EAR File dialog, enter a name for the application deployment profile and click **OK**.
4. In the Edit EAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

   Be sure that you:

- Select **Application Assembly** and then in the **Java EE Modules** list, select all the project profiles that you want to include in the deployment, including any **WAR** or **MAR** profiles.
- Select **Platform**, select the application server you are deploying to, and then select the target application connection from the **Target Connection** dropdown list.

> **Note:**
>
> If you are using a custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

5. If you have customization classes in your application, configure these classes so that they load from the EAR-level application class loader.

> **Note:**
>
> If you created your customization classes in an extension project of the application and included them using the **Libraries and Classpath** page of the Application Properties dialog, this step is not necessary because they will be packaged at the EAR level by default.

a. In the Edit EAR Deployment Profile Properties dialog, select **Application Assembly**.

b. Select the JAR deployment profile that contains the customization classes, and enter `lib` in the **Path in EAR** field at the bottom of the dialog.

> **Note:**
>
> You should have created this JAR as described in Adding Customization Classes into a JAR.

The JAR file containing the customization classes is added to the EAR file's `lib` directory.

> **Note:**
>
> If you have customization classes in your application, you must also make sure they are not loaded from the WAR. By default, customization classes that are added to the data model project's libraries and class path are packaged to the WAR class path.
>
> If you created your customization classes in the data model project of the consuming application, deselect any customization classes in the Edit WAR Deployment Profile Properties dialog Filters page.

6. Click **OK** again to exit the Edit EAR Deployment Profile Properties dialog.
7. Click **OK** again to exit the Application Properties dialog.

> **Note:**
>
> To verify that your customization classes are put correctly in the EAR class path, you can deploy the EAR profile to file system. Then you can examine the EAR to make sure that the customization class JAR is available in the EAR class path (the `EAR/lib` directory) and not available in the WAR class path (the `WEB-INF/lib` and `WEB-INF/classes` directories).

Adding Customization Classes into a JAR

If your application has customization classes, create a JAR that contains only these customization classes. When you create your EAR, you can add the JAR to the EAR assembly. And when you create WAR profiles for your web projects, you must make sure they don't include the customization classes JAR.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you add customization classes. For more information, see Preparing the Application.

You will need to complete this task:

> Make sure that your project has customization classes. You do not need to perform this procedure if the application does not have customization classes. For more information about customization classes, see How to Create Customization Classes.

To add customization classes into a JAR:

1. In the Applications window, right-click the data model project that contains the customization classes for which you want to create a JAR, and choose **New > From Gallery**.
2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **JAR File**, and click **OK**.

   Alternatively, if you want to create a shared library, select **Shared Library JAR File** from the list of profile types, and click **OK**.

   > **Note:**
   >
   > If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Features** tab.

3. In the Create Deployment Profile -- JAR File dialog, enter a name for the project deployment profile (for example, `CCArchive`) and click **OK**.
4. In the Edit JAR Deployment Profile Properties dialog, select **JAR Options**.
5. Enter the location for the JAR file.

6. Expand **Files Groups > Project Output > Filters** to list the files that can be selected to be included in the JAR.
7. In Filters page, in the **Files** tab, select the customization classes you want to add to the JAR file.

   If you are using a `customization.properties` file, it needs to be in the same class loader as the JAR file. You can select the `customization.properties` file to package it along with the customization classes in the same JAR.
8. Click **OK** to exit the Edit JAR Deployment Profile Properties dialog.
9. Click **OK** again to exit the Project Properties dialog.
10. In the Applications window, right-click the project containing the JAR deployment profile, and choose **Deploy > deployment profile > to JAR file**.

> **Note:**
>
> If this is the first time you deploy to a JAR from this deployment profile, you choose **Deploy > deployment profile** and select **Deploy to JAR** in the wizard.

Delivering Customization Classes as a Shared Library

As an alternative to adding your customization classes to the EAR, as described in Creating an Application Level EAR Deployment Profile, you can also include the customization classes in the consuming application as a shared library.

> **Note:**
>
> This procedure describes how to create and use a shared library if you are deploying to Oracle Weblogic Server.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create and use a shared library for customization classes. For more information, see Preparing the Application.

You will need to complete this task:

Add customization classes into a JAR using JDeveloper in Studio Developer role. Follow the procedure described in Adding Customization Classes into a JAR, and make sure that you select **Shared Library JAR File** as the type of archive to create.

To create and use a shared library for your customization classes:

1. In the Applications window, right-click the customization classes project, and choose **Deploy > deployment-profile**.
2. In the Deploy wizard, select **Deploy to Application Server** and click **Next**.
3. Select the appropriate application server, and click **Finish**.

This makes the shared library available on the application server. You must now add a reference to the shared library from the consuming application.

4. Open the application you want to customize in JDeveloper in the Studio Developer role.
5. In the Application Resources panel of the Applications window, double-click the **weblogic-application.xml** file.
6. In the overview editor, click the **Libraries** navigation tab.
7. On the Libraries page, in the **Shared Library References** section, click the **Add** icon.
8. In the **Library Name** field of the newly created row in the **Shared Library References** table, enter the name of the customization classes shared library you deployed, and save your changes.

Viewing and Changing Deployment Profile Properties

After you have created a deployment profile, you can view and change its properties.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you view deployment profiles. For more information, see Preparing the Application.

To view, edit, or delete a project's deployment profile:

1. In the Applications window, right-click the project which you want to view or edit and choose **Project Properties**.
2. In the Project Properties dialog, click **Deployment**.

   The **Deployment Profiles** list displays all profiles currently defined for the project.
3. In the Deployment Profiles section, select a deployment profile.
4. To edit or delete a deployment profile, click **Edit** or **Delete**.

How to Create and Edit Deployment Descriptors

Deployment descriptors are server configuration files that define the configuration of an application for deployment and that are deployed with the Java EE application as needed. The deployment descriptors that a project requires depend on the technologies the project uses and on the type of the target application server. Deployment descriptors are XML files that can be created and edited as source files, but for most descriptor types, JDeveloper provides dialogs or an overview editor that you can use to view and set properties. If you cannot edit these files declaratively, the XML file opens in the source editor for you to edit its contents.

In addition to the standard Java EE deployment descriptors (for example, `application.xml` and `web.xml`), you can also have deployment descriptors that are specific to your target application server. For example, if you are deploying to Oracle WebLogic Server, you can also have `weblogic.xml`, `weblogic-application.xml`, and `weblogic-ejb-jar.xml`.

For WebLogic Server, make sure that the application EAR file includes a `weblogic-application.xml` file that contains a reference to `adf.oracle.domain`, and that it includes an `ADFApplicationStateListener` to clean up application resources between deployment and undeployment actions. The following example shows a sample weblogic-application.xml file:

```
<weblogic-application xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
 xsi:schemaLocation="http://www.bea.com/ns/weblogic/weblogic-application.xsd"
 xmlns="http://www.bea.com/ns/weblogic/weblogic-application">
  <listener>
    <listener-class>oracle.adf.share.weblogic.listeners.
          ADFApplicationStateListener</listener-class>
  </listener>
  <listener>
    <listener-class>oracle.mds.lcm.weblogic.WLLifecycleListener</listener-class>
  </listener>
  <library-ref>
    <library-name>adf.oracle.domain</library-name>
  </library-ref>
</weblogic-application>
```

If you are deploying web services, you may need to modify your weblogic-application.xml and web.xml files as described in How to Deploy Web Services to Oracle WebLogic Server.

If you want to enable the application for Real User Experience Insight (RUEI) monitoring, you must add a parameter to the web.xml file, as described in Enabling the Application for RUEI and Click History.

During deployment, the application's security properties are written to the weblogic-application.xml file to be deployed with the application in the EAR file. For more information, see What Happens When You Configure Security Deployment Options.

Because Oracle WebLogic Server runs on the Java EE Platform, you may need to modify the application.xml and web.xml files to be compatible with the application server.

Creating Deployment Descriptors

JDeveloper automatically creates many of the required deployment descriptors for you. If they are not present, or if you need to create additional descriptors, you can use JDeveloper to create them.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create deployment descriptors. For more information, see Preparing the Application.

You will need to complete this task:

Check to see whether JDeveloper has already generated deployment descriptors.

To create a deployment descriptor:

1. In the Applications window, right-click the project for which you want to create a descriptor and choose **New > From Gallery**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then a descriptor type, and click **OK**.

   If you can't find the item you want, make sure that you chose the correct project, and then choose the **All Features** tab or use the **Search** field to find the descriptor. If the item is not enabled, check to make sure that the project does not already have a descriptor of that type. A project is allowed only one instance of a descriptor.

JDeveloper starts the Create Deployment Descriptor wizard and then opens the file in the overview or source editor, depending on the type of deployment descriptor you choose.

> **Note:**
>
> For EAR files, do not create more than one deployment descriptor file of the same type per application or workspace. These files can be assigned to projects, but have application workspace scope. If multiple projects in an application have the same deployment descriptor, the one belonging to the launched project will supersede the others. This restriction applies to `application.xml`, `weblogic-jdbc.xml`, `jazn-data.xml`, and `weblogic.xml`.
>
> The best place to create an application level descriptor is in the **Descriptors** node of the Application Resources panel in the Applications window. This ensures that the application is created with the correct descriptors.
>
> Application level descriptors created in the project will be ignored at runtime. Only the application resources descriptors or descriptors generated at the EAR level will be used by the runtime.

Viewing or Modifying Deployment Descriptor Properties

After you have created a deployment descriptor, you can change its properties by using JDeveloper dialogs or by editing the file in the source editor. The deployment descriptor is an XML file (for example, `application.xml`) typically located under the Application Sources node.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you view deployment descriptors. For more information, see Preparing the Application.

To view or change deployment descriptor properties:

1. In the Applications window or in the Application Resources panel, double-click the deployment descriptor.
2. In the editor window, select either the **Overview tab** or the **Source tab**, and configure the descriptor by setting property values.

   If the overview editor is not available, the file opens in the source editor.

Configuring the application.xml File for Application Server Compatibility

You may need to configure your `application.xml` file to be compliant with your Java EE version.

> **Note:**
>
> Typically, your project has an `application.xml` file that is compatible and you would not need to perform this procedure.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you configure `application.xml`. For more information, see Preparing the Application.

To configure the application.xml file:

1. In the Applications window, right-click the application and choose **New > From Gallery**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor Wizard**, and click **OK**.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select **application.xml** and click **Next**.
4. On the Select Version page, select **5.0** to be compatible with Java EE 5.0 or higher, and click **Next**.
5. On the Summary page, click **Finish**.
6. Edit the `application.xml` file with the appropriate values.

Configuring the web.xml File for Application Server Compatibility

You may need to configure your `web.xml` file to be compliant with your Java EE version. See web.xml.

> **Note:**
>
> Typically, your project has a `web.xml` file that is compatible and you would not need to perform this procedure. JDeveloper creates a starter `web.xml` file when you create a project.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you configure `web.xml`. See Preparing the Application.

To configure the web.xml file:

1. In the Applications window, right-click the project in which you want to configure a `web.xml` file and choose **New > From Gallery**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor**, and click **OK**.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select **web.xml** and click **Next**.

4. On the Select Version page, select the version you want to use and click **Next**.

   Version 3.0 is compatible with Java EE 6.0 or higher, and version 2.5 is compatible with Java EE 5.0.

5. On the Summary page, click **Finish**.

Enabling the Application for RUEI and Click History

Real User Experience Insight (RUEI) is a web-based utility to report on real-user traffic requested by, and generated from, your network. It measures the response times of pages and transactions at the most critical points in the network infrastructure. Session diagnostics allow you to perform root-cause analysis.

RUEI enables you to view server and network times based on the real-user experience, to monitor your Key Performance Indicators (KPIs) and Service Level Agreements (SLAs), and to trigger alert notifications on incidents that violate their defined targets. You can implement checks on page content, site errors, and the functional requirements of transactions. Using this information, you can verify your business and technical operations. You can also set custom alerts on the availability, throughput, and traffic of all items identified in RUEI.

For information about RUEI, see the *Oracle Real User Experience Insight documentation* at `http://docs.oracle.com/en/enterprise-manager/?tab=3`.

Click History is a feature that is built into ADF that reports user actions on UI components such as button clicks and mouse scrolling. Click History needs to be enabled on the WebLogic server as well as within the application using the `web.xml` and `weblogic.xml` files.

For information about Click History and how to enable it in WebLogic server, see Click History in *Administering Oracle ADF Applications*.

To enable RUEI and Click History in the web.xml file:

1. In the Applications window, expand **WEB-INF** and double-click **web.xml**.
2. In the overview editor, add the `context-param` tag to the `web.xml` file, as shown in the following example.

```
<context-param>
  <description>This parameter notifies ADF Faces that the
               ExecutionContextProvider service provider is enabled.
               When enabled, this will start monitoring and aggregating
               user activity information for the client initiated
               requests. By default this param is not set or is false.
  </description>
  <param-name>
        oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER
  </param-name>
  <param-value>true</param-value>
</context-param>
```

For Click History, in addition to adding the parameter to the `web.xml` file, you also need to define the `odl.clickhistory.webapp` library in the `weblogic.xml` file.

To finish enabling Click History using the weblogic.xml file:

1. In the Applications window, expand **WEB-INF** and double-click **weblogic.xml**.

2. In the overview editor, add the library entry to the `weblogic.xml` file, as shown in the following example.

   ```
   <library-ref>
          <library-name>odl.clickhistory.webapp</library-name>
   </library-ref>
   ```

If there is an `EndUserMonitoringService` service provider available, you can use it to log performance metrics and data by registering it in your application. The service provider should have been implemented by extending the `EndUserMonitoringService` class. For more information about this class, see the Javadoc.

Note that the context-parameter `oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER` needs to be set when an `EndUserMonitoringServive` provider is used within an ADF application.

To enable End User Monitoring in an application:

1. Verify that an `EndUserMonitoringService` service provider has been implemented.
2. Navigate to the application's `<`*`application_home`*`>/src/META-INF/services` folder using your operating system tools.

   If the `services` folder does not exist, create one.
3. In the `<`*`application_home`*`>/src/META-INF/services` folder, create a file named `oracle.adf.view.rich.monitoring.`*`EndUserMonitoringService`*

   where *`EndUserMonitoringService`* is the name of the service interface.
4. Open the file in an editor and add this entry: *`<package>.MyEndUserMonitoringService`*

   where *`package`* is the Java package name where the service provider resides and *`MyEndUserMonitoringService`* is the name of the `EndUserMonitoringService` service provider.

How to Deploy Applications with ADF Security Enabled

If you are developing an application in JDeveloper using Integrated WebLogic Server, application security deployment properties are configured by default, which means that the application and security credentials and policies will be overwritten each time you redeploy for development purposes. However, the application security deployment properties are the same for Integrated WebLogic Server and the standalone WebLogic Server.

You can change the default behavior in the Application Properties dialog, as described in How to Configure, Deploy, and Run a Secure Application in JDeveloper.

Applications That Will Run Using Oracle Single Sign-On (SSO)

Before you can deploy and run the web application with ADF Security enabled on the application server, the administrator of the target server must configure the domain-level `jps-config.xml` file for the Oracle Access Manager (OAM) security provider. To complete this configuration task, you can use Oracle WebLogic Scripting Tool (WLST) provided with the JDeveloper install. For details about running WLST (with command `addOAMSSOProvider(loginuri, logouturi, autologinuri)`), see Integrating Access Manager With Web Applications Using Oracle ADF Security and the OPSS SSO

Framework and Integrating Oracle ADF Applications with Access Manager SSO of the *Administrator's Guide for Oracle Access Management*.

Running the addOAMSSOProvider() command ensures that the ADF Security framework defers to the OAM service provider to clear the ObSSOCookie token. OAM uses this token to save the identity of authenticated users and, unless it is cleared during logout, the user will be unable to log out.

After the system administrator runs the command on the target server, the domain jps-config.xml file will contain the following security provider definition that is specific for ADF Security:

```
<propertySet name="props.auth.uri">
    <property name="login.url.FORM" value="/${app.context}/adfAuthentication"/>
    <property name="logout.url" value=""/>
</propertySet>
```

Additionally, the authentication type required by SSO is CLIENT-CERT. The web.xml authentication configuration for the deployed application must specify the <auth-method> element as one of the following CLIENT-CERT types.

WebLogic supports two types of authentication methods:

- For FORM-type authentication method, specify the elements like this:

```
<login-config>
  <auth-method>CLIENT-CERT,FORM</auth-method>
  <realm-name>myrealm</realm-name>
  <form-login-config>
     <form-login-page>/login.html</form-login-page>
     <form-error-page>/error.html</form-error-page>
  </form-login-config>
</login-config>
```

- For BASIC-type authentication method, specify the elements like this:

```
<login-config>
   <auth-method>CLIENT-CERT,BASIC</auth-method>
   <realm-name>myrealm</realm-name>
</login-config>
```

You can configure the web.xml file either before or after deploying the web application. For further details about setting up the authentication method for Single Sign-On, see Managing Access Manager SSO, Policies, and Testing of the *Administrator's Guide for Oracle Access Management*.

Configuring Security for Weblogic Server

In a development environment, JDeveloper will automatically migrate application level credentials, identities, and policies to the standalone WebLogic Server instance only if the server is set up to be in development mode. Integrated WebLogic Server is set up in development mode by default. You can set up a standalone WebLogic Server to be in development mode during Oracle WebLogic Server domain creation using the Oracle Fusion Middleware Configuration Wizard. For more information about configuring Oracle WebLogic Server domains, see Introduction to WebLogic Domains in *Creating WebLogic Domains Using the Configuration Wizard*.

JDeveloper will not migrate application level security credentials to WebLogic Server set up in production mode. Typically, in a production environment, administrators will use Enterprise Manager or WLST to deploy an application, including its security requirements.

When you deploy an application to WebLogic Server, credentials (in the `cwallet.sso` file) and security policies (in the `jazn-data.xml` file) will either overwrite or merge with the WebLogic Server's domain-level credential store, depending on whether an option in `weblogic-application.xml` is set to `OVERWRITE` or `MERGE`. In production-mode WebLogic Server, to avoid security risks, only `MERGE` is allowed. For development-mode WebLogic Server, you can set to `OVERWRITE` to test user names and passwords. You can also set the option by running `setDomainEnv.cmd` or `setDomainEnv.sh` with the following option added to the command (usually located in `ORACLE_HOME/user_projects/domains/`*`MyDomain`*`/bin`).

For `setDomainEnv.cmd`:

```
set EXTRA_JAVA_PROPERTIES=-Djps.app.credential.overwrite.allowed=true
    %EXTRA_JAVA_PROPERTIES%
```

For `setDomainEnv.sh`:

```
EXTRA_JAVA_PROPERTIES="-Djps.app.credential.overwrite.allowed=true
     ${EXTRA_JAVA_PROPERTIES}"
export EXTRA_JAVA_PROPERTIES
```

If the Administration Server is already running, you must restart it for this setting to take effect.

You can check to see whether WebLogic Server is in production mode by using the Oracle WebLogic Server Administration Console or by verifying the following line in WebLogic Server's `config.xml` file:

```
<production-mode-enabled>true</production-mode-enabled>
```

By default, JDeveloper sets the application's credential, identities, and policies to `OVERWRITE` mode. That is, the **Application Policies**, **Credentials**, and **Users and Groups** options are selected by default in the Application Properties dialog Deployment page. However, an application's credentials will be migrated only if the target WebLogic Server instance is set to development mode with `-Djps.app.credential.overwrite.allowed=true`

Policy migration only works in development-mode. Identity migration only works when using JDeveloper to directly deploy to WebLogic Server regardless of whether it is in development or production-mode.

When your application is ready for deployment to a production environment, you should remove the identities from the `jazn-data.xml` file or disable the migration of identities by deselecting **Users and Groups** from the Application Properties dialog. Application credentials must be manually migrated outside of JDeveloper.

> **Note:**
>
> Before you migrate the `jazn-data.xml` file to a production environment, check that the policy store does not contain duplicate permissions for a grant. If a duplicate permission (one that has the same name and class) appears in the file, the administrator migrating the policy store will receive an error and the migration of the policies will be halted. You should manually edit the `jazn-data.xml` file to remove any duplicate permissions from a grant definition.

For more information about migrating application credentials and other `jazn-data` user credentials, see the Configuring the OPSS Security Store chapter in *Securing Applications with Oracle Platform Security Services*.

Applications with JDBC URL for WebLogic

If your application has components that use JDBC URL connections, the connection user names and passwords are also stored in the application level credential and policy stores. For the deployed application to be able to connect to the database using the JDBC URL, these credentials and policies must be migrated. That is, if WebLogic Server is in production mode, system administrators must migrate this security information. If WebLogic Server is in development mode, it must have domain-level credential and policy stores set to `OVERWRITE` to allow the migration of security information.

Applications with JDBC Data Source for WebLogic

If your application uses application level JDBC data sources with password indirection for database connections, you may need to create credential maps in WebLogic Server to enable the database connection. See Creating a JDBC Data Source for Oracle WebLogic Server in *Administering Oracle ADF Applications*.

How to Replicate Memory Scopes in a Clustered Environment

If you are deploying an application that is intended to run in a clustered environment, you need to ensure that all managed beans with a lifespan longer than one request are serializable, and that Oracle ADF is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

For more information, see How to Set Managed Bean Memory Scopes in a Server-Cluster Environment.

How to Enable the Application for ADF MBeans

A Fusion web application uses many XML files for setting configuration information. Three of these configuration files have ADF MBean counterparts that are deployed with the application. After the application has been deployed, you can change configuration properties by accessing the ADF MBeans using the Enterprise Manager Fusion Middleware Control MBean browser.

To enable ADF MBeans, register them in the web.xml file. The following example shows a web.xml file with listener entries for connections, configuration, and business components.

```
<listener>
   <listener-class>
        oracle.adf.mbean.share.connection.ADFConnectionLifeCycleCallBack
   </listener-class>
</listener>
<listener>
   <listener-class>
        oracle.adf.mbean.share.config.ADFConfigLifeCycleCallBack</listener-class>
</listener>
<listener>
   <listener-class>
        oracle.bc4j.mbean.BC4JConfigLifeCycleCallBack</listener-class>
</listener>
```

Additionally, you must configure a writable MDS repository to enable post-deployment configuration of connections.xml using ADF Connections MBeans and bc4j.xcfg using ADF Business Components MBeans.

MDS configuration entries in the adf-config.xml file for a database-based MDS are shown in the example below. For more information about configuring MDS, see Changing MDS Configuration Attributes for Deployed Applications in *Administering Oracle Fusion Middleware*.

```
<adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
   <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
      <persistence-config>
         <metadata-store-usages>
            <metadata-store-usage
                default-cust-store="true" deploy-target="true" id="myStore">
            </metadata-store-usage>
         </metadata-store-usages>
      </persistence-config>
   </mds-config>
</adf-mds-config>
```

In a production environment, an MDS repository that uses a database is required. You can use JDeveloper, Enterprise Manager Fusion Middleware Control or scripts to switch from a file-based repository to a database MDS repository.

Additionally, if several applications are sharing the same MDS configuration, each application can achieve distinct customization layers by defining a adf:adf-properties-child property in the adf-config.xml file. JDeveloper automatically generates this entry when creating applications. If your adf-config.xml file does not have this entry, add it to the file with code similar to this one:

```
<adf:adf-properties-child xmlns="http://xmlns.oracle.com/adf/config/properties">
     <adf-property name="adfAppUID" value="Application3-4434"/>
     <adf-property name="partition_customizations_by_application_id"
            value="true"/>
</adf:adf-properties-child>
```

The value attribute is either generated by JDeveloper or you can set it to any unique identifier within the server farm where the application is deployed. This value can be set to the value attribute of the adfAppUID property.

When `adf-property name` is set to `adfAppUid`, then the corresponding `value` property should be set to the name of the application. By default, JDeveloper generates the `value` property using the application's package name. If the package name is not specified, JDeveloper generates the `value` property by using the workspace name and a four digit random number.

For more information about configuring ADF applications using ADF MBeans, see Modifying ADF Application Configurations Using MBeans in *Administering Oracle ADF Applications*.

What You May Need to Know About JDBC Data Source for Oracle WebLogic Server

ADF applications can use either a JDBC data source or a JDBC URL for database connections. You use the Oracle WebLogic Server Administration Console to configure a JDBC data source. For more information about database access, see Configuring Your Application Module Database Connection.

> **Note:**
>
> Fusion web applications are not compatible with data sources defined with the JDBC XA driver. When creating a data source on Oracle WebLogic Server, be sure to change the Fusion web application data source's JDBC driver from “Oracle's Driver (Thin XA)" to “Oracle's Driver (Thin)". Because XA data sources close all cursors upon commit, random JBO-27122 and closed statement errors may result when running the Fusion web application with an XA data source.

The **application module** in the data model project of a Fusion web application can be configured to use a JDBC URL connection type, a JDBC data source connection type, or a combination of both types. By default, Fusion web application modules use a JDBC URL connection. A component that uses a JDBC URL will attempt to connect directly to the database using the JDBC URL, and it will ignore any JDBC data sources (global or application level) that are available in WebLogic Server. For more information about migrating JDBC URL security information (user names and passwords) from the application to WebLogic Server, see How to Deploy Applications with ADF Security Enabled.

A Fusion web application can use a JDBC data source to connect to the database. A JDBC data source has three types: global, application level, and application level with password indirection. You generally set up a global JDBC data source in WebLogic Server. Any application that requires access to that database can use that JDBC data source. An application can also include application level JDBC data sources. When the application is packaged for deployment, if the **Auto Generate and Synchronize weblogic-jdbc.xml Descriptor During Deployment** option is selected, JDeveloper creates a *`connection_name`*`-jdbc.xml` file for each connection that was defined. Each connection's information is written to the corresponding *`connection_name`*`-jdbc.xml` file (entries are also changed in `weblogic-application.xml` and `web.xml`). When the application is deployed to WebLogic Server, the server looks for application level data source information before it looks for the global data source.

If the application is deployed with password indirection set to `true`, WebLogic Server will look for the *`connection_name`*`-jdbc.xml` file for user name information and it will then attempt to locate application level credential maps for these user names to obtain the password. If you are using JDeveloper to directly deploy the application to WebLogic Server, JDeveloper automatically creates the credential map and populates the map to the server using an MBean call.

However, if you are deploying to an EAR file, JDeveloper will not be able to make the MBean call to WebLogic Server. You must set up the credential maps using the Oracle WebLogic Administration Console. Even if you have a global JDBC data source set up, if you do not also have credential mapping set up, WebLogic Server will not be able to map the credentials with passwords and the connection will fail.

Once the data source has been created in Oracle WebLogic Server, it can be used by an application module. See Preparing the Standalone Application Server for Deployment in *Administering Oracle ADF Applications*.

Deploying the Application

Once the target environment is set up and the ADF application is prepared for deployment, the final step is to deploy the application to the target environment.

You can use JDeveloper to deploy ADF applications directly to the standalone application server or you can create an archive file and use other tools to deploy to the application server.

> **Note:**
>
> Before you begin to deploy applications that use Oracle ADF to the standalone application server, you need to prepare the application server environment by performing tasks such as installing the ADF runtime and creating and extending domains or cells. See Preparing the Standalone Application Server for Deployment.

Figure 55-5 show the process flow for deploying an application and also for deploying customizations to the target standalone application server.

Testing and Verifying Deployment
Start

Table 55-1 describes some common deployment techniques that you can use during the application development and deployment cycle. The deployment techniques are listed in order from deploying on development environments to deploying on production environments. It is likely that in the production environment, the system administrators deploy applications by using Enterprise Manager Fusion Middleware Control or scripts.

Table 55-1 Deployment Techniques for Development or Production Environments

Deployment Technique	Environment	When to Use
Run directly from JDeveloper	Test or Development	When you are developing your application. You want deployment to be quick because you will be repeating the editing and deploying process many times. JDeveloper contains Integrated WebLogic Server, on which you can run and test your application.
Use JDeveloper to directly deploy to the target application server	Test or Development	When you are ready to deploy and test your application on an application server in a test environment. On the test server, you can test features (such as LDAP and Oracle Single Sign-On) that are not available on the development server. You can also use the test environment to develop your deployment scripts, for example, using Ant.
Use JDeveloper to deploy to an EAR file, then use the target application server's tools for deployment	Test or Development	When you are ready to deploy and test your application on an application server in a test environment. As an alternative to deploying directly from JDeveloper, you can deploy to an EAR file and then use other tools to deploy to the application server. On the test server, you can test features (such as LDAP and Oracle Single Sign-On) that are not available on the development server. You can also use the test environment to develop your deployment scripts, for example, using Ant.
Use Enterprise Manager or WLST to deploy applications	Production	When your application is in a test and production environment. In production environments, system administrators usually use Enterprise Manager Fusion Middleware Control or run WLST to deploy applications.

Any necessary MDS repositories must be registered with the application server. If the MDS repository is a database, the repository maps to a data source with MDS-specific requirements.

If you are deploying the application to Oracle WebLogic Server, make sure to target this data source to the WebLogic Administration Server and to all Managed Servers to which you are deploying the application. For information about registering MDS, see Registering and Deregistering a Database-Based MDS Repository in *Administering Oracle Fusion Middleware*.

If you are using the application server's administrative console or scripts to deploy an application packaged as an EAR file that requires MDS repository configuration in `adf-config.xml`, you must run the `getMDSArchiveConfig` command to configure MDS before deploying the EAR file. MDS configuration is required if the EAR file contains a MAR file or if the application is enabled for DT@RT (Design Time At RunTime).

For information about WLST commands, see the *WLST Command Reference for Infrastructure Components*.

If you plan to configure ADF connection information, **ADF Business Components** information, or `adf-config.xml` using ADF MBeans after the application has been deployed, make sure that the application is configured with MDS and have the MBean listeners enabled in the `web.xml` file. See How to Enable the Application for ADF MBeans.

> **Note:**
>
> If your Fusion web application has business services that you want to deploy to WebLogic Server, see How to Deploy Web Services to Oracle WebLogic Server.

How to Deploy to the Application Server from JDeveloper

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you deploy an application. See Deploying the Application.

You will need to complete this task:

Create an application level deployment profile that deploys to an EAR file as described in Creating an Application Level EAR Deployment Profile.

> **Note:**
>
> When you are deploying to Oracle WebLogic Server from JDeveloper, ensure that the HTTP Tunneling property is enabled in the Oracle WebLogic Server Administration Console. This property is located under **Servers > *ServerName* > Protocols**. ***ServerName*** refers to the name of Oracle WebLogic Server.

> **Note:**
>
> JDeveloper does not support deploying applications to individual Managed Servers that are members of a cluster. You may be able to target one or more Managed Servers within a cluster using the Oracle WebLogic Server Administration Console or other Oracle WebLogic tools; however, the cluster can be negatively affected. For more information about deploying to Oracle WebLogic Server clusters, see Deploying an Application to Managed Servers in *Administering Oracle Fusion Middleware*.

To deploy to the target application server from JDeveloper:

1. In the Applications window, right-click the application and choose **Deploy > *deployment profile***.
2. In the Deploy wizard, on the Deployment Action page, select **Deploy to Application Server** and click **Next**.
3. On the Select Server page, select the application server connection, and click **Next**.
4. If you are deploying to a WebLogic Server instance, the WebLogic Options page appears. Select a deployment option and click **Next**.

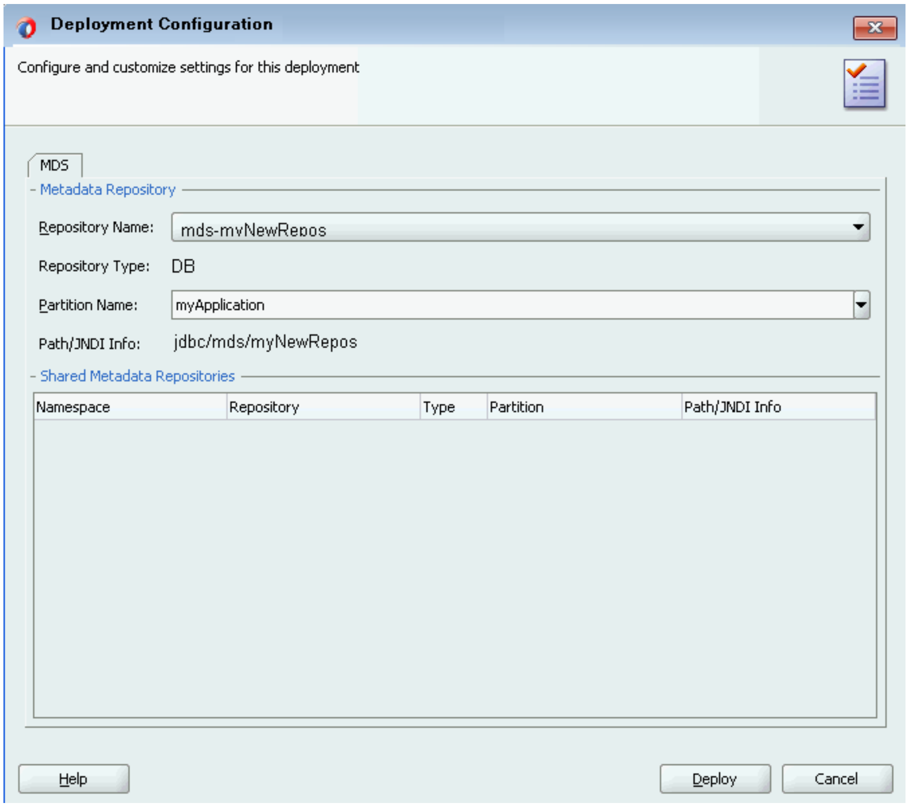
> **Note:**
>
> If you are deploying an ADF application, do not use the **Deploy to all instances in the domain** option.

5. Click **Finish**.

   During deployment, you can see the process steps displayed in the deployment Log window. You can inspect the contents of the modules (archives or exploded EAR) being created by clicking on the links that are provided in the log window. The archive or exploded EAR file will open in the appropriate editor or directory window for inspection.

   If the `adf-config.xml` file in the EAR file requires MDS repository configuration, the Deployment Configuration dialog appears for you to choose the target metadata repository or shared metadata repositories, as shown in Figure 55-6. The **Repository Name** dropdown list allows you to choose a target metadata repository from a list of metadata repositories registered with the Administration Server. The **Partition Name** dropdown list allows you to choose the metadata repository partition to which the application's metadata will be imported during deployment. You can use Oracle WebLogic Scripting Tool (WLST) and Oracle WebLogic Server Administration Tool to configure and register MDS. For more information about managing the MDS Repository, see Managing the MDS Repository in *Administering Oracle Fusion Middleware*.

Figure 55-6 MDS Configuration and Customization for Deployment



Deployment Configuration

Configure and customize settings for this deployment

Partition Name: myApplication

Path/JNDI Info: jdbc/mds/myNewRepos

Shared Metadata Repositories

Namespace	Repository	Type	Partition	Path/JNDI Info

> **Note:**
>
> If you are deploying a Java EE application, click the application menu next to the Java EE application in the Applications window.

For more information on creating application server connections, see How to Create a Connection to the Target Application Server.

How to Create an EAR File for Deployment

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using Enterprise Manager, Oracle WebLogic Scripting Tool (WLST), or Oracle WebLogic Server Administration Console.

Although a Fusion web application is encapsulated in an EAR file (which usually includes WAR, MAR, and JAR components), it may have parts that are not deployed with the EAR. For instance, ADF Business Services can be deployed as a JAR. For more information about business services, see How to Deploy Web Services to Oracle WebLogic Server.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an EAR file for deployment. For more information, see Deploying the Application.

You will need to complete this task:

Create an application level deployment profile that deploys to an EAR file as described in Creating an Application Level EAR Deployment Profile.

To create an EAR archive file:

1. In the Applications window, right-click the application containing the deployment profile, and choose **Deploy > *deployment profile***.
2. In the Deploy wizard, on the Deployment Action page, select **Deploy to EAR** and click **Finish**.

   If an EAR file is deployed at the application level, and it has dependencies on a JAR file in the data model project and dependencies on a WAR file in the user interface project, then the files will be located in the following directories by default:

   - `*ApplicationDirectory*/deploy/*EARdeploymentprofile*.EAR`
   - `*ApplicationDirectory*/*ModelProject*/deploy/*JARdeploymentprofile*.JAR`
   - `*ApplicationDirectory*/*ViewControllerProject*/deploy/*WARdeploymentprofile*.WAR`

> **Tip:**
>
> Choose **View** >**Log** to see messages generated during creation of the archive file.

How to Deploy New Customizations Applied to ADF Library

If you have created new customizations for an ADF Library, you can use the MAR profile to deploy these customizations to any deployed application that consumes that ADF Library. For instance, suppose `applicationA`, which consumes `ADFLibraryB`, is deployed to a standalone application server. Later on, when new customizations are added to `ADFLibraryB`, you only need to deploy the updated customizations into `applicationA`. You do not need to repackage and redeploy the whole application nor do you need to manually patch the MDS repository.

> **Note:**
>
> This procedure is for applying ADF Library customizations changes to an application that has already been deployed to a standalone application server. It is not for the initial packaging of customizations into a MAR that will eventually be a part of an EAR. For information about initial packaging of the customization using a MAR, see Creating a MAR Deployment Profile.

To deploy ADF Library customizations, create a new MAR profile and only include the customizations to be deployed and then use JDeveloper to:

- Deploy the customizations directly into the MDS repository in the standalone application server.
- Deploy the customizations to a JAR. And then import the JAR into the MDS repository using tools such as the Fusion Middleware Control.

Exporting Customization to a Deployed Application

You can export the customizations directly from JDeveloper into the MDS repository for the deployed application on the standalone application server.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you export customizations directly into the application server. For more information, see Deploying the Application.

You will need to complete this task:

Create new customizations to the ADF Library. For more information on customizations, see How to Customize ADF Library Artifacts in JDeveloper.

To export the customizations directly into the application server:

1. In the Applications window, right-click the application and choose **Deploy > metadata**.
2. In the Deploy metadata dialog, on the Deployment Action page, select **Export to a Deployed Application** and click **Next**.

   If the MAR profile is included in the EAR profile of any application, **Export to a Deployed Application** will be dimmed and disabled.

3. On the Application Server page, select the application server connection and click **Next**.
4. For WebLogic Server, the Server Instance page appears. In this page, select the server instance where the deployed application is located and click **Next**.
5. On the Deployed Application page, select the application you want to apply the customizations to and click **Next**.
6. On the Sandbox Instance page, if you want to deploy to a sandbox, select **Deploy to an associated sandbox**, choose the sandbox instance, and click **Next**.
7. On the Summary page, verify the information and click **Finish**.

Deploying Customizations to a JAR

When you deploy the ADF Library customizations to a JAR, you are packaging the contents as defined by the MAR profile.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you deploy customizations as a JAR. For more information, see Deploying the Application.

You will need to complete this task:

> Create new customizations to the ADF Library. For more information on customizations, see How to Customize ADF Library Artifacts in JDeveloper.

To deploy the customizations as a JAR:

1. In the Applications window, right-click the application and choose **Deploy > metadata**.
2. In the Deploy Metadata dialog, on the Deployment Action page, select **Deploy to MAR**.
3. On the Summary page, click **Finish**.
4. Use Enterprise Manager Fusion Middleware Control or the application server's administration tool to import the JAR into the MDS repository.

For information about Fusion Middleware Control, see Getting Started Using Oracle Enterprise Manager Fusion Middleware Control in *Administering Oracle Fusion Middleware*

What You May Need to Know About ADF Libraries

An ADF Library is a JAR file that contains JAR services registered for ADF components such as ADF task flows, pages, or application modules. If you want the ADF components in a project to be reusable, you create an ADF Library deployment profile for the project and then create an ADF Library JAR based on that profile.

An application or project can consume the ADF Library JAR when you add it using the Resources window or manually by adding it to the library classpath. When the ADF Library JAR is added to a project, it will be included in the project's WAR file if the **Deployed by Default** option is selected.

For more information, see Reusing Application Components.

What You May Need to Know About EAR Files and Packaging

When you package a Fusion web application into an EAR file, it can contain the following:

- WAR files: Each web-based view controller project should be packaged into a WAR file.
- MAR file: If the application has customizations that are deployed with the application, it should be packaged into a MAR.
- ADF Library JAR files: If the application consumes ADF Library JARs, these JAR files may be packaged within the EAR.
- Other JAR files: The application may have other dependent JAR files that are required. They can be packaged within the EAR.

How to Deploy the Application Using Scripts and Ant

You can deploy the application using commands and automate the process by putting those commands in scripts. The `ojdeploy` command can be used to deploy an application without JDeveloper. You can also use Ant scripts to deploy the application. JDeveloper has a feature to help you build Ant scripts. Depending on your requirements, you may be able to integrate regular scripts with Ant scripts.

For more information about commands, scripts, and Ant, see Deploying Using Scripts and Ants in *Administering Oracle ADF Applications*.

How to Deploy ADF Faces Library JARs with the Application

You can develop applications that only use ADF Faces without using ADF Model. In that case, you can deploy the ADF Faces JARs with the application into the application server.

Before you begin:

Create an application with a web-based project. If you used the Fusion Web Application (ADF) template, you should already have a default WAR deployment profile.

To deploy ADF Faces JARs as part of the application:

1. In the Applications window, right-click the web project that you want to deploy and choose **Project Properties**.
2. In the Project Properties dialog, select **Deployment** and then the deployment profile and click **Edit**.

   If your project does not have a WAR deployment profile, follow Steps 1 to 3 in Creating a WAR Deployment Profile, to create a new WAR deployment profile.
3. Navigate to **File Groups > WEB-INF/lib > Contributors** and select **ADF Faces Runtime 11**.
4. Click **OK** to exit the Deployment Profile Properties dialog.
5. Click **OK** again to exit the Project Properties dialog.

6. Deploy your application as described in this chapter either directly using JDeveloper or by creating a EAR and deploying it using the Enterprise Manager Fusion Middleware Control, the Oracle WebLogic Server Administration Console, or other methods.

   Make sure your application-level EAR contains the WAR file as described in Creating an Application Level EAR Deployment Profile.

What You May Need to Know About JDeveloper Runtime Libraries

When an application is deployed, it includes some of its required libraries with the application. The application may also require shared libraries that have already been loaded to WebLogic Server as JDeveloper runtime libraries. It may be useful to know which JDeveloper libraries are packaged within which WebLogic Server shared library. For a listing of the contents of the JDeveloper runtime libraries, see ADF Runtime Libraries in *Administering Oracle ADF Applications*.

Postdeployment Configuration

After deployment, you can perform configuration tasks such migrate a Fusion web application from one WebLogic Server to another and enable an application for ADF MBeans.

After you have deployed your application to WebLogic Server, you can perform configuration tasks.

How to Migrate an Application

If you want to migrate a Fusion web application from one WebLogic Server to another WebLogic Server, you may need to perform some of the same steps you did for a first time deployment.

In general, to migrate an application, you would:

- Load the ADF runtime (if it is not already installed) to the target application server. See Preparing the Standalone Application Server for Deployment in *Administering Oracle ADF Applications*.
- Configure the target application server with the correct database or URL connection information.
- Migrate security information from the source to the target. For instructions, see How to Deploy Applications with ADF Security Enabled.
- Deploy the application using Enterprise Manager, administration console, or scripts. See Deploying Using Oracle Enterprise Manager Fusion Middleware Control in *Administering Oracle ADF Applications*.

How to Configure the Application Using ADF MBeans

If ADF MBeans were enabled and packaged with the deployed application, you can configure ADF properties using the Enterprise Manager MBean Browser. For instructions on how to enable an application for MBeans, see How to Enable the Application for ADF MBeans.

For information on how to configure ADF applications using ADF MBeans, see Configuring Application Properties Using the MBean Browser in *Administering Oracle ADF Applications*.

Testing the Application and Verifying Deployment

In order to ensure the deployment of the ADF application has been successful, you should test-run the application.

After you deploy the application, you can test it from the application server. To test-run your ADF application, open a browser window and enter a URL:

- For non-Faces pages: `http://<host>:port/<context root>/<page>`
- For Faces pages: `http://<host>:port/<context root>/faces/<view_id>`

  where `<view_id>` is the view ID of the ADF task flow view activity.

> **Tip:**
>
> The context root for an application is specified in the user interface project settings by default as *`ApplicationName`*/*`ProjectName`*/`context-root`. You can shorten this name by specifying a name that is unique across the target application server. Right-click the user interface project, and choose **Project Properties**. In the Project Properties dialog, select **Java EE Application** and enter a unique name for the context root.

> **Note:**
>
> `/faces` has to be in the URL for Faces pages. This is because JDeveloper configures your `web.xml` file to use the URL pattern of `/faces` in order to be associated with the Faces Servlet. The Faces Servlet does its per-request processing, strips out `/faces` part in the URL, then forwards the URL to the JSP. If you do not include the `/faces` in the URL, then the Faces Servlet is not engaged (since the URL pattern doesn't match). Your JSP is run without the necessary JSF per-request processing.

Using State Management in a Fusion Web Application

This chapter describes the Fusion web application state management facilities for ADF application modules to support stateful applications on the web.
This chapter includes the following sections:

About Fusion Web Application State Management

State management in the ADF application is the process by which you maintain state and page information over multiple requests for the same or different pages.

Most real-world business applications need to support multi-step user tasks. Transactional web sites tend to use a step-by-step style user interface to guide the end user through a logical sequence of pages to complete these tasks. When the task is done, the user can save or cancel everything as a unit. However, the HTTP protocol is built on the concept of individual, stateless requests, so the responsibility of grouping a sequence of user actions into a logical, stateful unit of work falls to the application developer.

The limitations of the HTTP protocol have led developers to invent solutions involving a "shadow" set of database tables with no constraints and with all of the column types defined as character-based. Using such a solution becomes very complex very quickly. Ultimately, some kind of generic application state management facility is needed to address these issues in a more generic and workable way. The solution comes in the form of **ADF Business Components**, which implements this for you out of the box.

State management enables you to easily create web applications that support multi-step use cases without falling prey to the memory, reliability, or implementation complexity problems. Oracle ADF simplifies the process of implementing and maintaining session state through the use of application module pools, which are configurable resource managers that release application module caches safely. By default, the ADF Business Components project enables one application module pool for each application module definition in your application.

In Fusion web applications, state management is provided at these levels:

- Save For Later feature in the ADF Controller layer implemented in task flows, as described in Using Save Points in Task Flows.

  Save For Later is activated at the ADF Controller layer and automatically saves a "snapshot" of the current UI and controller states, and delegates to the ADF Model layer to save its state as well. Save for Later saves an incomplete transaction without enforcing validation rules or submitting the data. You can use it to save data and state information about a **region**, view port, or portlet. Later, you can restore application state and data associated with a save point that supports both explicit saves (initiated by the user) or implicit saves (without user action). The end user can resume working on the same transaction with the same data that was originally saved when the application was exited.

- Application state management facility in the ADF Model layer implemented in application modules.

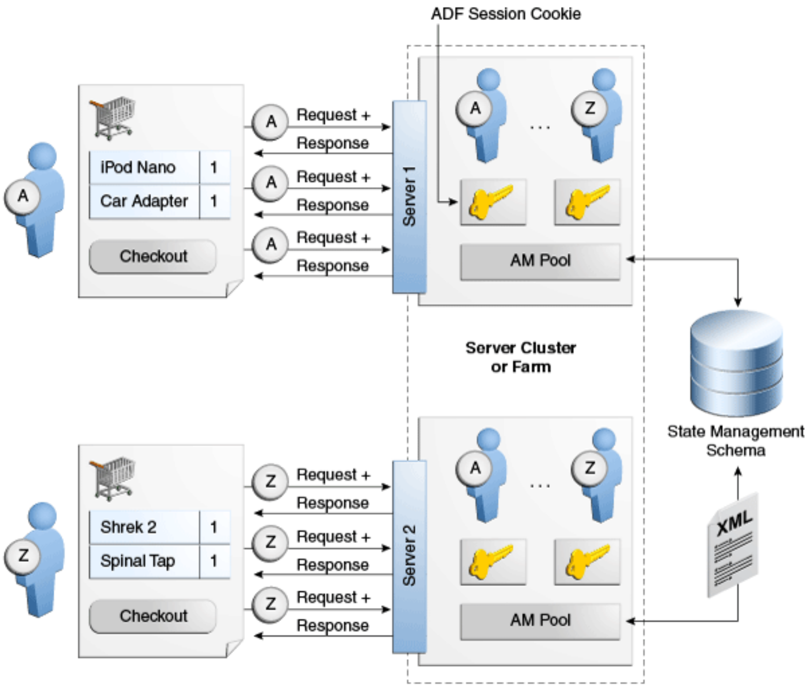
  Through the application state management facility, the ADF runtime automatically manages the application state of each user session and supports highly scalable applications. An application module supports *passivating* (storing) its pending transaction state to an XML document, which is stored either in-memory or in the database in a single, generic table, keyed by a unique passivation snapshot ID. It also supports the reverse operation of **activating** pending transaction state from one of these saved XML snapshots. This passivation and activation is performed automatically by the **application module pool** when needed, and is controlled by configuration properties that you can specify. Understanding what happens behind the scenes is essential to make the most efficient use of this important feature, as explained in Managing When Passivation and Activation Occurs.

- Application state management support for a server farm, or clustered server environment with failover.

  If you deploy in a multiple application server environment with failover enabled, then subsequent end-user requests may be handled by any server in your server farm or cluster. To support this scenario, the application state management facility passivates the application module at the end of every request. In the event failover occurs, where the user session is redirected to another server node, the session cookie can reactivate the pending application state from the database-backed XML snapshot, regardless of which server handles the request. Thus application module passivation and activation provides built-in support for cluster failover without additional configuration. For more information about ADF support for failover, see Configuring High Availability for Fusion Web Applications.

The ADF Business Components application module lets you implement completely stateless applications or support a unit of work that spans multiple browser pages. Figure 56-1 illustrates the basic architecture of the state management facility to support these multi-step scenarios.

Figure 56-1 ADF Provides Generic, Database-Backed State Management



The ADF **binding context** is the one object that lives in the `HttpSession` for each end user. It holds references to lightweight **application module data control** objects that manage acquiring an application module instance from the pool during the request (when the data control is accessed) and releasing it to the pool at the end of each request. The data control holds a reference to the application module handle that identifies the user session. In particular, serialized session objects of the application module state created or modified in the pending transaction are *not* saved in the `HttpSession` using this approach. This minimizes both the session memory required per user and eliminates the network traffic related to session replication if the servers are configured in a cluster.

What You May Need to Know About Multi-Step Tasks

In a typical search-then-edit scenario, the end user searches to find an appropriate row to update, then may open several different pages of related master-detail information to make edits before deciding to save or cancel work. Consider another scenario where the end user wants to book a vacation online. The process may involve the end user's entering details about:

- One or more flight segments that comprise the journey
- One or more passengers taking the trip
- Seat selections and meal preferences
- One or more hotel rooms in different cities
- Car they will rent

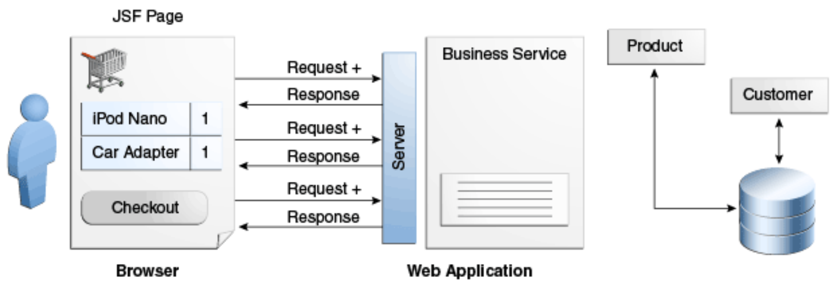
Along the way, the user might decide to complete the transaction, save the reservation for finishing later, or abandon the transaction before saving.

It's clear these scenarios involve a logical unit of work that spans multiple web pages. You've seen in previous chapters how to use JDeveloper's JSF page navigation diagram to design the page flow for these use cases, but that is only part of the puzzle. The pending changes the end user makes to business domain objects along the way — `Trip`, `Flight`, `Passenger`, `Seat`, `HotelRoom`, `Auto`, etc. — represent the in-progress state of the application for each end user. Along with this, other types of "bookkeeping" information about selections made in previous steps comprise the complete picture of the application state.

What You May Need to Know About the Stateless HTTP Protocol

While it may be easy to imagine the multi-step application scenarios, *implementing* them in web applications is complicated by the stateless nature of HTTP, the hypertext transfer protocol. Figure 56-2 illustrates how an end user's visit to a site comprises a series of HTTP request/response pairs. However, HTTP affords a web server no way to distinguish one user's request from another user's, or to differentiate between a single user's first request and any subsequent requests that user makes while interacting with the site. The server gets each request from any user always as if it were the first (and only) one they make.

Figure 56-2 Web Applications Use the Stateless HTTP Protocol



What You May Need to Know About Session Cookies

As shown in Figure 56-3, the technique used to recognize an ongoing sequence of requests from the same end user over the stateless HTTP protocol involves a unique identifier called a **cookie**. A cookie is a name/value pair that is sent in the header information of each HTTP request the user makes to a site. On the initial request made by a user, the cookie is not part of the request. The server uses the *absence* of the cookie to detect the start of a user's session of interactions with the site, and it returns a unique identifier to the browser that represents this session for this user. In practice, the cookie value is a long string of letters and numbers, but for the simplicity of the illustration, assume that the unique identifier is a letter like "A" or "Z" that corresponds to different users using the site.

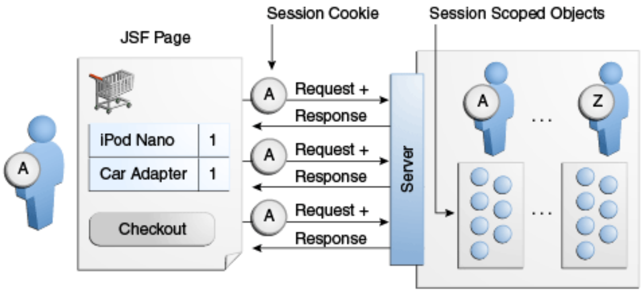
Web browsers support a standard way of recognizing the cookie returned by the server that allows the browser to identify the following:

- the site that sent the cookie
- how long it should remember the cookie value

On each subsequent request made by that user, until the cookie expires, the browser sends the cookie along in the header of the request. The server uses the value of the cookie to distinguish between requests made by different users.

Cookies can be set to live beyond a single browser session so that they might expire in a week, a month, or a year from when they were first created, while a session cookie expires when the user closes the browser.

Figure 56-3 Tracking State Using a Session Cookies and Server-Side Session



Java EE-compliant web servers provide a standard server-side facility called the `HttpSession` that allows a web application to store Java objects related to a particular user's session as named attribute/value pairs. An object placed in this session `Map` on one request can be retrieved by the application while handling a subsequent request during the same session.

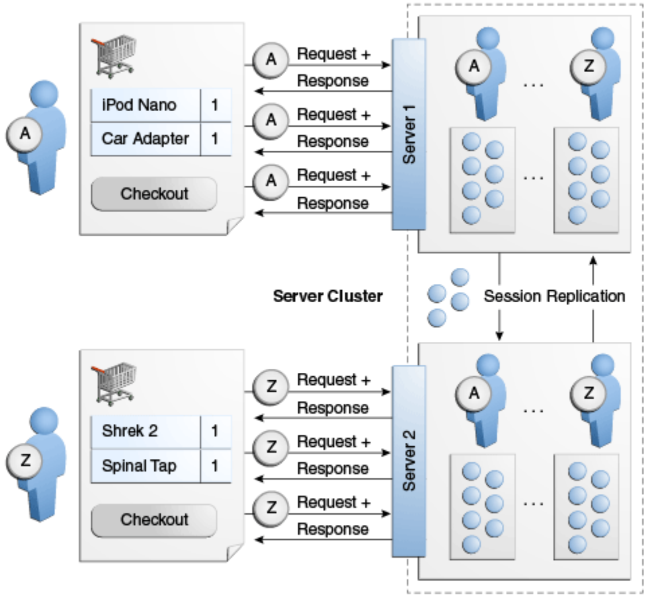
The session remains active while the user continues to send new requests within the timeframe specified by the `<session-timeout>` element in the `web.xml` file. The default session length is typically around 30 minutes, depending on the container.

What You May Need to Know About Using HttpSession

The `HttpSession` facility is an ingredient in most **application state management** strategies, but it can present performance and reliability problems if not used judiciously. First, because the session-scope Java objects the application creates are held in the memory of the Java EE web server, the objects in the HTTP session are lost if the server should fail.

As shown in Figure 56-4, one way to improve the reliability is to configure multiple Java EE servers in a cluster. By doing this, the Java EE application server replicates the objects in the HTTP session for each user across multiple servers in the cluster so that if one server goes down, the objects exist in the memory of the other servers in the cluster that can continue to handle the users requests. Since the cluster comprises separate servers, replicating the HTTP session contents among them involves broadcasting the changes to HTTP session objects over the network.

Figure 56-4 Session Replication in a Server Cluster



You can begin to see some of the performance implications of overusing the HTTP session:

- The more active users, the more HTTP sessions will be created on the server.
- The more objects stored in each HTTP session, the more memory you will need. Note that the memory is not reclaimed when the user becomes inactive; this only happens with a session timeout or an explicit session invalidation. Session invalidations don't always happen because users don't always logout.
- In a cluster, the more objects in each HTTP session that *change*, the more network traffic will be generated to replicate the changed objects to other servers in the cluster.

At the outset, it would seem that keeping the number of objects stored in the session to a minimum addresses the problem. However, this implies leveraging an alternative mechanism for temporary storage for each user's pending application state. The solution comes in the form of **ADF Business Components**, which implements this for you out of the box.

Managing When Passivation and Activation Occurs

Passivation and activation, in the ADF application is designed to keep temporary user data across requests, when there are more online users than the application pool can handle.

The passivation/activation cycle supports application module pooling and was designed originally to maintain a reasonable number of caches in memory, as well as to support failover in high-availability, clustered server environments. This process however requires the application module state to be written to and read from the database, and is itself an expensive operation. In legacy system, comprised of 32-bit platforms, where generally smaller amounts of memory were available than on today's middle-tier servers, the passivation of application module instances helped compensate for memory limitations.

In today's systems, where RAM generally is not a limitation, passivation/activation provides little benefit by reducing middle-tier server memory usage. Today the best use of the passivation/activation cycle built into application module pooling is to support failure conditions in a clustered server environment.

The following scenario depicts when the automatic passivation and activation of application module state occurs. This background may help you to understand later how application module pooling can be tuned to limit the use of passivation/activation.

1. At the beginning of an HTTP request, the application module data control handles the `beginrequest` event by checking out an application module instance from the pool.

   The application module pool returns an *unreferenced* instance. An unreferenced application module is one that is not currently managing the pending state for any other user session.

2. At the end of the request, the application module data control handles the `endrequest` event by checking the application module instance back into the pool in "managed state" mode.

   That application module instance is now *referenced* by the data control that just used it. And the application module instance is an object that still contains pending transaction state made by the data control (that is, **entity object** and **view object** caches; updates made but not committed; and cursor states), stored in memory. As you'll see below, the instance is not *dedicated* to this data control, just referenced by it.

3. On a subsequent request, the same data control — identified by its application module handle — checks out an application module instance again.

   Due to the "stateless with user affinity" algorithm the pool uses, the pool returns the exact same application module instance, with the state still there in memory.

The default configuration of application module pooling dictates, at peak usage times, with a high number of users simultaneously accessing the site, application module instances must be sequentially reused by different user sessions. In this case, the application pool will *recycle* a currently referenced application module instance for use by another session, as follows:

1. The application module data control for User A's session checks an application module instance into the application pool at the end of a request. Assume this instance is named `AM1`.

2. The application module data control for User Z's new session requests an application module instance from the pool for the first time, but there are no unreferenced instances available. The application module pool then:

   - Passivates the state of instance `AM1` to the database.
   - Resets the state of `AM1` in preparation to be used by another session.
   - Returns the `AM1` instance to User Z's data control.

3. On a subsequent request, the application module data control for User A's session requests an application module instance from the pool. The application module pool then:

   - Obtains an unreference instance.

This could be instance AM1, obtained by following the same tasks as in Step 2, or another AM2 instance if it had become unreferenced in the meantime.

- Activates the appropriate pending state for User A from the database.
- Returns the application module instance to User A's data control.

In summary, the process of passivation, activation, and recycling preserves the state referenced by the data control across requests without requiring a dedicated application module instance for each data control. Both browser users in the above scenario are carrying on an application transaction that spans multiple HTTP requests, but the end users are unaware whether the passivation and activation is occurring in the background. They just continue to see the pending changes. While the pending changes never need to be saved into the underlying application database tables until the end user is ready to commit the logical unit of work. The application module pool makes a best effort to keep an application module instance "sticky" to the current data control whose pending state it is managing. This is known as maintaining user session affinity.

The best performance is achieved by minimizing the need for passivation/activation cycle in the deployed Fusion web application. You can control this by changing the default configuration parameters that specify the size of the application module pool, control the resource cleanup behavior of the pool manager, and tune the JDBC connection disconnect behavior used by application module instance at the end of a user request. For more information about design time configuration parameters that let you tune application module pools to reduce passivation, see What You May Need to Know About Application Module Pooling Configuration Parameters.

How to Confirm That Fusion Web Applications Use Optimistic Locking

Oracle recommends using optimistic locking, the default mode for web applications. Pessimistic locking should not be used for web applications as it creates pending transactional state in the database in the form of row-level locks. If pessimistic locking is set, state management will work, but the locking mode will not perform as expected. Behind the scenes, every time an application module is recycled, a rollback is issued in the JDBC connection. This releases all the locks that pessimistic locking had created.

Note that under normal circumstances with optimistic locking, `RowInconsistentException` is thrown when inconsistent data is detected while locking a row during the commit operation. However, ADF can also raise `RowInconsistentException` outside of the commit operation, such as during application module activation, even though the framework is configured for optimistic lock.

> **Performance Tip:**
>
> Always use the default mode optimistic locking for web applications. Only optimistic locking is compatible with the application module unmanaged release level mode, which allows the application module instance to be immediately released when a web page terminates. This provides the best level of performance for web applications that expect many users to access the application simultaneously.

To ensure your configuration uses optimistic locking, open the Business Components page of the adf-config.xml overview editor and confirm that **Locking Mode** (corresponding to the jbo.locking.mode property) is set to optimistic or optupdate. To open the adf-config.xml editor, in the Application Resources window, expand **Descriptors** and **ADF META-INF** folders and double-click the file node.

Optimistic locking (optimistic) issues a SELECT FOR UPDATE statement to lock the row, then detects whether the row has been changed by another user by comparing the change indicator attribute — or, if no change indicator is specified, the values of all the persistent attributes of the current entity as they existed when the entity object was fetched into the cache.

Optimistic update locking (optupdate) does not perform any locking. The UPDATE statement determines whether the row was updated by another user by including a WHERE clause that will match the existing row to update only if the attribute values are unchanged since the current entity object was fetched.

What You May Need to Know About Pending Changes Across HTTP Requests

The ADF state management mechanism relies on passivation and activation to manage the state of an application module instance. Implementing this feature in a robust way is only possible if all pending changes are managed by the application module transaction in the middle tier. The most scalable strategy is to keep pending changes in middle-tier objects and not perform operations that cause pending database state to exist across HTTP requests. This allows the highest leverage of the performance optimizations offered by the application module pool and the most robust runtime behavior for your application.

> **Caution:**
>
> When the jbo.doconnectionpooling configuration parameter is set to true — typically in order to share a common pool of database connections across multiple application module pools — upon releasing your application module to the application module pool, its JDBC connection is released back to the database connection pool and a ROLLBACK will be issued on that connection. This implies that all changes which were posted but *not committed* will be lost. On the next request, when the application module is used, it will receive a JDBC connection from the pool, which may be a different JDBC connection instance from the one it used previously. Those changes that were posted to the database but not committed during the previous request are lost.
>
> The jbo.doconnectionpooling configuration parameter is set by checking the **Disconnect Application Module Upon Release** property on the **Database and Scalability** tab of the overview editor for application module configurations (on the bc4j.xcfg file).

What You May Need to Know About Release Levels and postChanges() Method

The transaction-level `postChanges()` method exists to force the transaction to post unvalidated changes without committing them. This method is not recommended for use in web applications unless you can guarantee that the transaction will definitely be committed or rolled back during the same HTTP request. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

If for some reason you need to create a transactional state in the database in a particular request by invoking the `postChanges()` method or by calling a PL/SQL stored procedure, but you cannot issue a commit or rollback by the end of that same request, then you *must* release the application module instance with the **reserved** level from that request until a subsequent request when you either commit or rollback.

> **Note:**
>
> Use as short a period of time as possible between creation of transactional state in the database and performing the concluding commit or rollback. This ensures that reserved level doesn't have to be used for a long time, as it has adverse effects on application's scalability and reliability.

Once an application module has been released with reserved level, it remains at that release level for all subsequent requests until release level is explicitly changed back to managed or unmanaged level. So, it is your responsibility to set release level back to managed level once commit or rollback has been issued.

Testing to Ensure Your Application Module is Activation-Safe

It is important during the development process that you test your ADF application modules for being activation-safe. This is done by disabling ADF application module pooling in the application module configuration.

If you have not *explicitly* tested that your application module functions when its pending state gets activated from a passivation snapshot, then you may encounter an unpleasant surprise in your production environment when heavy system load tests this aspect of your system for the first time.

How To Disable Application Module Pooling to Test Activation

As part of your overall testing plan, you should adopt the practice of testing your application modules with the `jbo.ampool.doampooling` configuration parameter set to `false`. This setting completely disables application module pooling and forces the system to activate your application module's pending state from a passivation snapshot on *each* page request. It is an excellent way to detect problems that might occur in your production environment due to assumptions made in your custom application code.

> **Note:**
>
> It is important to reenable application module pooling after you conclude testing and are ready to deploy the application to a production environment. The configuration property `jbo.ampool.doampooling` set to `false` is not a supported configuration for production applications and must be set to `true` before deploying the application.

For example, if you have transient view object attributes you believe *should* be getting passivated, this technique allows you to test that they are working as you expect. In addition, consider situations where you might have introduced:

- Private member fields in application modules, view objects, or entity objects
- Custom user session state in the `Session` user data hashtable

Your custom code likely assumes that this custom state will be maintained across HTTP requests. As long as you test with a single user on the JDeveloper Integrated WebLogic Server, or test with a small number of users, things will appear to work fine. This is due to the "stateless with affinity" optimization of the ADF application module pool. If system load allows, the pool will continue to return the same application module instance to a user on subsequent requests. However, under heavier load, during real-world use, it may not be able to achieve this optimization and will need to resort to grabbing any available application module instance and reactivating its pending state from a passivation snapshot. If you have not correctly overridden `passivateState()` and `activateState()` (as described in Managing Custom User-Specific Information During Passivation) to save and reload your custom component state to the passivation snapshot, then your custom state will be missing (i.e. `null` or back to your default values) after this reactivation step. Testing with `jbo.ampool.doampooling` set to false allows you to quickly isolate these kinds of situations in your code.

For more information about configuring Business Component configuration properties, How to Set Configuration Properties Declaratively.

What You May Need to Know About the jbo.ampool.doampooling Configuration Parameter

The `jbo.ampool.doampooling` configuration property corresponds to the **Enable Application Module Pooling** option in the **Database and Scalability** tab of the overview editor for application module configurations (on the `bc4j.xcfg` file). By default, this checkbox is checked so that application module pooling is enabled. Whenever you deploy your application in a production environment the default setting of `jbo.ampool.doampooling=true` is the way you will run your application. But, as long as you run your application in a test environment, setting the property to `false` can play an important role in your testing. When this property is false, there is effectively no application pool. When the application module instance is released at the end of a request it is immediately removed. On subsequent requests made by the same user session, a new application module instance must be created to handle it and the pending state of the application module must be reactivated from the passivation store.

For more information about configuring Business Component properties, How to Set Configuration Properties Declaratively.

What You May Need to Know About State Management and Data Consistency

When an entity object is updated concurrently by more than one user and one of those users loses affinity with their application module during the update, it is possible to experience data corruption if a change indicator has not been defined for the entity object.

Consider a scenario where two users (User A and User B) access the same entity object at the same time.

- After querying, User B changes the value of an attribute (for example, changing the `Dept` attribute value from `Accounting` to `Research`) and then commits.
- Meanwhile, User A has also queried and sees the same record where the value of the `Dept` attribute is `Accounting`.
- User A loses affinity with the application module that was used to query, resulting in passivation.
- User A then changes the `Dept` attribute value from `Accounting` to `Sales` and commits, resulting in activation.
- When activation occurs, the new value of the `Dept` attribute is activated but the browser is unaware of the data change, and the commit proceeds without issue.

To avoid this type of scenario, define a change indicator attribute for all entity objects. For more information, see How to Protect Against Losing Simultaneously Updated Data.

What You May Need to Know About State Management and Subclassed Entity Objects

If your application employs subclassed entity objects, the key attribute of new entities must be prepopulated. If the key is not prepopulated, passivation and activation will fail. You can prepopulate the key attribute by overriding the `create()` method or by using the `DBSequence` type that will assign a temporary negative value to the key before the real value is fetched from the database after commit. For more information, see How to Get Trigger-Assigned Primary Key Values from a Database Sequence.

Controlling Where Model State Is Saved

You can control where you want to save passivation snapshot by configuring an option in the ADF application module configuration. You can either save it in the database (default option) or in a file stored on the local file system.

By default, passivation snapshots are saved in the database, but you can configure it to use the file system as an alternative.

When saving to the database, the passivated XML snapshot is written to a `BLOB` column in a table named `PS_TXN`, using a connection specified by the `jbo.server.internal_connection` property. Each time a passivation record is saved, it is assigned a unique passivation snapshot ID based on the sequence number taken from the `PS_TXN_SEQ` sequence. The application module handle held by the application module data control in the ADF binding context remembers the latest passivation snapshot ID that was created on its behalf and remembers the previous ID that was used.

How to Control the Schema Where the State Management Table Resides

The ADF runtime recognizes a configuration property named `jbo.server.internal_connection` that controls which database connection and schema should be used for the creation of the `PS_TXN` table and the `PS_TXN_SEQ` sequence. If you don't set the value of this configuration parameter explicitly, then the state management facility creates the temporary tables using the credentials of the current application database connection.

To keep the temporary information separate, the state management facility uses a different connection *instance* from the database connection pool, but the database credentials are the same as the current user. Since the framework creates temporary tables, and possibly a sequence if they don't already exist, the implication of not setting a value for the `jbo.server.internal_connection` is that the current database user must have `CREATE TABLE`, `CREATE INDEX` and `CREATE SEQUENCE` privileges. Since this is often not desirable, Oracle recommends always supplying an appropriate value for the `jbo.server.internal_connection` property, providing the credentials for a state management schema where table and schema be created. Valid values for the `jbo.server.internal_connection` property in your configuration are:

- A fully qualified JDBC connection URL like:

  `jdbc:oracle:thin:`*`username/password@host`*`:`*`port`*`:`*`SID`*

- A JDBC datasource name like:

  `java:/comp/env/jdbc/YourJavaEEDataSourceName`

Performance Tip:

When creating the `PS_TXN` table, use securefiles to store LOB data (the content column), and create a primary column index on the `PS_TXN` table as global, partitioned reverse key index. The securefile configuration delivers superior performance over the basicfile configuration when working with LOB data. The reverse key index helps by reducing contention that can happen when the rate of inserts is high.

How to Configure the Passivation Store

Passivated information can be stored in several places. You can control it by configuring an option in the application module configuration. The choices are database or a file stored on local file system:

- **File**

This choice may be the fastest available, because access to the file is faster then access to the database. This choice is good if the entire middle tier is either installed on the same machine or has access to a commonly shared file system, so passivated information is accessible to all. Usually, this choice may be good for a small middle tier where one Oracle WebLogic Server domain is used. In other words this is a very suitable choice for small middle tier such as one Oracle WebLogic Server instance with all its components installed on one physical machine. The location and name of the persistent snapshot files are determined by `jbo.tmpdir` property if specified. It follows usual rules of ADF property precedence for a configuration property. If nothing else is specified, then the location is determined by `user.dir` if specified. This is a default property and the property is OS specific.

- **Database**

  This is the *default* choice. While it may be a little slower than passivating to file, it is by far the most reliable choice. With passivation to file, the common problem might be that it is not accessible to Oracle WebLogic Server instances that are remotely installed. In this case, in a cluster environment, if one node goes down the other may not be able to access passivated information and then failover will not work. Another possible problem is that even if file is accessible to the remote node, the access time for the local and remote node may be very different and performance will be inconsistent. With database access, time should be about the same for all nodes.

To set the value of your choice in design time, set the property `jbo.passivationstore` to `database` or `file`. The value `null` will indicate that a connection-type-specific default should be used. This will use database passivation for Oracle or DB2, and file serialization for any others.

What Happens at Runtime: What Model State Is Saved and When It Is Cleaned Up

The information saved by application model passivation is divided in two parts: transactional and nontransactional state. Transactional state is the set of updates made to entity object data – performed either directly on entity objects or on entities through view object rows – that are intended to be saved into the database. Nontransactional state comprises view object runtime settings, such as the current row index, `WHERE` clause, and `ORDER BY` clause.

The information saved as part of the application module passivation snapshot includes the following.

Transactional State

- New, modified, and deleted entities in the entity caches of the **root application module** for this user session's (including old/new values for modified ones).

Nontransactional State

- For each active view object (both statically and dynamically created):
  - Current row indicator for each row set (typically one)

- New rows and their positions. (New rows are treated differently then updated ones. Their index in the view object is traced as well.)
- ViewCriteria and all related parameters such as **view criteria** row, etc.
- Flag indicating whether or not a row set has been executed
- Range start and Range size
- Access mode
- Fetch mode and fetch size
- Any view object-level custom data

  > **Note:**
  >
  > Transient view object attributes can be saved if they are selected for passivation at design time. However, use this feature judiciously because this results in a snapshot that will grow in size with the number of rows that have been retrieved. See How to Manage the State of View Objects for information on enable the passivation of transient attributes.

- `SELECT`, `FROM`, `WHERE`, and `ORDER BY` clause if created dynamically or changed from the View definition

> **Note:**
>
> If you enable ADF Business Components runtime diagnostics, the contents of each XML state snapshot are also saved. See How to Enable ADF Business Components Debug Diagnostics for information on how to enable diagnostics.

Other information, such as user-specific information or instant variables in ADF Business Components objects, is not saved as part of the passivation snapshot. To save this type of information, use the techniques described in Managing Custom User-Specific Information During Passivation.

Cleaning Up the Model State

The adfbc_purge_statesnapshots.sql script in JDeveloper helps you to clean up the ADF application module passivation snapshot records time to time.

Under normal circumstances, the ADF state management facility provides automatic cleanup of the passivation snapshot records.

How to Clean Up Temporary Storage Tables Resulting from Passivation

JDeveloper supplies the `adfbc_purge_statesnapshots.sql` script to help with periodically cleaning up the application module state management table. You can find this file in the `oracle_common` subdirectory of your Oracle Middleware installation directory (for example, *`ORACLE_HOME`*`\oracle_common\common\sql`).

Persistent snapshot records can accumulate over time if the server has been shutdown in an abnormal way, such as might occur during development or due to a server failure. Running the script in SQL*Plus will create the `BC4J_CLEANUP` PL/SQL package. The two relevant procedures in this package are:

- `PROCEDURE Session_State(olderThan DATE)`

  This procedure cleans up application module session state storage for sessions older than a given date.

- `PROCEDURE Session_State(olderThan_minutes INTEGER)`

  This procedure cleans up application module session state storage for sessions older than a given number of minutes.

You can schedule periodic cleanup of your ADF temporary persistence storage by submitting an invocation of the appropriate procedure in this package as a database job.

You can use an anonymous PL/SQL block like the one shown in the following example to schedule the execution of `bc4j_cleanup.session_state()` to run starting tomorrow at 2:00 am and each day thereafter to cleanup sessions whose state is over 1 day (1440 minutes) old.

```
SET SERVEROUTPUT ON
DECLARE
  jobId    BINARY_INTEGER;
  firstRun DATE;
BEGIN
  -- Start the job tomorrow at 2am
  firstRun := TO_DATE(TO_CHAR(SYSDATE+1,'DD-MON-YYYY')||' 02:00',
              'DD-MON-YYYY HH24:MI');
   -- Submit the job, indicating it should repeat once a day
  dbms_job.submit(job       => jobId,
                  -- Run the ADF Purge Script for Session State
                  -- to cleanup sessions older than 1 day (1440 minutes)
                  what      => 'bc4j_cleanup.session_state(1440);',
                  next_date => firstRun,
                  -- When completed, automatically reschedule
                  -- for 1 day later
                  interval  => 'SYSDATE + 1'
                 );
  dbms_output.put_line('Successfully submitted job. Job Id is '||jobId);
END;
.
/
```

What Happens at Runtime: When a Passivation Record Is Updated

When a passivation record is saved to the database on behalf of a session cookie, this passivation record gets a new, unique snapshot ID. The passivation record with the previous snapshot ID used by that same session cookie is deleted as part of the same transaction. In this way, assuming no server failures, there will only ever be a single passivation snapshot record per active end-user session.

What Happens at Runtime: When a Passivation Snapshot is Removed on Unmanaged Release

The passivation snapshot record related to a session cookie is removed when the application module is checked into the pool with the unmanaged state level. This can occur when:

- Your code specifically calls `resetState()` on the application module data control.
- Your code explicitly invalidates the `HttpSession`, for example, as part of implementing an explicit "Logout" functionality.
- The `HttpSession` times out due to exceeding the session timeout threshold for idle time and failover mode is disabled (which is the default).

In each of these cases, the application module pool also resets the application module referenced by the session cookie to be "unreferenced" again. Since no changes were ever saved into the underlying database tables, once the pending session state snapshots are removed, there remains no trace of the unfinished work the user session had completed up to that point.

What Happens at Runtime: Passivation Snapshot Retained in Failover Mode

When the failover mode is enabled, if the `HttpSession` times out due to session inactivity, then the passivation snapshot is retained so that the end user can resume work upon returning to the browser.

After a break in the action, when the end user returns to the browser and continues to use the application, it continues working as if nothing had changed. The session cookie is used to reactivate any available application module instance with the user's last pending state snapshot before handling the request. So, even though the users next request will be processed in the context of a new `HttpSession` (perhaps even in a different application server instance), the user is unaware that this has occurred.

> **Note:**
>
> If an application module was released with Reserved level then when the `HttpSession` times out, the user will have to go through an authentication process, and all unsaved changes are lost.

Managing the HttpSession in Fusion Web Applications

The <session-timeout> tag in the web.xml file allows you to configure the timeout threshold so that the HTTP session is freed in Fusion web applications when the user is away or inactive.

Since HTTP is a stateless protocol, the server receives no implicit notice that a client has closed the browser or gone away for the weekend. Therefore any Java EE-compliant server provides a standard, configurable session timeout mechanism to allow resources tied to the HTTP session to be freed when the user has stopped performing requests. You can also programmatically force a timeout.

How to Configure the Implicit Timeout Due to User Inactivity

You configure the session timeout threshold using the `<session-timeout>` tag in the `web.xml` file. The default value is typically around 30 minutes, depending on the container.

How to Code an Explicit HttpSession Timeout

To end a user's session before the session timeout expires, you can call the `invalidate()` method on the `HttpSession` object from a backing bean in response to the user's click on a Logout button or link. This cleans up the `HttpSession` in the same way as if the session time had expired. Using JSF and ADF, after invalidating the session, you *must* perform a redirect to the next page you want to display, rather than just doing a forward. The following example shows sample code to perform this task from a Logout button.

```
public String logoutButton_action() throws IOException{
  ExternalContext ectx = FacesContext.getCurrentInstance().getExternalContext();
  HttpServletResponse response = (HttpServletResponse)ectx.getResponse();
  HttpSession session = (HttpSession)ectx.getSession(false);
  session.invalidate();
  response.sendRedirect("Welcome.jspx");
  return null;
}
```

As with the implicit timeouts, when the HTTP session is cleaned up this way, it ends up causing any referenced application modules to be marked unreferenced.

What Happens at Runtime: How Application Modules are Handled When the HTTP Times Out

When the `HttpSession` times out, the `BindingContext` goes out of scope, and along with it, any data controls that might have referenced application modules released to the pool in the managed state level. The application module pool resets any of these referenced application modules and marks the instances unreferenced again.

Managing Custom User-Specific Information During Passivation

You can add custom user-defined information in the ADF application module by overriding the passivateState() and activateState() methods in the ApplicationModuleImpl class.

It is fairly common practice to add custom user-defined information in the application module in the form of member variables or some custom information stored in `oracle.jbo.Session` user data hashtable. The ADF state management facility provides a mechanism to save this custom information to the passivation snapshot as well, by overriding the `passivateState()` method and the `activateState()` methods in the `ApplicationModuleImpl` class.

> **Note:**
>
> Similar methods are available on the `ViewObjectImpl` class and the `EntityObjectImpl` class to save custom state for those objects to the passivation snapshot as well.

How to Passivate Custom User-Specific Information

You can override `passivateState()` and `activateState()` to ensure that custom application module state information is included in the passivation/activation cycle. The following example shows how this is done.

In the example, `jbo.counter` contains custom values you want to preserve across passivation and activation of the application module state. Each application module has an `oracle.jbo.Session` object associated with it that stores application module-specific session-level state. The session contains a user data hashtable where you can store transient information. For the user-specific data to "survive" across application module passivation and reactivation, you need to write code to save and restore this custom value into the application module state passivation snapshot.

```
/**
 * Overridden framework method to passivate custom XML elements
 * into the pending state snapshot document
 */
public void passivateState(Document doc, Element parent) {
  // 1. Retrieve the value of the value to save
  int counterValue = getCounterValue();
  // 2. Create an XML element to contain the value
  Node node = doc.createElement(COUNTER);
  // 3. Create an XML text node to represent the value
  Node cNode = doc.createTextNode(Integer.toString(counterValue));
  // 4. Append the text node as a child of the element
  node.appendChild(cNode);
  // 5. Append the element to the parent element passed in
  parent.appendChild(node);
}
/**
 * Overridden framework method to activate  custom XML elements
 * into the pending state snapshot document
 */
public void activateState(Element elem) {
  super.activateState(elem);
  if (elem != null) {
    // 1. Search the element for any <jbo.counter> elements
    NodeList nl = elem.getElementsByTagName(COUNTER);
    if (nl != null) {
      // 2. If any found, loop over the nodes found
      for (int i=0, length = nl.getLength(); i < length; i++) {
        // 3. Get first child node of the <jbo.counter> element
        Node child = nl.item(i).getFirstChild();
        if (child != null) {
          // 4. Set the counter value to the activated value
          setCounterValue(new Integer(child.getNodeValue()).intValue()+1);
          break;
        }
      }
    }
  }
}
/*
 * Helper Methods
 */
private int getCounterValue() {
  String counterValue = (String)getSession().getUserData().get(COUNTER);
  return counterValue == null ? 0 : Integer.parseInt(counterValue);
}
private void setCounterValue(int i) {
  getSession().getUserData().put(COUNTER,Integer.toString(i));
}
private static final String COUNTER = "jbo.counter";
```

What Happens When You Passivate Custom Information

As the example in How to Passivate Custom User-Specific Information illustrates, when `activateState()` is overridden, the following steps are performed:

1. Search the element for any `jbo.counter` elements.
2. If any are found, loop over the nodes found in the node list.
3. Get first child node of the `jbo.counter` element.

   It should be a DOM Text node whose value is the string you saved when your `passivateState()` method above got called, representing the value of the `jbo.counter` attribute.
4. Set the counter value to the activated value from the snapshot.

When `passivateState()` is overridden, it performs the reverse job by doing the following:

1. Retrieve the value of the value to save.
2. Create an XML element to contain the value.
3. Create an XML text node to represent the value.
4. Append the text node as a child of the element.
5. Append the element to the parent element passed in.

> **Note:**
>
> The API's used to manipulate nodes in an XML document are provided by the Document Object Model (DOM) interfaces in the `org.w3c.dom` package. These are part of the Java API for XML Processing (JAXP). See the Javadoc for the `Node`, `Element`, `Text`, `Document`, and `NodeList` interfaces in this package for more details.

What You May Need to Know About Activating Custom Information

The `activateState()` method is called at the end of the activation process after the view objects have been activated. Most of the time this is where you want to place the application module state activation logic. However, if your application module activation logic needs to set up custom state information before the ADF state management facility activates the view objects (for example, you might need to write custom code to allow the view objects to internally reference custom values at execution time), then the `prepareForActivation()` method in the `ApplicationModuleImpl` class would be the right place because it fires at the beginning of the activation process.

Managing the State of View Objects During Passivation

ADF Business Components view objects are marked as passivated by default. But a transient view object (containing only transient attributes) only passivates the updates related to the current row and other nontransactional state.

By default, all view objects are marked as passivation-enabled, so their state will be saved. However, view objects that have transient attributes do not have those attributes passivated by default. You can change how a view object is passivated, and even which attributes are passivated, using the Tuning page of the view object overview editor.

How to Manage the State of View Objects

Each view object can be declaratively configured to be passivation-enabled or not. If a view object is not passivation enabled, then no information about it gets written in the application module passivation snapshot.

> **Performance Tip:**
>
> There is no need to passivate read-only view objects that are not used to display values in the UI but are simply used in re-entrant methods for calculation or derivation of values. This eliminates the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

Before you begin:

It may be helpful to have an understanding of passivation in view objects. For more information, see Managing the State of View Objects During Passivation.

To set the passivation state of a view object:

1. In the Applications window, double-click the view object for which you want to set the passivation state.
2. In the overview editor, click the **General** navigation tab.
3. On the General page, expand the **Tuning** section and select **Passivate State** to make sure the view object data is saved.
4. Optionally, you can select **Including All Transient Attributes** to passivate all transient attributes at this time, but see What You May Need to Know About Passivating Transient View Objects for additional information.

What You May Need to Know About Passivating View Objects

The activation mechanism is designed to return your view object to the state it was in when the last passivation occurred. To ensure that, **Oracle ADF** stores in the state snapshot the values of any bind variables that were used for the last query execution. These bind variables are in addition to those that are set on the row set at the time of passivation. The passivated state also stores the user-supplied WHERE clause on the view object related to the row set at the time of passivation.

How to Manage the State of Transient View Objects and Attributes

Because view objects are marked as passivated by default, a transient view object — one that contains only transient attributes — is marked to be passivation enabled, but only passivates its information related to the current row and other nontransactional state. Note that to enable a transient view object to passivate or activate correctly, it needs a non-null key attribute value.

> **Performance Tip:**
>
> Transient view object attributes are not passivated by default. Due to their nature, they are usually intended to be read-only and are easily re-created. So, it often doesn't make sense to passivate their values as part of the XML snapshot. This also avoids the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

Before you begin:

It may be helpful to have an understanding of passivation in view objects. For more information, see Managing the State of View Objects During Passivation.

You will also need to perform the following task:

- Open the application in JDeveloper.

To individually set the passivation state for transient view object attributes:

1. In the Applications window, double-click the view object that contains the transient attributes for which you want to specify the passivation state.
2. In the overview editor, click the **Attributes** navigation tab.
3. On the Attributes page, select the transient attribute you want to passivate and click the **Details** tab.
4. In the Details page, select the **Passivate** checkbox.

What You May Need to Know About Passivating Transient View Objects

Passivating transient view object attributes is more costly resource-wise and performance- wise, because transactional functionality is usually managed on the entity object level. Since transient view objects are not based on an entity object, this means that all updates are managed in the view object row cache and not in the entity cache. Therefore, passivating transient view objects or transient view object attributes requires special runtime handling. For a transient VO to passivate or activate correctly, it needs a non-null key attribute value.

Usually passivation only saves the values that have been changed, but with transient view objects passivation has to save entire row. The row will include only the view object attributes marked for passivation.

> **Note:**
>
> The ADF passivation and activation logic will take care of restoring transient attribute values in the entity object and view object *only* as long as the entity object is in an unposted state. Once the user Saves their changes to the database, the entity object is posted to the database and in the next activation cycle, the view row is restored using the database query. Since the attribute is transient, its value will remain null. If you want your entity object or view object-based transient attribute values to survive failover, you need to define the transient attribute value using an expression and the expression should point to a getter method that can supply the value.

How to Use Transient View Objects to Store Session-level Global Variables

Using passivation, you can use a view object to store one or more global variables, each on a different transient attribute. When you mark a transient attribute as passivated, the ADF Business Components framework will remember the transient values across passivation and activation in high-throughput and failover scenarios. Therefore, it is an easy way to implement a session-level global value that is backed up by the state management mechanism, instead of the less-efficient HTTP Session replication. This also makes it easy to bind to controls in the UI if necessary.

There are two basic approaches to store values between invocations of different screens, one is controller-centric, and the other is model-centric.

To implement this task in the **ADF Controller** layer using the controller-centric approach involves storing and referencing values using attributes in the pageFlow scope. This approach might be appropriate if the global values do not need to be referenced internally by any implementations of ADF Business Components. For more information about pageFlow scope, see What You May Need to Know About Memory Scope for Task Flows.

The model-centric approach involves creating a transient view object, which is conceptually equivalent to a nondatabase block in Oracle Forms.

Before you begin:

It may be helpful to have an understanding of passivation in view objects. For more information, see Managing the State of View Objects During Passivation.

You will also need to perform the following tasks:

1. Open the application in JDeveloper.

2. Create a new view object using the View Object wizard, as described in How to Create an Entity-Based View Object.
   a. On Page 1 of the wizard, select the option for **Data Source: Programmatic**.
   b. On Page 2, click **New** to define the transient attribute names and types the view object should contain.
   c. On Page 3, set the **Updatable** option to **Always** for each attribute.
   d. Click **Finish** and the newly created view object appears in the overview editor.
3. Add an instance of the view object with transient attributes to your application module's data model, as described in Adding Master-Detail View Object Instances to an Application Module.

To store session-level global variables using the model-centric approach:

1. Disable any entries from being performed in the view object:
   a. In the overview editor, on the General page, expand the **Tuning** section.
   b. In the **Retrieve from the Database** group, select the **No Rows** option.
2. Make sure data in the view object is not cleared out during a rollback operation. To implement this, you enable a custom Java class for the view object and override two rollback methods.
   a. In the overview editor, click the **Java** navigation tab, and click the **Edit** icon for the **Java Classes** section.
   b. In the Select Java Options dialog, select **Generate View Object Class** and click **OK**.
   c. In the overview editor, click the link next to View Object Class in the **Java Classes** section.
   d. From the main menu, choose **Source > Override Methods**.
   e. In the Override Methods dialog, select the `beforeRollback()` and `afterRollback()` methods to override, and click then **OK**.
   f. In both the `beforeRollback()` and `afterRollback()` methods, comment out the call to `super` in the Java code.
3. Create an empty row in the view object when a new user begins using the application module:
   a. In the Applications window, double-click the application module.
   b. Generate an application module Java class if you don't have one yet, as described in How to Generate a Custom Class for an Application Module.
   c. Override the `prepareSession()` method of the application module, as described in How to Override a Built-in Framework Method.
   d. After the call to `super.prepareSession()`, add code to create a new row in the transient view object and insert it into the view object.

Now you can bind read-only and updatable UI elements to the "global" view object attributes just as with any other view object using the **Data Controls panel**.

57
Tuning Application Module Pools

This chapter describes how ADF Business Components application module pools work and how you can tune application module pools to optimize application performance.
This chapter includes the following sections:

About Application Module Pooling

An ADF application module pool is a collection of instances of a single application module type which are shared by multiple application clients. The amount of time between submitting web pages enables a smaller number of application module components to serve a larger number of active users. This reduces memory usage and improves performance.

An application module pool is a collection of application module runtime instances of the same type. To provision a number of users visiting it, the Fusion web application can be configured to provide one or more application module instances from the pool to service users at runtimee.

Each application module instance in a pool is shared by multiple browser clients whose typical "think time" between submitting web pages allows optimizing the number of application module components to be effectively smaller than the total number of active users working on the system. For example, twenty users visiting the website from their browser might be able to be serviced by 5 or 10 application module instances instead of having as many application module instances as you have browser users. Therefore, not only can the pool service more users than the number of application modules available, but in addition the middle tier requires less memory to service this smaller set of application modules allowing ADF applications to scale further on limited hardware resources.

Through your design-time configuration, application modules can be used to support Fusion web application scenarios that are completely stateless, or they can be used to support a unit of work that spans multiple browser pages. As a performance optimization, when an instance of an application module is returned to the pool in "managed state" mode, the pool tracks session references to the application module. The application module instance is still in the pool and available for use, but it would *prefer* to be used by the same session that was using it the last time because maintaining this "session affinity" improves performance.

So, at any one moment in time, the instances of application modules in the pool are logically partitioned into three groups, reflecting their state:

- Checked into the pool and unconditionally *available* for use

- Checked into the pool and available for use, but *referenced* for session affinity reuse by an active user session
- Checked out of the pool and *un*available, inasmuch as it's currently in use (at that very moment) by some thread in the web container

Understanding what happens behind the scenes is essential to make the most efficient use of application module pooling. For details about session state management of application modules, see Managing When Passivation and Activation Occurs.

For details about the configuration parameters that can be set at design time to affect the behavior of the application module pool, see What You May Need to Know About Application Module Pool Configuration Parameters.

Application Module Pools

Application Module components can be used at runtime in two ways:

- As an application module the client accesses directly
- As a reusable component aggregated (or "nested") inside of another application module instance

When a client accesses it directly, an application module is called a **root application module**. Clients access nested application modules *indirectly* as a part of their containing application module instance. It's possible, but not common, to use the same application module at runtime in both ways. The important point is that **ADF Business Components** only creates an application module pool for a *root* application module.

The basic rule is that one application module pool is created for each *root* application module used by a Fusion web application in *each* Java VM where a root application module of that type is used by the **ADF Controller** layer. For advanced topics related to the number of application module pools your application may need, see Deployment Environment Scenarios and Pooling.

Deployment Environment Scenarios and Pooling

The number of pools and the type of pools that your application will utilize will depend upon how the target platform is configured. For example, will there be more than one Java Virtual Machine (JVM) available to service the web requests coming from your application users and will there be more than one Oracle WebLogic Server domain? To understand how many pools of which kinds are created for an application in both a single-JVM scenario and a multiple-JVM runtime scenario, review the following assumptions:

- Your Fusion web application makes use of two application modules `HRModule` and `PayablesModule`.
- You have a `CommonLOVModule` containing a set of commonly used view objects to support list of values in your application, and that both `HRModule` and `PayablesModule` aggregate a nested instance of `CommonLOVModule` to access the common LOV view objects it contains.
- You have configured both `HRModule` and `PayablesModule` to use the same JDeveloper connection definition named `appuser`.

Single Oracle WebLogic Server Domain, Single Oracle WebLogic Server Instance, Single JVM

If you deploy this application to a single Oracle WebLogic Server domain, configured with a single Oracle WebLogic Server instance, there is only a single Java VM available to service the web requests coming from your application users.

Assuming that all the users are making use of web pages that access both the `HRModule` and the `PayablesModule`, this will give:

- One application module pool for the `HRModule` root application module
- One application module pool for the `PayablesModule` root application module

This gives a total of two application module pools in this single Java VM.

> **Note:**
>
> There is no separate application module pool for the nested instances of the reusable `CommonLOVModule`. Instances of `CommonLOVModule` are wrapped by instances of `HRModule` and `PayablesModule` in their respective application module pools.

Multiple Oracle WebLogic Server Domains, Multiple Oracle WebLogic Server Instance, Multiple JVMs

Next consider a deployment environment involving multiple Java VMs. Assume that you have configured four different physical machines as two Oracle WebLogic Server domains, with a hardware load-balancer in front. On these four machines, each Oracle WebLogic Server instance will have a single JVM. As users of your application access the application, their requests are shared across these two Oracle WebLogic Server domains, and within each domain, across the two JVMs that its Oracle WebLogic Server instances have available.

Again assuming that all the users are making use of web pages that access both the `HRModule` and the `PayablesModule`, this will give:

- Four application module pools for `HRModule`, one in each of four JVMs.

  (1 `HRModule` root application module) x (2 Oracle WebLogic Server domains) x (2 Oracle WebLogic Server JVMs each)

- Four application module pools for `PayablesModule`, one in each of four JVMs.

  (1 `PayablesModule` root application module) x (2 Oracle WebLogic Server domains) x (2 Oracle WebLogic Server JVMs each)

This gives a total of eight application module pools spread across four JVMs.

As you begin to explore the configuration parameters for the application module pools in What You May Need to Know About Application Module Pool Configuration Parameters, keep in mind that the parameters apply to a given application module pool for a given application module in a single JVM.

As the load balancing spreads user requests across the multiple JVMs where Oracle ADF is running, each individual application module pool in each JVM will have to support one *n* th of the user load — where *n* is the number of JVMs available to service those user requests. The appropriate values of the application module pools need to be set with the number of Java VMs in mind. The basic approach is to base sizing parameters on load testing and the results of the application module pooling statistics, then divide that total number by the *n* number of pools you will have based on your use of multiple application server domains and multiple Oracle WebLogic Server instances. For example, if you decide to set the minimum number of application modules in the pool to ten and you end up with five pools due to having five Oracle WebLogic Server instances servicing this application, then you would want to configure the parameter to 2 (ten divided by five), not 10 (which would only serve a given application module in a single JVM).

For details about available sizing parameters, see Pool Sizing Parameters.

Setting Pool Configuration Parameters

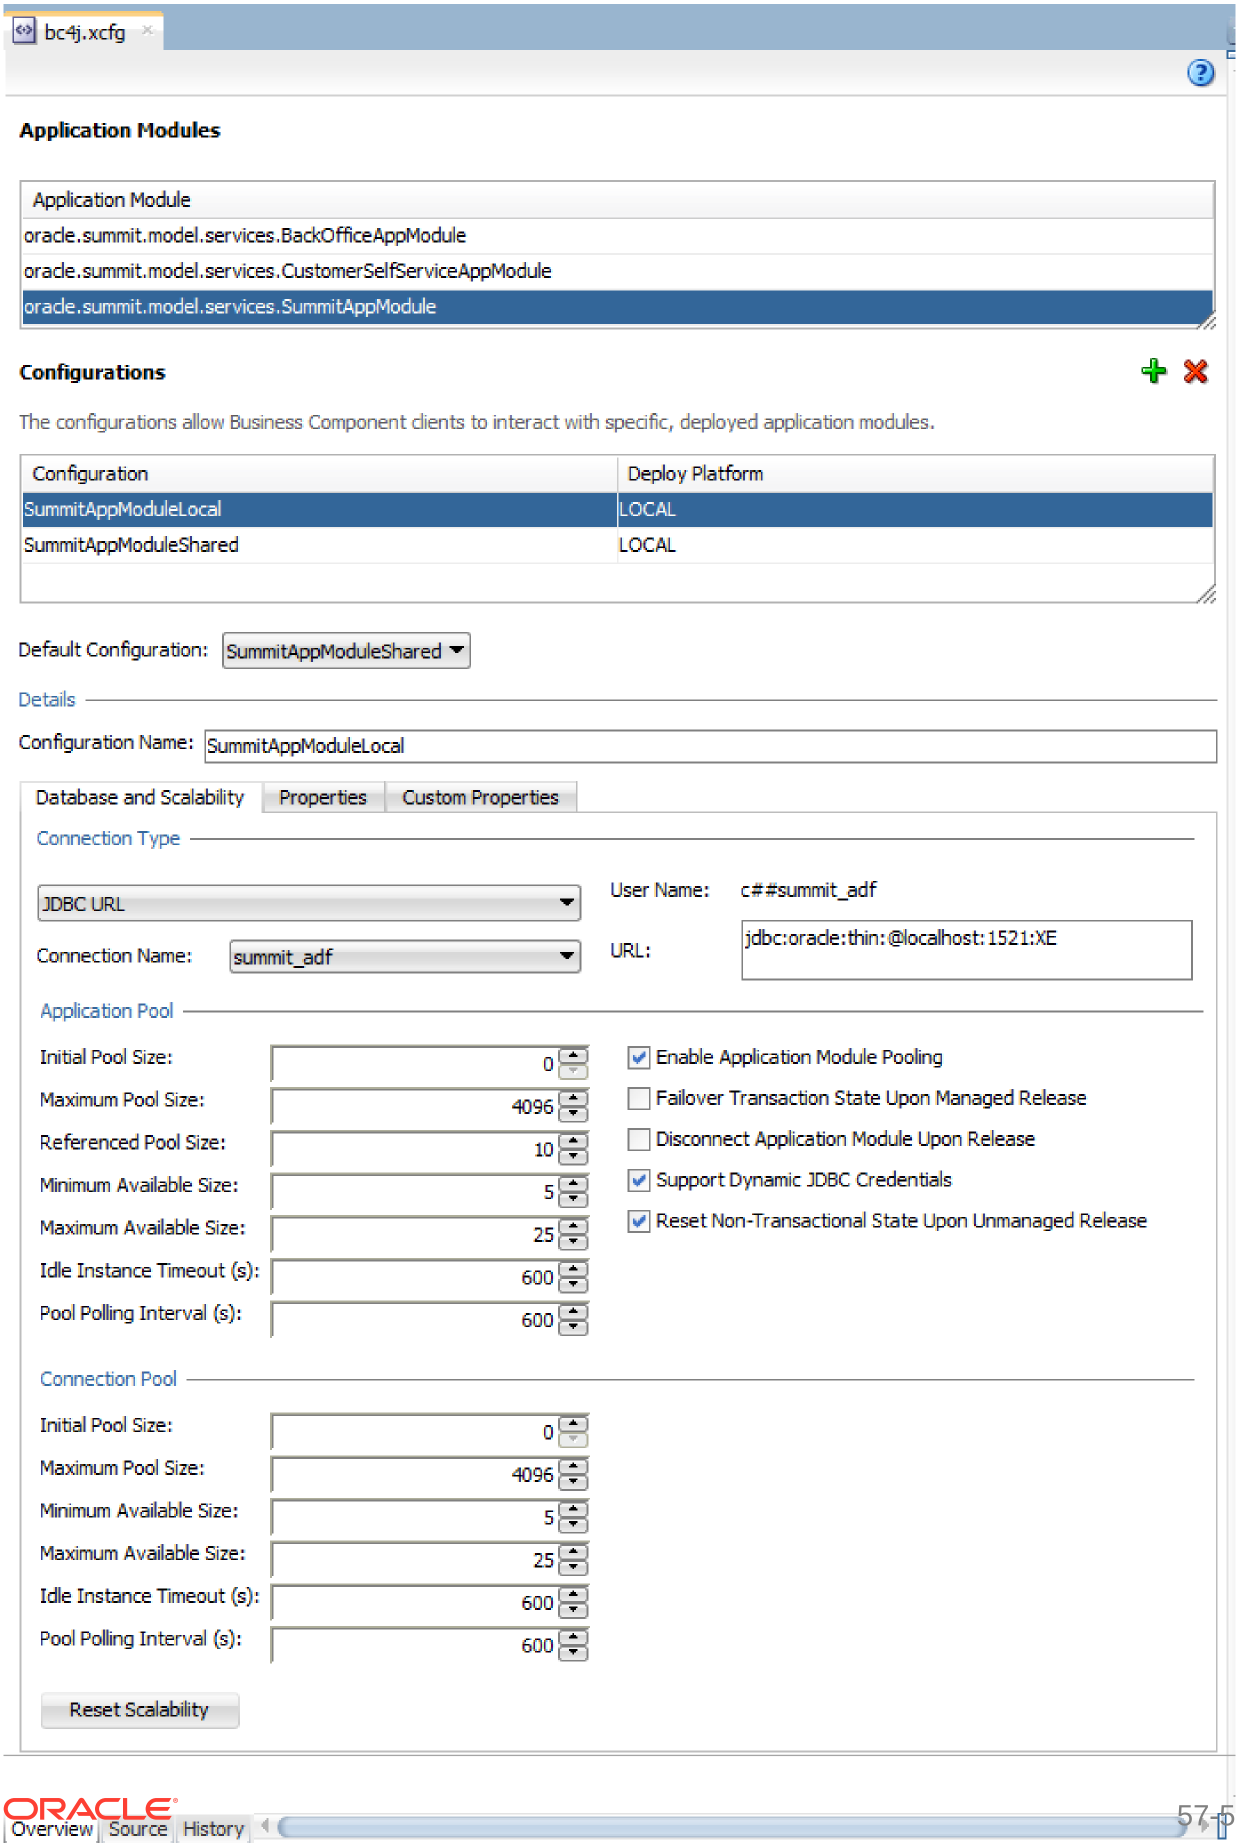
Configuration parameters set in the ADF application allow you to control the runtime behavior of an application module pool. There are three logical categories of the application module pool configuration parameters: Pool behavior, Pool Sizing, and Pool Cleanup Behavior.

You control the runtime behavior of an application module pool by setting appropriate configuration parameters. You can set these declaratively in an application module configuration, supply them as Java System parameters, or set them programmatically at runtime.

How to Set Configuration Properties Declaratively

You use the **Database and Scalability** tab of the overview editor for application module configurations shown in Figure 57-1 for viewing and setting runtime configuration properties of individual application modules.

Figure 57-1 Database and Scalability Tab of the Edit Configuration Dialog



Application Modules

Application Module
oracle.summit.model.services.BackOfficeAppModule
oracle.summit.model.services.CustomerSelfServiceAppModule
oracle.summit.model.services.SummitAppModule

Configurations

The configurations allow Business Component clients to interact with specific, deployed application modules.

Configuration	Deploy Platform

Reset Scalability

Before you begin:

It may be helpful to have an understanding of application module pooling. For more information, see Setting Pool Configuration Parameters.

Familiarize yourself with the application module configuration parameters. For more information about configuration parameters for application module pool tuning, see What You May Need to Know About Application Module Pool Configuration Parameters.

For best practice guidelines that may help you to tune the Fusion web application for an expected level of usage, see the Tuning Oracle Application Development Framework chapter of *Tuning Performance*.

Note that if your application defines a JDBC URL connection type (legacy only), refer to the 11*g* release version of this guide to obtain documentation on the ADF database connection pool configuration parameters.

To edit your application module's pooling configuration:

1. In the Applications window, double-click the application module.
2. In the overview editor, click the **Configurations** navigation tab.
3. In the Configurations page, click the configuration hyperlink for the configuration you want to edit.
4. In the overview editor for application module configurations, click the **Database and Scalability** tab and edit the desired runtime properties and click **OK** to save the changes for your configuration.

What Happens When You Set Configuration Properties Declaratively

The values that you supply through the overview editor for application module configurations are saved in an XML file named `bc4j.xcfg` in the `./common` subdirectory relative to the application module's XML definition. All of the configurations for all of the application modules in a single Java package are saved in that same file. Typically, you do not modify the `bc4j.xcfg` file directly and use the overview editor to change configuration settings for specific application modules. To display the application module configuration overview editor, double-click the application module in the Applications window and, in the overview editor, select the **Configurations** navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink.

For example, if you look at the overview editor for application module configurations for the `BackOfficeAppModule` application module in the `SummitADF` application (on the `bc4j.xcfg` file in the `./src/oracle/summit/model/services/common` directory), you will see the two named configurations for the `BackOfficeAppModule` application module. In this case, as the following example shows, the `BackOfficeAppModuleLocal` and the `BackOfficeAppModuleShared` configurations specify JDBC URL connections for use by the Oracle ADF Model Tester. The connection details for the JDBC connections appear in the `connections.xml` file located in the `./.adf/META-INF` subdirectory relative to the project directory.

```
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
...
   <AppModuleConfigBag
      ApplicationName="oracle.summit.model.services.BackOfficeAppModule">
      <AppModuleConfig
```

```
            name="BackOfficeAppModuleLocal"
            jbo.project="oracle.summit.model.Model"
            ApplicationName="oracle.summit.model.services.BackOfficeAppModule"
            DeployPlatform="LOCAL" JDBCName="summit_adf">
         <Database jbo.TypeMapEntries="Java"/>
         <Security

AppModuleJndiName="oracle.summit.model.services.BackOfficeAppModule"/>
      </AppModuleConfig>
      <AppModuleConfig
            name="BackOfficeAppModuleShared"
            jbo.project="oracle.summit.model.Model"
            ApplicationName="oracle.summit.model.services.BackOfficeAppModule"
            DeployPlatform="LOCAL" JDBCName="summit_adf">
         <AM-Pooling jbo.ampool.maxpoolsize="1"
                     jbo.ampool.isuseexclusive="false"/>
         <Database jbo.TypeMapEntries="Java"/>
         <Security

AppModuleJndiName="oracle.summit.model.services.BackOfficeAppModule"/>
      </AppModuleConfig>
   </AppModuleConfigBag>
</BC4JConfig>
```

Note that attributes of child elements of the `<AppModuleConfig>` tag have names beginning with `jbo` that match the names of their ADF Business Components properties (for example, the `<AM-Pooling>` tag defines the attribute `jbo.ampool.maxpoolsize` that corresponds to the property `jbo.ampool.maxpoolsize`). It's also important to understand that if a property is currently set to its runtime *default* value in the application module configurations editor, then JDeveloper does *not* write the entry to the `bc4j.xcfg` file.

How to Programmatically Set Configuration Properties

When your application requires control over application module configuration properties at runtime, you can dynamically set these properties using ADF Business Components API. For example, in a typical ADF application, your application module may configure a static JDBC data source. However, when the application needs to display data, depending upon the user, from various databases, you might set the data source name and application module pool parameters at runtime.

You can set configuration properties programmatically by creating a Java class that implements the `EnvInfoProvider` interface in the `oracle.jbo.common.ampool` package. In your class, you override the `getInfo()` method and call `put()` to put values into the environment Hashtable passed in as shown in the following example.

```
package devguide.advanced.customenv.view;
import java.util.Hashtable;
import oracle.jbo.common.ampool.EnvInfoProvider;
/**
 * Custom EnvInfoProvider implementation to set
 * environment properties programmatically
 */
public class CustomEnvInfoProvider implements EnvInfoProvider {
  /**
   * Overridden framework method to set custom values in the
   * environment hashtable.
   *
   * @param string - ignore
   * @param environment Hashtable of config parameters
   * @return null - not used
   */
  public Object getInfo(String string, Object environment) {
    Hashtable envHashtable = (Hashtable)environment;
    envHashtable.put("some.property.name","some value");
    return null;
  }
  /* Required to implement EnvInfoProvider */
  public void modifyInitialContext(Object object) {}
  /* Required to implement EnvInfoProvider */
  public int getNumOfRetries() {return 0;}
}
```

When creating an application module for a stateless or command-line-client, with the `createRootApplicationModule()` method of the `Configuration` class, you can pass the custom `EnvInfoProvider` as the optional second argument. In order to use a custom `EnvInfoProvider` in an ADF web-based application, you need to implement a custom session cookie factory class as shown in the following example. To use your custom session cookie factory, set the `jbo.ampool.sessioncookiefactoryclass` configuration property to the fully qualified name of your custom session cookie factory class.

```
package devguide.advanced.customenv.view;
import java.util.Properties;
import oracle.jbo.common.ampool.ApplicationPool;
import oracle.jbo.common.ampool.EnvInfoProvider;
import oracle.jbo.common.ampool.SessionCookie;
import oracle.jbo.http.HttpSessionCookieFactory;
/**
 * Example of custom http session cookie factory
 * to install a custom EnvInfoProvider implementation
 * for an ADF web-based application.
 */
public class CustomHttpSessionCookieFactory
       extends HttpSessionCookieFactory {
  public SessionCookie createSessionCookie(String appId,
                                           String sessionId,
                                           ApplicationPool pool,
                                           Properties props) {
    SessionCookie cookie =
      super.createSessionCookie(appId, sessionId,pool, props);
    EnvInfoProvider envInfoProv = new CustomEnvInfoProvider();
    cookie.setEnvInfoProvider(envInfoProv);
    return cookie;
  }
}
```

Then add the JAR file containing the `oracle.jbo.http.HttpSessionCookieFactory` class to the project file. The JAR file `adfmweb.jar` can be found in the `[JDEV_INSTALL]\Oracle_common\modules\oracle.adf.model\` directory. This file is also called ADF Web Runtime in the libraries. To add the JAR file follow these steps:

1. Right-click the project and select **Project Properties**.
2. Select **Libraries and Classpath**.
3. Click **Add Library**.
4. Select **ADF Web Runtime** and click **OK**.

> **Note:**
>
> If you do not add the JAR file, the IDE displays an error when you set `jbo.envinfoprovider` to set the Data Source name and Application Module Pool parameters dynamically at runtime

What You May Need to Know About Configuration Property Scopes

Each runtime configuration property used by ADF Business Components has a scope. The scope of each property indicates when the property's value is evaluated and whether its value is effectively shared (i.e. static) in a single Java VM, or not. The ADF Business Components `PropertyManager` class is the registry of all supported properties. It defines the property names, their default values, and their scope. This class contains a `main()` method so that you can run the class from the command line to see a list of all the configuration property information.

Assuming JDEVHOME is the JDeveloper installation directory, to see this list of settings for reference, do the following:

```
$ java -cp JDEVHOME/BC4J/lib/bc4jmt.jar oracle.jbo.common.PropertyManager
```

Issuing this command will send all of the ADF Business Components configuration properties to the console. It also lists a handy reference about the different levels at which you can set configuration property values and remind you of the precedence order these levels have:

```
---------------------------------------------------------------
Properties loaded from following sources, in order:
1. Client environment [Provided programmatically
                       or declaratively in bc4j.xcfg]
2. Applet tags
3. -D flags (appear in System.properties)
4. bc4j.properties file (in current directory)
5. /oracle/jbo/BC4J.properties resource
6. /oracle/jbo/commom.jboserver.properties resource
7. /oracle/jbo/common.Diagnostic.properties resource
8. System defined default
---------------------------------------------------------------
```

You'll see each property is listed with one of the following scopes:

- MetaObjectManager

  Properties at this scope are initialized once per Java VM when the ADF PropertyManager is first initialized.

- SessionImpl

  Properties at this scope are initialized once per invocation of `ApplicationModule.prepareSession()`.

- Configuration

  Properties at this scope are initialized when the application module pool is first created and the application module's configuration is read the first time.

- Diagnostic

Properties at this scope are specific to the built-in ADF Business Components diagnostic facility.

At each of these scopes, the layered value resolution described above is performed when the properties are initialized. Whenever property values are initialized, if you have specified them in the *Client Environment* (level 1 in the resolution order) the values will take precedence over values specified as System parameters (level 3 in the resolution order).

The Client Environment is a hashtable of name/value pairs that you can either programmatically populate, or which will be automatically populated for you by the `Configuration` object when loaded, with the name/value pairs it contains in its entry in the `bc4j.xcfg` file. The implication of this is that for any properties scoped at MetaObjectManager level, the most reliable way to ensure that all of your application modules use the same default value for those properties is to do both of the following:

1. Make sure the property value does not appear in any of your application module's `bc4j.xcfg` file configuration name/value pair entries.
2. Set the property value using a Java system property in your runtime environment.

If, instead, you leave any MetaObjectManager-scoped properties in your `bc4j.xcfg` files, you will have the undesirable behavior that they will take on the value specified in the configuration of the *first* application module whose pool gets created after the Java VM starts up.

What You May Need to Know About Application Module Pool Configuration Parameters

The application module pool configuration parameters fall into three logical categories relating to pool behavior, pool sizing, and pool cleanup behavior. By default Fusion web applications enable application module pooling.

Pool Behavior Parameters

The application module defines configuration parameters that affect the behavior of the application module pool and whether application module instances holds onto JDBC connection that they obtain from the connection pool after an instance is removed from the application module pool.

How ADF application module pools use the database connection pool depends on the setting of the **Disconnect Application Module Upon Release** configuration parameter `jbo.doconnectionpooling`. As shown in Figure 57-1, by default the setting is disabled and the parameter has the setting `jbo.doconnectionpooling=false`.

.

> **Note:**
>
> The setting `jbo.doconnectionpooling=false` does not mean that there is no database connection pooling happening. What it means is that the application module is not disconnected from its JDBC connection upon check in back to the application module pool.

When an application module instance is created in the application module pool it acquires a JDBC connection. By default, ADF favors maintaining session affinity so that across the request of a single user, ADF will try and reuse the same application module instance (including its associated memory and JDBC connection and state), with the goal of speeding up performance for such users. The default setting of `jbo.doconnectionpooling=false` enables this behavior which enforces application module instances keep their JDBC `PreparedStatement` objects cached and reusable across subsequent requests by clients.

However, as the number of users who access the Fusion web application increases, so does the memory requirement on the server to hold onto the JDBC connection, prepare statement, and result sets. When the application module pool is configured to support several thousand users, the demands of not releasing JDBC connections after each request can place demands on server load with a fraction of the supported managed user sessions. This situation is particularly notable in a deployment environment configured to use database drivers that optimize performance over memory consumption, as has been the case for Oracle JDBC drivers since Oracle Database 10g.

To avoid the situation where server memory can be rapidly consumed by the JDBC driver, you can override the default application module instance connection behavior by setting `jbo.doconnectionpooling=true`, then each time a user session finishes using an application module (typically at the end of each HTTP request), the application module instance disassociates itself with the JDBC connection it was using on that request and it returns the connection to the JDBC connection pool. The next time that application module instance is used by a user session, it will reacquire a JDBC connection from the JDBC connection pool and use it for the span of time that application module is checked out of the application module pool (again, typically the span of one HTTP request). Since the application module instance "unplugs" itself from the JDBC connection object used to create each `PreparedStatement`, in this situation it follows that the `prepareSession()` method will fire each time the application module is checked out of the pool to reinitialize the database state. So, when releasing JDBC connections is enabled for sessions, the trade-off is slightly more JDBC overhead setup each time, in return for holding onto a smaller number of overall database connections.

The key difference is seen when many application module pools are all using the same underlying database user for their application connection.

- If 50 different application module pools each have even just a single application module instance in them, with `jbo.doconnectionpooling=false` there will be 50 JDBC application connections in use. If the application module pooling size parameters are set such that the application module pools are allowed to shrink to 0 instances after an appropriate instance idle timeout by setting the **Minimum Available Size** configuration parameter `jbo.ampool.minavailablesize=0`, then when the application module is removed from its pool, it will put back the connection its holding onto. This situation is optimal when the number of managed application module instances remains low, outside of peak demand times or when the application needs to support a low number of simultaneous users.
- In contrast, if 50 different application module pools each have a single application module instance and `jbo.doconnectionpooling=true`, then the amount of JDBC connections in use will depend on how many of those application modules are *simultaneously* being used by different clients. If an application module instance is in the pool and is not currently being used by a user session, then with `jbo.doconnectionpooling=true` it will have released its JDBC connection back to the connection pool and while the application module instance is sitting there

waiting for either another user to need it again, or to eventually be cleaned up by the application module pool monitor, it will not be "hanging on" to a JDBC connection. This situation is optimal in ensuring the scalability of the Fusion web application during peak demand times or when the number of simultaneous users is expected to increase.

When you set `jbo.doconnectionpooling` to `true`, the default setting 1 for the **Transaction Disconnect Level** configuration parameter `jbo.txn.disconnect_level` ensures that all application modules, view objects and row sets remain in memory and stay valid after their corresponding references to JDBC connections are dropped. This configuration reduces the memory requirement associated with this situation where application module passivation is normally performed upon release. Instead, upon activation, the framework only needs to reexecute and synchronize the cursor positions.

Alternatively, you may be able to achieve a balance between conserving JDBC connections and holding onto connections by configuring the **Connection Threshold** configuration parameter `jbo.ampool.connection_threshold`. This parameter specifies the maximum number of connections that application modules in all application module pools combined may hold onto without releasing back to the connection pool during application module pool cleanup. Note that setting the `jbo.ampool.connection_threshold` parameter to a maximum number of connections (greater than 0) implies disconnecting application modules during pool cleanup is desired and therefore the configuration parameter `jbo.doconnectionpooling` must not be enabled. For more details about how the `jbo.ampool.connection_threshold` parameter affects application module pooling, see What You May Need to Know About Optimizing Application Module Pooling.

Pool Sizing Parameters

The application module defines configuration parameters that affect the sizing of the application module pool. When the pool monitor performs one of its resource cleanup passes, it will try to bring the number of application module instances into the range specified by the maximum and minimum available size parameters.

When the pool monitor cannot reduce the pool size below the maximum size by removing unused and idle application module instance, it will then remove active instances that have not timed out and passivate the state of these active application modules. The **Referenced Pool Size** configuration parameter `jbo.recyclethreshold` determines how many active application modules will remain in the pool monitor when passivation occurs. By default, the threshold over which the pool monitor will begin passivating is 10 application module instances.

You can use the **Maximum Available Pool Size** configuration parameter `jbo.ampool.maxavailablesize` to specify the upper range of the pool size after resource cleanup by the pool monitor. Typically, you override the default maximum available size 25 based on the number of concurrent users and how frequently the users need to access the services of the application module. However, when server memory is not the limiting factor for application performance, the maximum available size may be set to an arbitrarily large value to minimize the affect of passivation and activation of application module instances that are still tied to active user sessions.

> **Note:**
>
> Specifying a sufficiently large maximum pool size is especially important when configuring pool cleanup not to reclaim unused application module instances and to allow idle times of 30 minutes for a typical HTTP session timeout. For more information about configuring pool cleanup, see Pool Behavior Parameters.

Similarly, you can use the **Minimum Available Pool Size** configuration parameter `jbo.ampool.minavailablesize` to specify the lower range of the pool size, when the default of 5 instances is not sufficient to ensure a baseline of available application module instance. Typically, consider setting this value equal to the number of concurrent users at non-peak usage. Setting this value too low results in needless instantiation of application module instances that can affect performance.

Pool Cleanup Parameters

The application module defines configuration parameters that affect how resources are reclaimed when the pool monitor does one of its resource cleanup passes.

A single application module pool monitor per Java VM runs in a background thread and wakes up to scan through the pool to perform cleanup at the interval of 600000 milliseconds (10 minutes) by default. To change the default Pool Polling Interval, you can configure the **Pool Polling Interval** parameter `jbo.ampool.monitorsleepinterval`.

The pool monitor uses the following two, independent strategies to identify which application module instances are candidates to be removed from the pool and reclaimed as a potential new resource.

1. The application module pool monitor removes application module instances from the pool that have not been used for more than 3600000 milliseconds (which is the default value and is exactly one hour). These unused application module instances will be reclaimed regardless of the minimum available size configured for the pool. To override the maximum time to live for an application module, you can set the **Maximum Instance Time to Live** configuration parameter `jbo.ampool.timetolive`. However, for most Fusion web applications, you will not need to reclaim unused application module instance and can set this parameter value to `-1`.
2. The application module pool monitor removes application module instances that have remained idle for 600000 milliseconds (which is the default value and is exactly 10 minutes). This cleanup stops when the number of instances in the pool reaches the minimum available size. You can override the idle timeout for application module instances using the **Idle Instance Timeout** configuration parameter `jbo.ampool.maxinactiveage` when you want to allow idle user sessions of more than 10 minutes.

> **Best Practice:**
>
> When you specify the length of time between application module pool cleanup passes, set the same value for **Pool Polling Interval** configuration parameter `jbo.ampool.monitorsleepinterval` for all application modules. Since there is only a single application monitor pool monitor per Java VM, the value that will effectively be used for the application module pool monitor polling interval will be the value found in the application module configuration read by the *first* application module pool that gets created. Setting all application modules to use the same value ensures that this value is set in a predictable way.

What You May Need to Know About Optimizing Application Module Pooling

You may be able to achieve a balance between conserving JDBC connections and holding onto connections by configuring the **Connection Threshold** configuration parameter `jbo.ampool.connection_threshold`. This parameter specifies the maximum number of connections that application modules in all application module pools combined may hold onto without releasing back to the connection pool upon the next pool cleanup cycle.

When the **Connection Threshold** parameter `jbo.ampool.connection_threshold` is enabled (value greater than `0`), application module connections are released during pool cleanup, not during checkin. The cleanup monitor makes a best effort to disconnect *least recently-used* application modules until the total number of JDBC connections falls below the specified threshold limit. Since enabling the `jbo.ampool.connection_threshold` parameter changes when application module pool cleanup is performed, this implies setting the parameter `jbo.ampool.connection_threshold=true` is not compatible.

> **Note:**
>
> When configuring a threshold value for disconnecting application modules during the pool cleanup cycle, be sure to disable `jbo.doconnectionpooling` so the value is `false` (default). The **Connection Threshold** parameter is not compatible with the setting `jbo.doconnectionpooling=true` since this setting causes JDBC connections to release back to the connection pool upon *checkin* of the application module, and the setting works in combination with the `jbo.txn.disconnect_level` parameter to ensure business components remain in memory. For more information about the `jbo.doconnectionpooling` parameter, see Pool Behavior Parameters.

For example, assume the **Connection Threshold** parameter is set to 10 for two application module pools, where application module pool 1 has seven application modules and pool 2 has eight application modules for a total of 15 JDBC connections. When the application module pool cleanup monitor runs, the monitor will make a best effort to reclaim five connections (15 connection resources - 10 connection threshold). The monitor disconnects application modules proportional to the total number of connected application modules for each pool. In this case, one third of the application modules connections (5/15) from each pool will be disconnected. So pool 1 will loose two connections (7/3) and pool 2 will release three connections (8/3), where the fraction of the pool size will be rounded up.

The cleanup monitor makes a best effort to disconnect application modules until the connected resource number falls below the specified limit but note that it may not be able to do so if there are not enough application modules in an available state. To ensure JDBC connections are released efficiently, you can configure the **Pool Polling Interval** parameter `jbo.ampool.monitorsleepinterval` to shorten the monitor sleep period.

Initializing Database State and Pooling Considerations

You can set database state on a per-user basis for your Fusion web application. This is of great benefit as there may be a need to call upon stored procedures to initialize database state related to a particular user's session.

Sometimes you may need to invoke stored procedures to initialize database state related to the current user's session. The correct place to perform this initialization is in an overridden `prepareSession()` method of your application module.

How to Set Database State Per User

The Fusion web application can set database state on a per-user basis. You typically create a database `CONTEXT` namespace, associate a PL/SQL procedure with it, and then use the `SYS_CONTEXT()` SQL function to reference values from the context.

For example, you can use the PL/SQL package to set and get a package-level variable that holds the name of the currently authenticated Fusion web application user as shown in the following example.

```
create or replace package context_pkg as
  procedure set_app_user_name(username varchar2);
  function app_user_name return varchar2;
end context_pkg;
```

Then your application can define the `WHERE` clause of a view object to reference the `context_pkg.app_user_name` function and query the per-user state.

To set the database state, the application module framework extension class (*AppModuleImpl*`.java`) defines a `callStoredProcedure()` helper method similar to the ones in How to Invoke Stored Procedure with Only IN Arguments. The custom application module class then extends this framework extension class and defines the `setCurrentUserInPLSQLPackage()` helper method shown in the following example. The helper method uses the `callStoredProcedure()` method to invoke the `context_pkg.set_app_user_name()` stored procedure, passing the value of the currently authenticated user as a parameter value.

```
// In CustomAppModuleImpl.java
public void setCurrentUserInPLSQLPackage() {
  String user = getUserPrincipalName();
  callStoredProcedure("context_pkg.set_app_user_name(?)",new Object[]{user});
}
```

With this helper method in place, the custom application module class then overrides the `prepareSession()` method as shown in the following example.

```
// In CustomAppModuleImpl.java
  protected void prepareSession(Session session) {
    super.prepareSession(session);
    getLoggedInUser().retrieveUserInfoForAuthenticatedUser();
    setUserIdIntoUserDataHashtable();
    setCurrentUserInPLSQLPackage();
  }
```

Part VII

Appendixes

This part provides information that developers may need to know when building Fusion web applications with Oracle ADF.

Specifically, it contains the following appendixes:

- Oracle ADF XML Files
- Oracle ADF Binding Properties
- ADF Security Permission Grants
- Most Commonly Used ADF Business Components Methods
- ADF Business Components Java EE Design Pattern Catalog
- ADF Equivalents of Common Oracle Forms Triggers
- Performing Common Oracle Forms Tasks in Oracle ADF
- Deploying ADF Applications to GlassFish

A

Oracle ADF XML Files

This appendix provides a reference for the Oracle ADF metadata files that you create in your data model and user interface projects. You may use this information when you want to edit the contents of the metadata these files define.
This appendix includes the following sections:

About ADF Metadata Files

An Oracle Fusion web application uses various metadata XML files that summarizes basic information about data, which can make finding and working with particular instances of data easier. These files are used to configure the runtime behavior of the system.

Metadata files in a Fusion web application are structured XML files used by the application to:

- Specify the parameters, methods, and return values available to your application's Oracle ADF **data control** usages
- Create objects in the Oracle ADF **binding context** and define the runtime behavior of those objects
- Define configuration information about the UI components in JSF and **ADF Faces**
- Define application configuration information for the Java EE application server

In the case of **ADF bindings**, you can use the binding-specific editors to customize the runtime properties of the binding objects. You can open a binding editor when you display the Structure window for a page definition file and choose **Go to Properties** from the context menu.

Additionally, you can view and edit the contents of any metadata file in JDeveloper's XML editor. The easiest way to work with these files is through the Structure window and Properties window. In the Structure window, you can choose an element and in the Properties window, you can define attribute values for the element, often by choosing among dropdown menu choices. Use this appendix to learn the choices you can choose in the case of the Oracle ADF-specific elements.

ADF File Overview Diagram

The Oracle ADF File Hierarchy diagram helps you to understand the interrelationship of the metadata files used to work with the ADF Business Components data control in a view layer project.

The relationship between the Oracle ADF metadata files defines dependencies between the model data and the user interface projects. The dependencies are defined as file references within XML elements of the files, where these design time definitions in the Model project reference the DataBindings.jpx file in the ViewController project, which in turn references the page definition files.

Figure A-1 illustrates the hierarchical relationship of the XML metadata files that you might work with in a Fusion web application that uses an ADF Business Components **application module** as a service interface to JSF web pages.

Oracle ADF Data Control Files

In a Fusion web application containing **ADF Business Components**, the data control implementation files are contained within the application. The application module and **view object** XML component descriptor files provide the references for the data control. These files, with the `bc4j.xcfg` file, provide the necessary information for the data control.

An application that uses ADF Business Components in one project and a non-ADF Business Components data control in another project may have a `DataControls.dcx` file, as well as supporting `<`*`sessionbeanname`*`>.xml` and `<`*`beanname`*`>.xml` files.

Oracle ADF Data Binding Files

These standard XML configuration files for a Fusion web application appear in your user interface project:

- `adfm.xml`: This file lists the `DataBindings.cpx` file that is available in the current project.

  See adfm.xml for more information.

- `DataBindings.cpx` : This file contains the page map, page definitions references, and data control references. The file is created the first time you create a data binding for a UI component (either from the Structure window or from the **Data Controls panel**). The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application. The binding context provides access to the bindings and data controls across the entire application. The `DataBindings.cpx` file also contains references to the `<`*`pagename`*`>PageDef.xml` files that define the metadata for the Oracle ADF bindings in each web page.

  For more information, see DataBindings.cpx.

- `<`*`pagename`*`>PageDef.xml`: This is the page definition XML file. It associates web page UI components with data, or data controls. JDeveloper creates this file each time you design a new web page using the Data Controls panel or Structure window. These XML files contain the metadata used to create the bindings that populate the data in the web page's UI components. For every web page that refers to an ADF binding, there must be a corresponding page definition file with binding definitions.

  For more information, see pageNamePageDef.xml.

Web Configuration Files

These standard XML configuration files required for a JSF application appear in your user interface project:

- `web.xml`: Part of the application's configuration is determined by the contents of its Java EE application deployment descriptor, `web.xml`. The `web.xml` file defines everything about your application that a server needs to know. The file plays a role in configuring the Oracle ADF data binding by setting up the `ADFBindingFilter`. Additional runtime settings include servlet runtime and initialization parameters, custom tag library location, and security settings.

For more information about ADF data binding and JSF configuration options, see web.xml.

An ADF Faces application typically uses its own set of configuration files in addition to `web.xml`. For more information, see Configuration in trinidad-config.xml in *Developing Web User Interfaces with Oracle ADF Faces*.

- `adfc-config.xml:` The configuration file for an ADF unbounded task flow. The configuration file contains metadata about the activities and control flows contained in the unbounded task flow. The default name for this file is `adfc-config.xml`, but an end user can change the name.

  For more information, see adfc-config.xml.

- `task-flow-definition.xml`: The configuration file for an ADF bounded task flow. The configuration file contains metadata about the activities and control flows contained in the bounded task flow. The default name for this file can be `task-flow-defintion.xml` or whatever an end user specifies in the Create ADF Task Flow dialog. The same application can contain multiple task flow definition files.

  For more information, see task-flow-definition.xml.

ADF File Syntax Diagram

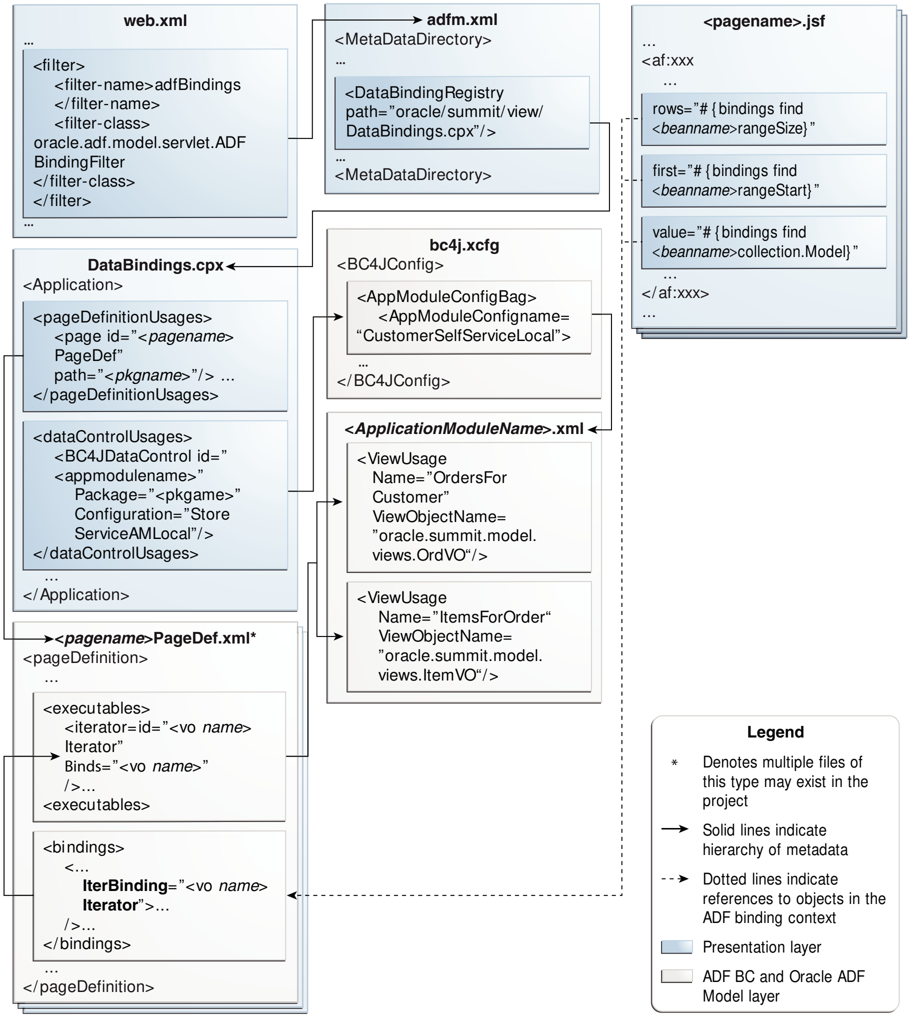
Oracle ADF File Syntax Diagram helps you to understand the hierarchical interrelationship of the XML metadata files in a web application that uses an ADF application module as a service interface to ADF Business Components.

Figure A-2 illustrates the hierarchical relationship of the XML metadata files that you might work with in a web application that uses an ADF application module as a service interface to ADF Business Components. At runtime, the objects created from these files interact in this sequence:

1. When the first request for an ADF databound web page occurs, the servlet registers the Oracle ADF servlet filter `ADFBindingFilter` named in the `web.xml` file.
2. The binding filter creates an empty binding context.
3. When a page is rendered, the binding filter asks the binding context to load a corresponding `PageDef.xml` for the page.
4. The binding context creates the **binding container** by loading the `<page>` file as referenced by the `<pagemap>` element in the `DataBindings.cpx` file.
5. The `adfm.xml` file loads the `DataBindings.cpx` contents and finds the right `PageDef.xml` based on the `<pagemap>` element reference to the `<pageDefinitionUsage>` element.
6. The binding container's `prepareModel` phase prepares and refreshes all relevant executables (most are marked `deferred` by default).
7. An **iterator binding** gets executed by referencing the named method on the data control found through the data control factory named in the case of ADF Business Components in the `bc4j.xcfg` file.
8. The binding container also creates the bindings defined in the `<bindings>` section of the *`pagename`*`PageDef.xml` file for the mapped web page.
9. The web page references to ADF bindings through EL using the expression `#{bindings}` are resolved by accessing the binding container of the page.

10. The page pulls the available data from the bindings in the binding container.

Figure A-2 Oracle ADF File Hierarchy and Syntax Diagram for an ADF BC-based Web Application



adfm.xml

The adfm.xml file is a registry of registries used by the ADF framework to quickly find all metadata files used at runtime. This registry XML file records four types of metadata files —.cpx, .dcx, .xcfg, .jpx.

The `adfm.xml` file contains the classpath-relative paths for the `.cpx`, `.dcx`, `.jpx`, and `.xcfg` files in each design time project that is included in the runtime deployed application. The `adfm.xml` file operates as a dynamically maintained "Registry of Registries" that is used to quickly find all `.cpx`, `.dcx`, `.jpx`, and `.xcfg` files (which are themselves registries of metadata).

The file registry is used extensively by the ADF Library resource catalog browsing implementations, by **ADF Model** layer design time, and at runtime during merge and discovery.

When a developer creates a binding on a page, JDeveloper adds metadata files (for example, page definitions) in the project source tree. The adfm.xml file then notes the location of each.

When a project is built, the adfm.xml file is put in *project-root*/adfmsrc/META-INF/adfm.xml. The project-level archive deployment profiles locate the file at META-INF/adfm.xml.

At runtime, the application classpath is scanned to build the list of .cpx files that comprise the application. The application then loads each.cpx as needed to create the binding context. For details about ADF Model layer usage, see What Happens When You Use the Data Controls Panel.

Four types of sub registries are recorded by the adfm.xml file:

- DataBindingRegistry (.cpx)
- DataControlRegistry (.dcx)
- BusinessComponentServiceRegistry (.xcfg)
- BusinessComponentProjectRegistry (.jpx)

modelProjectName.jpx

JDeveloper uses the modelProjectName.jpx file as a registry to track the contents of the model packages. It also contains metadata for shared ADF application modules present in the project, which is used by both design-time and runtime components.

The.jpx file contains configuration information that JDeveloper uses in the design time to allow you to create the data model project with ADF Business Components. It also contains metadata that defines how a **shared application module** is used at runtime. Because the shared application module can be accessed by any data model project in the same Fusion web application, JDeveloper maintains the scope of the shared application module in the ADF Business Components project configuration file.

This file is saved in the src directory of the project. For example, the Summit sample application for Oracle ADF stores the Model.jpx file in the .src/oracle/summit/model subdirectory of the Model project.

The following example displays a sample default.jpx file.

```
<JboProject
   xmlns="http://xmlns.oracle.com/bc4j"
   Name="Model"
   Version="12.1.2.66.11"
   SeparateXMLFiles="true"
   PackageName="oracle.summit.model">
   <DesignTime>
      <Attr Name="_appModuleNames2"
         Value="oracle.summit.model.services.BackOfficeAppModule"/>
      <Attr Name="_jprName" Value="../../../../Model.jpr"/>
      <Attr Name="_appModuleNames1"
         Value="oracle.summit.model.services.CustomerSelfServiceAppModule"/>
      <Attr Name="_appModuleNames0"
         Value="oracle.summit.model.services.SummitAppModule"/>
      <Attr Name="_jbo.TypeMapEntries" Value="Java"/>
      <Attr Name="_NamedConnection" Value="summit_adf"/>
   </DesignTime>
   <Containee
```

```
      Name="assoc"
      PackageName="oracle.summit.model.entities.assoc"
      ObjectType="JboPackage">

         <Attr Name="_VO" Value="true"/>
      </DesignTime>
   </Containee>
</JboProject>
```

bc4j.xcfg

The bc4j.xcfg file contains metadata information about the ADF application module and runtime parameters that have been configured to manage the runtime behavior of each application module instance.

The `bc4j.xcfg` file contains metadata information about application module names, the database connection used by the application module, and the runtime parameters the user has configured for the application module.

The bc4j.xcfg file is located in the ./common subdirectory relative to the application module's XML component definition. All of the configurations for all of the application modules in a single Java package are saved in that same file. For example, if you look at the bc4j.xcfg file in the /Model/src/oracle/summit/model/services/common directory of the Summit ADF sample application's Model project, you see the configurations for its application modules. For details about editing the configurations, see How to Change Your Application Module's Runtime Configuration and Setting Pool Configuration Parameters.

Example A-1 displays a sample bc4j.xcfg file from the Summit ADF sample application.

Example A-1   Sample bc4j.xcfg File

```

DataBindings.cpx

In an ADF web application, as soon as you drop a databound component on your page, a DataBindings.cpx file gets created. The DataBindings.cpx keeps track of the individual page definition files used within the project, as well as the DataControls mapping to things such as ADF Business Components Application Modules.

The `DataBindings.cpx` file is created in the user interface project the first time you drop a data control usage onto a web page in the visual editor. The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime. It is used extensively by the ADF Library resource catalog browsing implementations, and also by the `.cpx` and `.dcx` design time and runtime merge and discovery. When you insert a databound UI component into your document, the page will contain binding expressions that access the Oracle ADF binding objects at runtime.

The `DataBindings.cpx` file appears in the `/src` directory of the user interface project. When you double-click the file node, the binding context description appears in the XML source editor. (To edit the binding context parameters, use the Properties window and choose the desired parameter in the Structure window.)

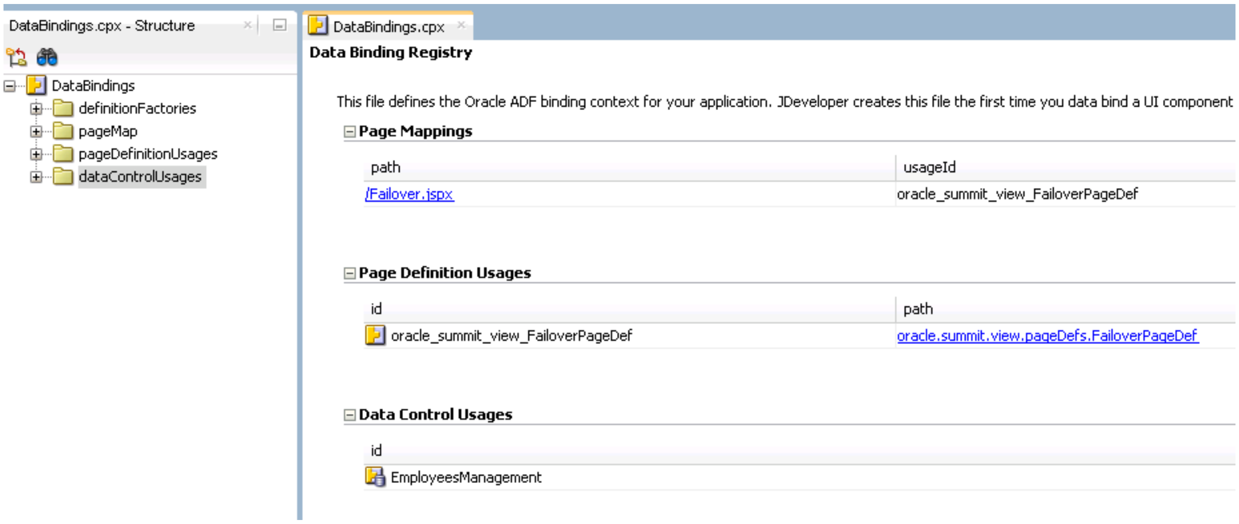
DataBindings.cpx Syntax

The top level element of the `DataBindings.cpx` file is `<Application>`. For example:

```
<?xml version="1.0" encoding="UTF-8" ?>
<Application xmlns="http://xmlns.oracle.com/adfm/application"
             version="11.1.1.56.60" id="DataBindings" SeparateXMLFiles="false"
             Package="oracle.summit.view" ClientType="Generic">
```

Figure A-3 shows the structure definition of the `DataBindings.cpx` file in the Summit standalone sample applications for Oracle ADF.

Figure A-3 Structure of the DataBindings.cpx File



Data Binding Registry

This file defines the Oracle ADF binding context for your application. JDeveloper creates this file the first time you data bind a UI component

Page Mappings

path	usageId
/Failover.jspx	oracle_summit_view_FailoverPageDef

Page Definition Usages

id	path
oracle_summit_view_FailoverPageDef	oracle.summit.view.pageDefs.FailoverPageDef

Data Control Usages

id
EmployeesManagement

The child elements have the following usages:

- `<definitionFactories>` registers a factory class to create the ADF binding objects associated with a particular namespace at runtime. The factory class is specific to the namespace associated with the type of ADF binding (for instance, a task flow binding).
- `<pageMap>` maps all user interface URLs and the corresponding page definition usage name. This map is used at runtime to map a URL to its page definition.
- `<pageDefinitionUsages>` maps a page definition usage (`BindingContainer` instance) name to the corresponding page definition. The `id` attribute represents the usage ID. The path attribute represents the full path to the page definition.
- `<dataControlUsages>` declares a list of data control usages (shortnames) and corresponding path to the data control definition entries in the `.dcx` or `.xcfg` file.

Table A-1 describes the attributes of the `DataBindings.cpx` elements.

Table A-1 Attributes of the DataBindings.cpx File Elements

Element Syntax	Attributes	Attribute Description
`<definitionFactories> <factory/></ definitionFactories>`	`nameSpace`	A URI. Identifies the location of the executable elements in the page definition usage.
	`className`	The fully qualified class name. Identifies the location of the factory class that creates the page definition usage objects.
`<pageMap> <page /></ pageMap>`	`path`	The full directory path. Identifies the location of the user interface page.
	`usageId`	A unique qualifier. Names the page definition ID that appears in the ADF **page definition file**. The ADF binding servlet looks at the incoming URL requests and checks that the `bindings` variable is pointing to the ADF page definition associated with the URL of the incoming HTTP request.

Table A-1 (Cont.) Attributes of the DataBindings.cpx File Elements

Element Syntax	Attributes	Attribute Description
`<pageDefinitionUsages><page/></pageDefinitionUsages>`	`id`	A unique qualifier. References the page definition ID that appears in the ADF page definition file.
	`path`	The fully qualified package name. Identifies the location of the user interface page's ADF page definition file.
`<dataControlUsages><dc.../></dataControlUsages>`	`id`	A unique qualifier. Identifies the data control usage as is defined in the `DataControls.dcx` file.
	`path`	The fully qualified package name. Identifies the location of the data control.

DataBindings.cpx Sample

Example A-2 shows the syntax for the `DataBindings.cpx` file in the Summit ADF sample application.

The ADF executable definition factory (`factory` element) is named by a `className` attribute and is associated with a `namespace`. At runtime, the factory class creates the executable definition objects that leads to the creation of the binding objects for the ADF binding container associated with a particular page definition. The factory locates the page definition through two `DataBindings.cpx` file elements: the `pageMap` element that maps the page URL to the page definition ID (`usageId` attribute) assigned at design time and the `pageDefinitionUsages` element that maps the ID to the location of the page definition from the project or project classpath.

Additionally, the ADF Business Components data control (`BC4JDataControl` element) is named by the `id` attribute. The combination of the `Package` attribute and the `Configuration` attribute is used to locate the `bc4j.xcfg` file in the `./common` subdirectory of the indicated package. The configuration contains the information of the application module name and all the runtime parameters the user has configured.

Example A-2 Sample DataBindings.cpx File

```
<?xml version="1.0" encoding="UTF-8" ?>
<Application xmlns="http://xmlns.oracle.com/adfm/application"
             version="11.1.1.56.60" id="DataBindings" SeparateXMLFiles="false"

          path="oracle.summit.view.pageDefs.indexPageDef"/>
    <page id="oracle_summit_view_OrdersPageDef"
          path="oracle.summit.view.pageDefs.OrdersPageDef"/>
    <page id="oracle_summit_view_InventoryControlTestPageDef"
          path="oracle.summit.view.pageDefs.InventoryControlPageDef"/>
  </pageDefinitionUsages>
  <dataControlUsages>
    <BC4JDataControl id="BackOfficeAppModuleDataControl"
                     Package="oracle.summit.model.services"
                     FactoryClass="oracle.adf.model.bc4j.DataControlFactoryImpl"
                     SupportsTransactions="true" SupportsFindMode="true"
                     SupportsRangesize="true" SupportsResetState="true"
                     SupportsSortCollection="true"
                     Configuration="BackOfficeAppModuleLocal"
                     syncMode="Immediate"
                     xmlns="http://xmlns.oracle.com/adfm/datacontrol"/>
  </dataControlUsages>
</Application>
```

*pageName*PageDef.xml

In an ADF web application, as soon as you draga component from Data Control panel to a JSF page, a page definition file gets created with the name pageNamePageDef.xml. The pageNamePageDef.xml file contains binding metadata for each data bound UI element present on the page.

The *pageName*`PageDef.xml` files are created each time you insert a databound component into a web page using the Data Controls panel or Structure window. These XML files define the Oracle ADF binding container for each web page in the application. The binding container provides access to the bindings within the page. You will have one XML file for each databound web page.

> **Caution:**
>
> The `DataBindings.cpx` file maps JSF pages to their corresponding page definition files. If you change the name of a page definition file or a JSF page, JDeveloper does *not* automatically refactor the `DataBindings.cpx` file. You must manually update the page mapping in the `DataBindings.cpx` file.

The `PageDef.xml` file appears in the `/src/view` directory of the user interface project. The Applications window displays the file in the view package of the Application Sources node. When you double-click the file node, the page description appears in the XML source editor. To edit the page description parameters, use the Properties window and choose the desired parameter in the Structure window. See Working with Page Definition Files.

There are important differences in how the page definitions are generated for methods that return a single value and a collection.

PageDef.xml Syntax

The top-level element of the `PageDef.xml` file is `<pageDefinition>`:

```
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
                version="11.1.1.59.23" id="<pagename>PageDef"
                Package="oracle.summit.view.pageDefs">
```

where the XML namespace attribute (`xmlns`) specifies the URI to which the ADF binding container binds at runtime. Only the package name is editable; all other attributes should have the values shown.

The following example displays the child element hierarchy of the `<pageDefinition>` element. Note that each business service for which you have created a data control will have its own `<AdapterDataControl>` definition.

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition>
    <parameters>
        ...
    </parameters>
    <executables>
        ...
    </executables>
    <bindings>
        ...
    </bindings>
</pageDefinition>
```

The child elements have the following usages:

- `<parameters>` defines page-level parameters that are EL accessible. These parameters store information local to the web page request and may be accessed in the binding expressions.
- `<executables>` defines the list of items (methods, view objects, and accessors) to execute during the `prepareModel` phase of the ADF page lifecycle. Methods to be executed are defined by `<methodIterator>`. The lifecycle performs the execute in the sequence listed in the `<executables>` section. Whether or not the method or operation is executed depends on its `Refresh` or `RefreshCondition` attribute value. Built-in operations on the data control are defined by:
  - `<page>`: definition for a nested page definition (binding container)
  - `<iterator>`: definition to a named collection in `DataControls`
  - `<accessorIterator>`: definition to get an accessor in a data control hierarchy
  - `<methodIterator>`: definition to get to an iterator returned by an invoked method defined by a `methodAction` in the same file
  - `<variableIterator>`: internal iterator that contains variables declared for the binding container
  - `<invokeAction>`: definition of which method to invoke as an executable

> **Note:**
>
> Only use `invokeAction` when your application does not use the ADF Controller module from the Fusion web application technology stack. If your application uses the ADF Controller module, Oracle recommends that you use a task flow method call activity, as described in Using Method Call Activities.

- `<bindings>` refers to an entry in `<executables>` to get to the collection from which bindings extract/submit attribute level data.

Table A-2 describes the attributes of the top-level `<pageDefinition>` element.

Table A-2 Attributes of the PageDef.xml File <pageDefinition> Element

Element Syntax	Attributes	Attribute Description
`<pageDefinition>`	`ControllerClass`	Fully qualified class name to create when controller requests a `PageController` object for this `bindingContainer`.
	`EnableTokenValidation`	Enables currency validation for this bindingContainer when a postback occurs. This is to confirm that the web tier state matches the state that particular page was rendered with.
	`FindMode`	FindMode is for legacy (10.1.2) use only and indicates whether this bindingContainer should start out in findMode when initially prepared.
	`MsgBundleClass`	Fully qualified package name. Identifies the class which contains translation strings for any bindings.
	`SkipValidation`	Determines if data validation occurs. The supported values are: • `true`: skips data validation. Note that attribute validation on the client side at the binding level still occurs. For example, validates non-null and type conversion errors. • `false`: validates all rows for all data controls referenced in the current page. This is the default value. • `skipDataControls`: validates the current rows of iterator bindings modified in the current page. • `custom`: set to `custom` if your application implements an instance of the `oracle.binding.BindingContainerValidator` interface and references it through an EL expression entry named `CustomValidator` in the binding container. Setting a value for this attribute can be useful if you want to skip data validation on, for example, a train component. For more information, see How to Create the Train Model in *Developing Web User Interfaces with Oracle ADF Faces*.
	`Viewable`	An EL expression that should resolve at runtime to whether this binding and the associated component should be rendered or not.

Table A-3 describes the attributes of the child element of `<parameters>`.

Table A-3 Attributes of the PageDef.xml File <parameters> Element

Element Syntax	Attributes	Attribute Description
`<parameter>`	`evaluate`	Specifies when the parameter should be evaluated: `eachUse`, `firstUse`, or `inPrepareModel`.
	`id`	Unique identifier. May be referenced by ADF bindings.
	`option`	Indicates the usage of the variable within the binding container: • `Final` indicates that this parameter cannot be passed in by a usage of this binding container. It must use the default value in the definition. • `Optional` indicates that the variable value need not be provided. • `Mandatory` specifies that the parameter value must be provided at runtime using Java or an EL expression. Failure to provide a value for a mandatory parameter or binding leads to an exception being thrown during binding validation.
	`readonly`	Indicates whether the parameter value may be modified or not. Set to `true` when you do not want the application to modify the parameter value.
	`value`	A default value, which can be an EL expression.

Table A-4 describes the attributes of the `PageDef.xml` `<executables>` elements.

Table A-4 Attributes of the PageDef.xml File <executables> Element

Element Syntax	Attributes	Attribute Description
`<accessorIterator>`	`Accessor`	Specifies any other accessor defined by this binding.
	`Binds`	Specifies the view or action to which the iterator is bound.
	`BeanClass`	Identifies the Java type of beans in the associated iterator or collection.
	`CacheResults`	If `true`, manages the data collection between requests.
	`ChangeEventRate`	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	`DataControl`	Interprets and returns the collection referred to by this iterator binding.
	`id`	Unique identifier. May be referenced by any ADF value binding.
	`MasterBinding`	Reference to the `methodIterator` (or iterator) that binds the data collection that serves as the master to the accessor iterator's detail collection.
	`ObjectType`	Used for ADF Business Components only. A boolean value determines whether the collection is an object type or not.

Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element

Element Syntax	Attributes	Attribute Description
	`RangeSize`	Specifies the number of data objects in a range to fetch from the bound collection. The range defines a window you can use to access a subset of the data objects in the collection. Typically, when you create a component by dragging an object from the Data Controls panel, the range size is set to 25. Use `RangeSize` when you want to work with an entire set or when you want to limit the number of data objects to display in the page. Note that the values -1 and 0 have specific meaning: the value -1 returns all available objects from the collection, while the value 0 will return the same number of objects as the collection uses to retrieve from its data source. If the `RangeSize` attribute is not specified at all, all available objects are returned.

Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element

Element Syntax	Attributes	Attribute Description
	`Refresh`	Determines when to invoke the executable. Oracle recommends that you do not change from the default value (`deferred`) for the `Refresh` attribute and that you do use an EL expression for the `RefreshCondition` attribute to determine if an executable should be refreshed. For completeness' sake, the following is the list of valid attribute values: • `always`: Invokes the executable each time the binding container is prepared. This occurs when the page displays and when the user submits changes, or when the application posts back to the page. • `deferred`: Refresh occurs when another binding requires or refers to this executable. Since refreshing an executable may impact performance, you can set the refresh to occur only if `deferred` is used in a binding that is being rendered. This is the default value for ADF Faces applications. • `<default>`: Always set to `deferred` by default. • `ifNeeded`: Whenever the framework needs to refresh the executable because it has not been refreshed to this point. For example, when you have an accessor hierarchy such that a detail is listed first in the page definition, the master could be refreshed twice (once for the detail and again for the master's iterator). Using `ifNeeded` avoids duplicate refreshes. This is the default value for all view technologies other than ADF Faces. • `never`: The application itself calls refresh on the executable during one of the controller phases and does not want the framework to refresh the executable at all. • `prepareModel`: Invokes the executable each time the page's binding container is prepared. • `prepareModelIfNeeded`: Invokes the executable during the Prepare Model phase if this executable has not been refreshed to this point. See also `ifNeeded`. • `renderModel`: Invokes the executable each time the page is rendered. • `renderModelIfNeeded`: Invokes the executable during the page's Render Model phase on the condition that it is needed. See also `ifNeeded`.
	`RefreshCondition`	An EL expression that determines if the executable should be refreshed. Use with the executable's `Refresh` attribute to make the refresh of the executable predictable. The `Refresh` attribute is evaluated if the EL expression that you set for `RefreshCondition` returns `true`.
	`RefreshAfter`	Use to handle dependencies between executables. For example, you can set a condition so that this executable refreshes after another executable.

Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element

Element Syntax	Attributes	Attribute Description
	`RowCountThreshold`	Specify a value to determine if a result set returns the number of rows you specify as a value. If you set `RowCountThreshold` to `0`, the iterator returns the estimated row count in the result set by executing the count query. If you set `RowCountThreshold` to less than `0`, the iterator does not execute the count query. Set `RowCountThreshold` to a value greater than `0` if you want the iterator to execute the count query with the maximum value equal to the value you specify for `RowCountThreshold`. If the estimated row count is less than the value of `RowCountThreshold`, return the number of rows in the estimated row count. If the estimated row count is greater than the value of RowCountThreshold, return `-1`.
	`Sortable`	Specifies whether the iterator is sortable or not.
`<invokeAction>`		Only use `<invokeAction>` when your application does not use the ADF Controller module from the Fusion web application technology stack. Oracle recommends that you use a task flow method call activity, as described in Using Method Call Activities, if your application uses the ADF Controller module.
	`Binds`	Determines the action to invoke. This may be on any `actionBinding`. Additionally, in the case, of the EJB session facade data control, you may bind to the finder method exposed by the data control. Built-in actions supported by the EJB session facade data control include: • `Execute` executes the bound action defined by the data collection. • `Find` retrieves a data object from a collection. • `First` navigates to the first data object in the data collection range. • `Last` navigates to the first data object in the data collection range. • `Next` navigates to the first data object in the data collection range. If the current range position is already on the last data object, then no action is performed. • `Previous` navigates to the first data object in the data collection range. If the current position is already on the first data object, then no action is performed. • `setCurrentRowWithKey` passes the row key as a `String` converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection. When passing the key, the URL for the form will not display the row key value. You may use this operation when the data collection defines a multipart attribute key. • `setCurrentRowWithKeyValue` is used as above, but when you want to use a primary key value instead of the stringified key.
	`id`	Unique identifier. May be referenced by any ADF action binding.

Table A-4 (Cont.) Attributes of the PageDef.xml File <executables> Element

Element Syntax	Attributes	Attribute Description
	Refresh	See Refresh for <accessorIterator>.
	RefreshCondition	See RefreshCondition for <accessorIterator>.
<iterator> and <methodIterator>	BeanClass	Identifies the Java type of beans in the associated iterator or collection.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. Not used in current JDeveloper release.
	Binds	See Binds for <invokeAction>.
	CacheResults	See CacheResults for <accessorIterator>.
	ChangeEventRate	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	DataControl	Name of the DataControl usage in the bindingContext (.cpx) which this iterator is associated with.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF value binding.
	ObjectType	Not used by EJB session facade data control (used by ADF Business Components only).
	RangeSize	See RangeSize for <accessorIterator>.
	Refresh	See Refresh for <accessorIterator>.
	RefreshAfter	Specifies the condition after which the page should be refreshed.
	RefreshCondition	See RefreshCondition for <accessorIterator>.
	RowCountThreshold	See RowCountThreshold for <accessorIterator>.
<page> and <variableIterator>	id	Unique identifier. In the case of <page>, refers to nested page or **region** that is included in this page. In the case of the <variableIterator> executable, the identifier may be referenced by any ADF value binding.
	ChangeEventRate	Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.
	path	Used by <page> executable only. Advanced, a fully qualified path that may reference another page's binding container.
	Refresh	See Refresh for <accessorIterator>.
	RefreshAfter	Specifies the condition after which the page should be refreshed.
	RefreshCondition	See RefreshCondition for <accessorIterator>.

Table A-5 describes the attributes of the PageDef.xml <bindings> element.

Table A-5   Attributes of the PageDef.xml File <bindings> Element

Element Syntax	Attributes	Attribute Description
`<action>`	`Action`	Fully qualified package name. Identifies the class for which the data control is created. In the case of the EJB session facade, this is the session bean.
	`BindingClass`	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	`DataControl`	Name of the `DataControl` usage in the `bindingContext (.cpx)` which this `iteratorBinding` or `actionBinding` is associated with.
	`Execute`	Used by default when you drop an operation from the Data Controls panel in the automatically configured `ActionListener` property. It results in executing the action binding's operation at runtime.
	`InstanceName`	Specifies the instance name for the action.
	`IterBinding`	Specifies the `iteratorBinding` instance in this `bindingContainer` to which this binding is associated.
	`Outcome`	Use if you want to use the result of a method action binding (once converted to a `String`) as a JSF navigation outcome name.
`<attributeValues>`	`ApplyValidation`	Set to `true` by default. When `true`, `controlBinding` executes validators defined on the binding. You can set to `false` in the case of ADF Business Components, when running in local mode and the same validators are already defined on the corresponding attribute.
	`BindingClass`	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	`ChangeEventPolicy`	Specifies the event strategy for the component when run with ADS (Active Data Services). Can be specified as push poll ppr none
	`ControlClass`	Used internally by ADF.
	`CustomInputHandler`	This is the class name for a `oracle.jbo.uicli.binding.JUCtrlValueHandler` implementation that is used to process the `inputValue` for a given value binding.
	`DefClass`	Used internally by ADF.
	`id`	Unique identifier. May be referenced by any ADF action binding.
	`IterBinding`	Refers to the `iteratorBinding` instance in this `bindingContainer` to which this binding is associated.

Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element

Element Syntax	Attributes	Attribute Description
	NullValueId	Refers to the entry in the message bundle for this bindingContainer that contains the String to indicate the null value in a list display.
<button>	ApplyValidation	Set to true by default. When true, controlBinding executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	BindingClass	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	BoolVal	Identifies whether the value at the zero index in the static value list in this boolean list binding represents true or false.
	ControlClass	Used internally by ADF.
	CustomInputHandler	This is the class name for a oracle.jbo.uicli.binding.JUCtrlValueHandler implementation that is used to process the inputValue for a given value binding.
	DefClass	Used internally by ADF.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the iteratorBinding instance in this bindingContainer to which this binding is associated.
	ListIter	Refers to the iteratorBinding that is associated with the source list of this listBinding.
	ListOperMode	Determines whether this list binding is for navigation, contains a static list of values or is an LOV type list.
	NullValueFlag	Describes whether this list binding has a null value and, if so, whether it should be displayed at the beginning or the end of the list.
	NullValueId	Refers to the entry in the message bundle for this bindingContainer that contains the String to indicate the null value in a list display.
<gantt>	ChangeEventPolicy	Identifies the update policy for the component. Valid values are none, ppr, and push. The default is ppr.
	xmlns	Used internally by ADF.
	CustomInputHandler	This is the class name for a oracle.jbo.uicli.binding.JUCtrlValueHandler implementation that is used to process the inputValue for a given value binding.
	id	Unique identifier. May be referenced by any ADF action binding.
	IterBinding	Refers to the iteratorBinding instance in this bindingContainer to which this binding is associated.

Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element

Element Syntax	Attributes	Attribute Description
	`NullValueId`	Refers to the entry in the message bundle for this `bindingContainer` that contains the `String` to indicate the null value in a list display.
	`ganttDataMap`	Wraps the data binding XML for the ADF Faces Gantt chart component.
`<gauge>`	`type`	Identifies the gauge type.
	`ledStyle`	Identifies the LED style for the gauge.
	`ChangeEventPolicy`	Identifies the update policy for the component. Valid values are `none`, `ppr`, and `push`. The default is `ppr`.
	`xmlns`	Used internally by ADF.
	`CustomInputHandler`	This is the class name for a `oracle.jbo.uicli.binding.JUCtrlValueHandler` implementation that is used to process the `inputValue` for a given value binding.
	`id`	Unique identifier. May be referenced by any ADF action binding.
	`IterBinding`	Refers to the `iteratorBinding` instance in this `bindingContainer` to which this binding is associated.
	`NullValueId`	Refers to the entry in the message bundle for this `bindingContainer` that contains the `String` to indicate the null value in a list display.
	`gaugeDataMap`	Wraps the data binding XML for the ADF Faces `gauge` component.
`<graph>`	`type`	Identifies the graph type.
	`ChangeEventPolicy`	Identifies the update policy for the component. Valid values are `none`, `ppr`, and `push`. The default is `ppr`.
	`xmlns`	Used internally by ADF.
	`CustomInputHandler`	This is the class name for a `oracle.jbo.uicli.binding.JUCtrlValueHandler` implementation that is used to process the `inputValue` for a given value binding.
	`id`	Unique identifier. May be referenced by any ADF action binding.
	`IterBinding`	Refers to the `iteratorBinding` instance in this `bindingContainer` to which this binding is associated.
	`NullValueId`	Refers to the entry in the message bundle for this `bindingContainer` that contains the `String` to indicate the null value in a list display.
	`graphDataMap`	Wraps the data binding XML for the ADF Faces `graph` component.

Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element

Element Syntax	Attributes	Attribute Description
`<list>`	`ApplyValidation`	Set to `true` by default. When `true`, `controlBinding` executes validators defined on the binding. You can set to `false` in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	`BindingClass`	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	`ControlClass`	Used internally by ADF.
	`CustomInputHandler`	This is the class name for a `oracle.jbo.uicli.binding.JUCtrlValueHandler` implementation that is used to process the `inputValue` for a given value binding.
	`DefClass`	Used internally by ADF.
	`id`	Unique identifier. May be referenced by any ADF action binding.
	`IterBinding`	Refers to the `iteratorBinding` instance in this `bindingContainer` to which this binding is associated.
	`ListIter`	Refers to the `iteratorBinding` that is associated with the source list of this `listBinding`.
	`ListOperMode`	Determines whether this list binding is for navigation, contains a static list of values, or is an LOV type list.
	`Mode`	The value of this attribute determines if the list binding passes the actual value (`Object`) or the location of the value in an index (`Index`). For more information about setting this attribute, see What You May Need to Know About Values in a Selection List .
	`MRUCount`	Specifies the number of items to display in a choice list when you want to provide a shortcut for the end user to display their most recent selections. For example, a form might display a choice list of supplier ID values to drive a purchase order form. In this case, you can allow users to choose from a list of their most recently view suppliers, where the number of supplier choices is determined by the count you enter. The default for the choice list is to display all values for the attribute and is specified by the count 0 (zero).
	`MRUId`	Specifies the `String` that will be the discriminator line for the MRU list.
	`NullValueFlag`	Describes whether this list binding has a null value and, if so, whether it should be displayed at the beginning of the list or the end.
	`NullValueId`	Refers to the entry in the message bundle for this `bindingContainer` that contains the `String` to indicate the null value in a list display.
	`StaticList`	Defines a static list of values that will be rendered in the bound list component.

Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element

Element Syntax	Attributes	Attribute Description
`<mapTheme>`	`ChangeEventPolicy`	Identifies the update policy for the component. Valid values are `none`, `ppr`, and `push`. The default is `ppr`.
	`xmlns`	Used internally by ADF.
	`CustomInputHandler`	This is the class name for a `oracle.jbo.uicli.binding.JUCtrlValueHandler` implementation that is used to process the `inputValue` for a given value binding.
	`id`	Unique identifier. May be referenced by any ADF action binding.
	`IterBinding`	Refers to the `iteratorBinding` instance in this `bindingContainer` to which this binding is associated.
	`NullValueId`	Refers to the entry in the message bundle for this `bindingContainer` that contains the `String` to indicate the null value in a list display.
	`mapThemeDataMap`	Wraps the data binding XML for the ADF Data Visualization geographic map component.
`<methodAction>`	`Action`	Fully qualified package name. Identifies the class for which the data control is created. In the case of the EJB session facade, this is the session bean.
	`BindingClass`	This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper.
	`ClassName`	This is the class to which the method being invoked belongs.
	`DataControl`	Name of the `DataControl` usage in the `bindingContext (.cpx)` which this `iteratorBinding` or `actionBinding` is associated with.
	`DefClass`	Used internally by ADF.
	`id`	Unique identifier. May be referenced by any ADF action binding.
	`InstanceName`	A dot-separated EL path to a Java object instance on which the associated method is to be invoked.
	`IsLocalObjectReference`	Set to `true` if the `instanceName` contains an EL path relative to this `bindingContainer`.
	`IsViewObjectMethod`	Set to `true` if the `instanceName` contains an instance path relative to the associated data control's application module.
	`MethodName`	Indicates the name of the operation on the given instance or class that needs to be invoked for this `methodActionBinding`.
	`RequiresUpdateModel`	Whether this action requires that the model be updated before the action is to be invoked.
	`ReturnName`	The EL path of the result returned by the associated method.

Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element

Element Syntax	Attributes	Attribute Description
`<pivotTable>`	`ChangeEventPolicy`	Identifies the update policy for the component. Valid values are `none`, `ppr`, and `push`. The default is `ppr`.
	`xmlns`	Used internally by ADF.
	`CustomInputHandler`	This is the class name for a `oracle.jbo.uicli.binding.JUCtrlValueHandler` implementation that is used to process the `inputValue` for a given value binding.
	`id`	Unique identifier. May be referenced by any ADF action binding.
	`IterBinding`	Refers to the `iteratorBinding` instance in this `bindingContainer` to which this binding is associated.
	`NullValueId`	Refers to the entry in the message bundle for this `bindingContainer` that contains the `String` to indicate the null value in a list display.
	`pivotTableDataMap`	Wraps the data binding XML for the ADF Data Visualization pivot table component.
`<table>` and `<tree>`	`ApplyValidation`	Set to `true` by default. When `true`, `controlBinding` executes validators defined on the binding. You can set to `false` in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute.
	`BindingClass`	This is for backward compatibility to indicate which class implements the runtime for this binding definition.This is used by earlier versions of JDeveloper.
	`CollectionModel`	Accesses the `CollectionModel` object, the data model that is used by ADF table components. A table's value is bound to the `CollectionModel` attribute. The table wraps the result set from the iterator binding in a `CollectionModel` object. The `CollectionModel` attribute allows each item in the collection to be available within the table component using the `var` attribute.
	`ControlClass`	Used internally for testing purposes.
	`CustomInputHandler`	This is the class name for a `oracle.jbo.uicli.binding.JUCtrlValueHandler` implementation that is used to process the `inputValue` for a given value binding.
	`DefClass`	Used internally by ADF.
	`DiscrValue`	Indicates the discriminator value for a hierarchical type binding (type definition for a tree node). This value is used to determine whether a given row in a collection being rendered in a polymorphic tree binding should be rendered using the containing hierarchical type binding.
	`id`	Unique identifier. May be referenced by any ADF action binding.
	`IterBinding`	Refers to the `iteratorBinding` instance in this `bindingContainer` to which this binding is associated.

Table A-5 (Cont.) Attributes of the PageDef.xml File <bindings> Element

Element Syntax	Attributes	Attribute Description
	`TreeModel`	The data model used by ADF Tree components. `TreeModel` extends `CollectionModel` to add support for container rows. Rows in the `TreeModel` may (recursively) contain other rows.

adfc-config.xml

ADF Faces uses adfc-config.xml to store its configurations. It is an unbounded taskflow and the `adfc-config.xml` file contains activies, control flow rules, and managed beans interacting to allow a user to complete a task.

The `adfc-config.xml` file is the source file for the ADF unbounded task flow that JDeveloper creates by default when you create an application using the ADF Fusion Web Application template. By default, JDeveloper stores the `adfc-config.xml` file in the following directory:

`application_root``\ViewController\Web Content\WEB-INF`

If you create additional unbounded task flows, JDeveloper proposes the following file name for the source files of the additional unbounded task flows:

`adfc-config`*`N`*`.xml`

where *N* is a number that increments each time you create a new unbounded task flow. Alternatively, you choose the file name you want for an unbounded task flow's source file.

Each source file for an unbounded task flow contains the metadata for activities, control flow rules, and managed beans that you added to an unbounded task flow so that end users can interact with the Fusion web application to complete a task.

The XML schema definition file (XSD) that defines valid metadata entries for the `adfc-config.xml` file is `adfc-config_1_0.xsd`. The `adfc-config_1_0.xsd` file is stored in the `adf-controller-schema.jar` file in the following directory of your JDeveloper installation:

`jdev_install``\oracle_common\modules\oracle.adf.model_12.1.2`

Use JDeveloper's XSD Visual Editor to view the `adfc-config_1_0.xsd` file. Using this editor, you can identify the valid metadata elements and attributes for the `adfc-config.xml` file.

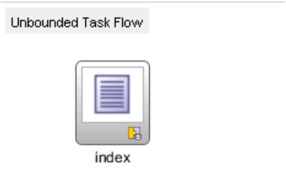
The following example shows the source file for an unbounded task flow where view activities, control flow rules, and so on have yet to be added.

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
</adfc-config>
```

Figure A-4 shows the Diagram view of the Summit sample application for ADF task flows' `adfc-config.xml` file. Example A-3 shows the corresponding source view of the unbounded task flow that appears in Figure A-4.

For more information about unbounded task flows, see Getting Started with ADF Task Flows .

Figure A-4 Diagram View of Summit ADF Task Flow Sample Application´s adfc-config.xml File



Example A-3 Source View of Summit ADF Task Flow Sample Application´s adfc-config.xml File

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <view id="index">
    <page>/index.jsf</page>
  </view>
  <managed-bean id="__1">
    <managed-bean-name>login</managed-bean-name>
    <managed-bean-class>oracle.summit.bean.LoginBean</managed-bean-class>
    <managed-bean-scope>request</managed-bean-scope>
  </managed-bean>
  <managed-bean id="__2">
    <managed-bean-name>WelcomePageBean</managed-bean-name>
    <managed-bean-class>oracle.summit.bean.WelcomePageBean</managed-bean-class>
    <managed-bean-scope>request</managed-bean-scope>
  </managed-bean>
</adfc-config>
```

task-flow-definition.xml

The task-flow-definition.xml file stores metadata definition for a bounded task flow. You can specify the task flow definition XML filename and location when you generate the task flow.

The default file name that JDeveloper proposes for the source file of the first ADF bounded task flow that you create is `task-flow-definition.xml`. This file stores the metadata for a bounded task flow. It contains entries for each view activity, method call activity, task flow call, and so on that you add to the bounded task flow.

JDeveloper proposes the following file name for subsequent bounded task flows that you create:

`task-flow-definition`*`N`*`.xml`

where *N* is a number that increments each time you create a new bounded task flow. Alternatively, you choose the file name you want for a bounded task flow's source file. By default, JDeveloper stores the `task-flow-definition.xml` file in the following directory:

`application_root``\ViewController\Web Content\WEB-INF`

The XML schema definition files (XSD) that define the valid metadata entries for the source file of a bounded task flow are stored in the `adf-controller-schema.jar` file in the following directory of your JDeveloper installation:

`jdev_install``\oracle_common\modules\oracle.adf.model_12.1.2`

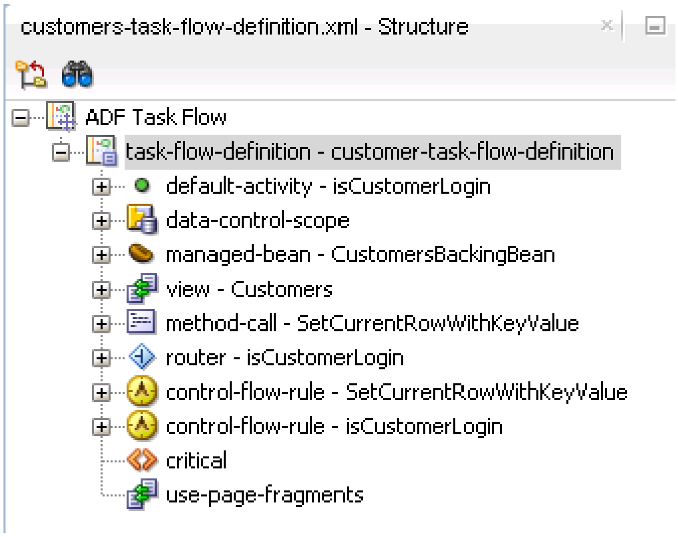
Use JDeveloper's XSD Visual Editor to view these XSD files and identify the valid metadata elements and attributes for the source file of a bounded task flow.

The following example shows the content of a source file when you create a new bounded task flow using the Create Task Flow dialog. The `<task-flow-definition>` element identifies this file as a bounded task flow. JDeveloper generates the `<task-flow-definition>` element when you select the **Create as Bounded Task Flow** checkbox in the Create Task Flow dialog. The value of the `<task-flow-definition>` element's `id` attribute (`task-flow-definition`) corresponds to the value that you enter in the **Task Flow ID** field of the Create Task Flow dialog. The `<use-page-fragments/>` element indicates that all view activities in this bounded task flow must be associated with page fragments. JDeveloper generates this entry when you select the **Create with Page Fragments** checkbox in the Create Task Flow dialog.

```
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <task-flow-definition id="task-flow-definition">
    <use-page-fragments/>
  </task-flow-definition>
</adfc-config>
```

Example A-4 shows the Summit ADF task flow sample application's `customers-task-flow-definition.xml` file. You can view entries for the activities shown in the Structure window in Figure A-5. See Getting Started with ADF Task Flows .

Figure A-5 Structure View of the customers-task-flow-definition.xml File



customers-task-flow-definition.xml - Structure

- ADF Task Flow
  - task-flow-definition - customer-task-flow-definition
    - default-activity - isCustomerLogin
    - data-control-scope
    - managed-bean - CustomersBackingBean
    - view - Customers

</adfc-config>
```

adf-config.xml

The adf-config.xml file contains application-level settings, that manages the runtime infrastructure such as failover behavior for the ADF application modules, global fetch limit for all the view objects, caching of resource bundles, automated refresh of page bindings, and so on for your application.

JDeveloper generates the `adf-config.xml` file when you create an application using the ADF Fusion Web Application template. JDeveloper stores this application-level descriptor file in the following directory:

application_root\.adf\META-INF

In JDeveloper, you can locate the file in the Application Resources panel of the Applications window by expanding the **Descriptors > ADF META-INF** nodes.

The `adf-config.xml` file specifies application-level settings that you define during development. You can use a deployment profile to specify settings that are used at application deploy time. You can change some of the settings at runtime using Oracle Enterprise Manager.

Examples of tasks that you can accomplish by changing settings in the `adf-config.xml` file include the following:

- Enable or disable the validation of ADF Controller metadata
- Replicate memory scope if you deploy your Fusion web application in a clustered environment
- Configure properties to manage the caching of resource bundles where your application uses EL expressions to retrieve strings at runtime from resource bundles

  The properties that you can configure are:

  - `initial-size`

    Specifies the initial number of resource bundles that your application can cache. The default value is `100`.

  - `max-size`

    Specifies the maximum number of resource bundles that your application can cache. The default value is `100`.

  - `load-factor`

    The default value is `0.75`.

  - `expire-time`

    The default value is `43200` seconds (12 hours).

    You specify these properties as attribute values of the `<resource-bundle-cache>` element in the `adf-config.xml` file. Example A-5 demonstrates how you might configure these values for your application in the `adf-config.xml` file.

  As an alternative to configuring the caching of resource bundles in the `adf-config.xml` file, you can specify the resource bundle caching properties as parameters for the Java Virtual Machine (JVM). If you specify the properties as parameters for the JVM, the changes apply to all applications managed by the JVM. For this reason, consider configuring the resource bundle caching properties in the `adf-config.xml` file for you application. Use the following property names if you decide to specify the resource bundle caching properties as parameters for the JVM:

  - `resource-bundle-cache-initial-size`
  - `resource-bundle-cache-max-size`
  - `resource-bundle-cache-load-factor`
  - `resource-bundle-cache-expire-time`

At runtime, the Fusion web application loads the `adf-config.xml` file from the `META-INF` directory. If the Fusion web application finds more than one `adf-config.xml` file, it stops loading the file and logs a warning.

The following tasks modify or require you to modify the `adf-config.xml` file:

- In the ADF Controller layer
  - Creating task flows

    By default, the ADF Controller uses a user session level cache to store the application's unbounded task flow metadata. This enables support for user specific seeded customization or design time at runtime customization of unbounded task flow metadata in your application. Clear the **Allow Unbounded Task Flow Customizations** checkbox in the Controller page of the `adf-config.xml`'s file overview editor to disable this behavior and set the value of the `<allow-unbounded-task-flow-customizations>` element to `false`. You can still have customizations of the unbounded task flow metadata in your application. However, these customizations are shared by all users of the application. For information about customizations, see Customizing Applications with MDS . For information about task flows, see Getting Started with ADF Task Flows .
  - Configure an integer value for the `root-view-port-request-lock-timeout` property that specifies the number of seconds a request can hold a lock on the root view port before timing out and allowing other requests to acquire the lock. The default value is 600 seconds. For information about the root view port, see About View Ports and ADF Regions.
  - Minimize the number of active root view ports in an application by specifying a value for the `<max-root-view-ports>` property. See Minimizing the Number of Active Root View Ports in an Application.
  - Modify the number of events collected or stop the collection of events by ADF Controller. Both tasks involve configuring the value of the `<debug-history-size>` element in your application's `adf-config.xml` file. See Reporting Incidents to the Diagnostic Framework.
  - Enabling implicit save points

    See How to Enable Implicit Save Points.
  - Specify a bounded task flow that does not require authorization to invoke when a user attempts to invoke a bounded task flow in a region for which they do not have security permissions. See Handling Access to Secured Task Flows by Unauthorized Users.
  - Enable ADF Controller to track changes to ADF memory scopes and replicate the page flow scope and view scope within the server cluster. You must set the ADF Controller parameter `<adf-scope-ha-support>` in the application's `adf-config.xml` file to `true`. See How to Ensure Oracle ADF Receives Notifications From Managed Bean Changes .
- In the ADF Model layer
  - Disable automatic partial page rendering as the default behavior for an application. This requires you to change the value for the `changeEventPolicy` attribute from the default value of `ppr`:

    ```
    <defaults changeEventPolicy="ppr"/>
    ```

    See What You May Need to Know About Partial Page Rendering and Iterator Bindings.

  - Configure all Query components in the user interface project to render input search fields using a bind variable.

    See What You May Need to Know About Named Bind Variables in Search Forms.

  - Control the dispatch of contextual events

    See How to Control Contextual Events Dispatch.

- Persisting saved searches in MDS

  See How to Persist Saved Searches into MDS.

- Creating RESTful web services from ADF application modules and managing the release version identifiers of REST resources

  See Creating ADF REST Resources Using the Application Module and see Versioning the ADF REST Resource.

- Configuring ADF Business Components global settings

  See Using Fetch Size to Limit the Maximum Number of Records Fetched for a View Object and How to Initialize the Data Model Project With a Database Connection.

- Enabling or disabling Oracle ADF Security

  See Enabling ADF Security and Disabling ADF Security.

- Enabling seeded customizations

  See How to Enable Seeded Customizations for User Interface Projects and How to Enable Seeded Customizations in Existing Pages.

- Configuring change persistence

  See How to Enable User Customizations.

- Enabling user customizations

  See What Happens When You Enable User Customizations.

Example A-5 shows example entries for an application's `adf-config.xml` file.

Example A-5   Sample adf-config.xml File

```
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
            xmlns:sec="http://xmlns.oracle.com/adf/security/config">
  <sec:adf-security-child xmlns="http://xmlns.oracle.com/adf/security/config">
    <CredentialStoreContext credentialStoreClass=

"oracle.adf.share.security.providers.jps.CSFCredentialStore"
                                      credentialStoreLocation="../../src/META-
INF/jps-config.xml"/>

</adf-config>
```

adf-settings.xml

The adf-settings.xml file is used by ADF application developers to extend and customize the ADF lifecycle with custom ADF phase listeners.

The `adf-settings.xml` file holds project-level and library-level settings such as ADF Faces help providers and ADF Controller phase listeners.

The configuration settings for `adf-settings.xml` are fixed and cannot be changed during or after application deployment. There can be multiple `adf-settings.xml` files in an application. The users of `adf-settings.xml` files are responsible for merging the contents of their configuration.

JDeveloper creates an `adf-settings.xml` file when you:

- Create an application using the ADF Fusion Web Application template
- Add ADF Page Flow (ADF Controller) as a feature to an existing project

By default, JDeveloper stores the `adf-settings.xml` file in the following directory:

```
application_root\ViewController\src\META-INF
```

The following tasks modify or require you to modify the `adf-settings.xml` file:

- Registering a phase listener

  See How to Register a Listener Globally.
- Creating help for ADF Faces components

  See Displaying Help for Components in *Developing Web User Interfaces with Oracle ADF Faces*.

For information about how to edit the `adf-settings.xml` file, see How to Configure for ADF Faces in adf-settings.xml in *Developing Web User Interfaces with Oracle ADF Faces*.

Example A-6 shows a sample `adf-setting.xml` file with settings configured for a phase listener and a help provider.

Example A-6 Sample adf-settings.xml File

```
<?xml version="1.0" encoding="windows-1252" ?>
<adf-settings xmlns="http://xmlns.oracle.com/adf/config">
  <adfc-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
    <lifecycle>
      <phase-listener>
        <listener-id>SummitPhaseListener</listener-id>
        <class>oracle.summit.listeners.SummitPhaseListener</class>
      </phase-listener>
    </lifecycle>
  </adfc-controller-config>
  <adf-faces-config>
    <help-provider prefix="MYAPP">
      <help-provider-class>oracle.summit.MyHelpProvider</help-provider-class>
      <property>
        <property-name>myCustomProperty</property-name>
      <value>someValue</value>
    </property>
  </help-provider>
</adf-faces-config>
</adf-settings>
```

web.xml

The web.xml file is used as a deployment descriptor file by Java web applications to determine how URLs map to servlets, which URLs require authentication, and other information. This file is an XML document that defines everything about your ADF application that a server needs to know.

Oracle ADF has specific configuration settings for the standard `web.xml` deployment descriptor file.

When you create a project in JDeveloper that uses JSF technology, a starter `web.xml` file with default settings is created for you in the `/WEB-INF` folder. To edit the file, double-click **web.xml** in the Applications window to open it in the XML editor.

The following must be configured in `web.xml` for all applications that use JSF and ADF Faces:

- ADF Library resource servlet and mapping: Serves up web application resources (images, style sheets, JavaScript libraries) from ADF Library JAR files on the application class path.

  By default, static web application resources (including resources in ADF Libraries), such as images, have a staleness period setting of 364 days. This staleness period setting requests that the client not make a request to the server to validate the static web application resources until one of the following events occur:

  - Staleness period expires
  - Browser cache no longer contains the static resource
  - User executes a page refresh

  If the client does make a request to the server and the resources have not changed, the server returns a HTTP 304 response (Not Modified) with no body.

  You can override the staleness period setting of 364 days for all static web application resources in ADF Libraries by adding initialization parameters to the `web.xml` file. The following example demonstrates how to set these initialization parameters using a number of examples.

  ```
  <!-- Expires all static resources in 30 days -->
   <init-param>
     <param-name>expires</param-name>
     <param-value>60*60*24*30</param-value>
   </init-param>

  <!-- Expires static resources with the .js file extension in 1 day -->
   <init-param>
     <param-name>expires.js</param-name>
     <param-value>60*60*24</param-value>
   </init-param>

  <!-- Turns off staleness setting. Use for testing -->
   <init-param>
     <param-name>expires</param-name>
  ```

```
    <param-value>OFF</param-value>
  </init-param>
```

The following example shows the default file extensions. You can add additional file extensions by configuring the `extensions` parameter value to include the file extensions that you want. Note that you must prepend and append "`.`" to the file extension. The example also shows how you specify visibility for cache control.

```
<!-- Specify file extensions for a number of different file formats -->
  <init-param>
    <param-name>extensions</param-name>
    <param-value>.png.jpg.jpeg.gif.js.css.</param-value>
  </init-param>

<!-- Specify visibility for cache control, for example -->
  <init-param>
    <param-name>visibility</param-name>
    <param-value>Public</param-value>
  </init-param>
```

- JSF servlet and mapping: The servlet `javax.faces.webapp.FacesServlet` that manages the request-processing lifecycle for web applications utilizing JSF to construct the user interface.
- ADF Faces filter and mapping: A servlet filter to ensure that ADF Faces is properly initialized by establishing a `AdfFacesContext` object. This filter also processes file uploads.

The JSF servlet and mapping configuration settings are automatically added to the starter `web.xml` file when you first create a JSF project. When you insert an ADF Faces component into a JSF page for the first time, JDeveloper automatically inserts the configuration settings for ADF Faces filter and mapping, and resource servlet and mapping. See ADF Faces Configuration in *Developing Web User Interfaces with Oracle ADF Faces*.

logging.xml

ADF Logger is integrated in the WebLogic enterprise manager, and gives you the flexibility to adjust your log-levels at runtime. You can configure the logging session by editing the logging.xml file.

ADF Logger is a diagnostic tool that you can use in JDeveloper to capture runtime traces messages when you debug an application. You configure the use of this tool by editing the `logging.xml` file.

For information about the `logging.xml` file and using the ADF Logger, see Using the ADF Logger.

B

Oracle ADF Binding Properties

This appendix describes the properties of the **ADF bindings** that you use can access at runtime in an **Oracle ADF** application.

Table B-1 shows the properties that you can use in EL expressions to access values of the ADF binding objects at runtime. The properties appear in alphabetical order.

Table B-1 EL Properties of Oracle ADF Bindings

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
`actionEnabled`	Use `operationEnabled` instead.	n/a	yes	n/a	n/a	n/a	n/a	n/a
`allRowsInRange`	Returns an array of the current set of rows from the associated collection. Calls `getAllRowsInRange()` on the `RowSetIterator` object.	yes	n/a	n/a	n/a	n/a	n/a	n/a
`attributeDef`	Returns the attribute definition for the first attribute with which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
`attributeDefs`	Returns the attribute definitions for all the attributes to which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
`attributeValue`	Returns an unformatted and typed (appropriate Java type) value in the current row, for the attribute to which the control binding is bound.	n/a	n/a	yes	yes	yes	n/a	n/a
`attributeValues`	Returns the value of all the attributes to which the binding is associated in an ordered array. Returns an array of unformatted and typed (appropriate Java type) values in the current row for all the attributes to which the control binding is bound.	n/a	n/a	yes	yes	yes	n/a	n/a
`bindings`	Returns a new binding for each cell or attribute exposed under the rows of a tree node binding.	no	no	no	no	no	no	yes
`children`	Returns the child nodes of a tree node binding.	n/a	n/a	n/a	n/a	n/a	n/a	yes
`currentRow`	Returns the current row on an action binding bound to an iterator (for example, built-in navigation actions).	n/a	yes	n/a	n/a	n/a	n/a	n/a

Table B-1 (Cont.) EL Properties of Oracle ADF Bindings

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
`dataControl`	Returns the iterator's associated data provider.	yes	n/a	n/a	n/a	n/a	n/a	n/a
`displayData`	Returns a list of map elements. Each map entry contains the following elements: • `selected`: A boolean `true` if the current entry should be selected. • `index`: The index value of the current entry. • `prompt`: A string value that may be used to render the entry in the UI. • `displayValues`: An ordered list of display attribute values for all display attributes in the list binding.	n/a	n/a	n/a	n/a	yes	n/a	n/a
`displayHint`	Returns the display hint for the first attribute to which the binding is associated. The hint identifies whether the attribute should be displayed or not. For more information, see `oracle.jbo.AttributeHints.displayHint`.	n/a	n/a	n/a	n/a	yes	n/a	n/a

Table B-1 (Cont.) EL Properties of Oracle ADF Bindings

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
`displayHints`	Returns a list of name-value pairs for UI hints for all display attributes to which the binding is associated. The map contains the following elements: • `label`: The label to display for the current attribute. • `tooltip`: The tooltip to display for the current attribute. • `displayHint`: The display hint for the current attribute. • `displayHeight`: The height in lines for the current attribute. • `displayWidth`: The width in characters for the current attribute. • `controlType`: The control type hint for the current attribute. • `format`: The format to be used for the current attribute.	n/a	n/a	n/a	yes	yes	n/a	n/a
`enabled`	Use the `operationEnabled` property.	n/a	n/a	n/a	n/a	n/a	n/a	n/a
`enabledString`	Returns `disabled` if the action binding is not ready to be invoked. Otherwise, returns an empty string (`""`).	n/a	yes	n/a	n/a	n/a	n/a	n/a
`error`	Returns any exception that was cached while updating the associated attribute value for a value binding or when invoking an operation bound by an operation binding.	yes	yes	yes	yes	yes	yes	yes
`estimatedRowCount`	Returns the maximum row count of the rows in the collection with which this **iterator binding** is associated	yes	n/a	n/a	n/a	n/a	yes	yes
`findMode`	Returns `true` if the iterator is currently operating in find mode. Otherwise, returns `false`.	yes	n/a	n/a	n/a	n/a	n/a	n/a

Table B-1 (Cont.) EL Properties of Oracle ADF Bindings

Runtime Property	Description	Iterator	Actio n	Attribute	Button	List	Table	Tree
`fullName`	Returns the fully qualified name of the binding object in the Oracle ADF **binding context**.	yes	yes	yes	yes	yes	yes	yes
`hints`	Returns the value of the UI hint indicated for the binding. See `displayHints` for the list of UI hint keywords.	yes	yes	yes	yes	yes	yes	yes
`inputValue`	Returns the value of the first attribute to which the binding is associated. If the binding was used to set the value on the attribute and the set operation failed, this method returns the invalid value that was being set.	n/a	n/a	yes	yes	yes	yes	yes
`iteratorBinding`	Returns the iterator binding that provides access to the data collection.	n/a	yes	yes	yes	yes	yes	yes
`label`	Returns the label (if supplied by control hints) for the first attribute of the binding.	n/a	n/a	yes	yes	yes	n/a	n/a
`labels`	Returns a map of labels (if supplied by control hints) keyed by attribute name for all attributes to which the binding is associated.	n/a	n/a	yes	yes	yes	yes	n/a
`labelSet`	Returns an ordered set of labels for all the attributes to which the binding is associated.	n/a	n/a	yes	yes	yes	yes	n/a
`mandatory`	Returns whether the first attribute to which the binding is associated is required.	n/a	n/a	yes	yes	yes	n/a	n/a
`name`	Returns the name of the binding object in the context of the **binding container** to which it is registered. Note this property is not visible in the EL expression builder dialog.	yes	yes	yes	yes	yes	yes	yes
`operationEnabled`	Returns `true` or `false`, depending on the state of the action binding. For example, the action binding may be enabled (`true`) or disabled (`false`) based on the currency (as determined, for example, when the user clicks the First, Next, Previous, Last navigation buttons).	n/a	yes	n/a	n/a	n/a	n/a	n/a

Table B-1 (Cont.) EL Properties of Oracle ADF Bindings

Runtime Property	Description	Iterator	Action	Attribute	Button	List	Table	Tree
`rangeSet`	Returns a list of map elements over the range of rows from the associated iterator binding. The elements in this list are wrapper objects over the indexed row in the range that restricts access to the attributes to which the binding is bound. The properties returned on the reference object are: • `index`: The range index of the row this reference is pointing to. • `key`: The key of the row this reference is pointing to. • `keyStr`: The string format of the key of the row this reference is pointing to. • `currencyString`: The current indexed row as a string. Returns "*" if the current entry belongs to the current row; otherwise, returns " ". This property is useful in JSP applications to display the current row. • `attributeValues`: The array of applicable attribute values from the row. You may also access an attribute value by name on a range set like `rangeSet.dname` if `dname` is a bound attribute in the range binding.	n/a	n/a	n/a	n/a	n/a	yes	yes
`rangeSize`	Returns the range size of the ADF iterator binding's row set. This allows you to determine the number of data objects to bind from the data source.	yes	n/a	n/a	n/a	n/a	yes	yes
`rangeStart`	Returns the absolute index in a collection of the first row in range. See the javadoc for `oracle.jbo.RowSetIterator.getRangeStart()`.	yes	n/a	n/a	n/a	n/a	yes	yes
`result`	Returns the result of a method that is bound and invoked by a method action binding.	n/a	yes	n/a	n/a	n/a	n/a	n/a

Table B-1 (Cont.) EL Properties of Oracle ADF Bindings

Runtime Property	Description	Iterator	Actio n	Attribute	Button	List	Table	Tree
`rootNodeBinding`	Returns the root node of a tree binding.	n/a	n/a	n/a	n/a	n/a	n/a	yes
`selectedValue`	Returns the value corresponding to the current selected index in the list or button binding.	n/a	n/a	n/a	yes	yes	n/a	n/a
`tooltip`	Returns the tooltip hint for the first attribute to which the binding is associated.	n/a	n/a	yes	yes	yes	n/a	n/a
`updateable`	Returns `true` if the first attribute to which the binding is associated is updateable. Otherwise, returns `false`.	n/a	n/a	yes	yes	yes	n/a	n/a

C

ADF Security Permission Grants

This appendix lists the security-aware components of Oracle ADF and the actions that their Permission implementation classes define.

Table C-1 shows the ADF components and their permission grants that you can define to create ADF security policies. You add grants to the policy store using the overview editor for ADF security policies. A permission grant specifies the fully qualified permission class name, the fully qualified resource name, the action that can be performed against the resource, and the application role target of the grant. When you enable ADF security to enforce authorization checking against the security policies of the policy store, the operations supported by ADF components will be inaccessible to users who do not possess sufficient access rights as defined by grants to their application role.

For complete details about defining ADF security policies in Fusion web applications, see Enabling ADF Security in a Fusion Web Application.

Table C-1 ADF Security Permission Grants

ADF Component	Grantable Action	Corresponding Implementation
ADF bounded task flow	`View`	The `View` action controls who can read and execute a bounded task flow. Pages that the user accesses within the process of executing a bounded task flow will not be individually security checked and will run under the permission of the task flow.
ADF bounded task flow	`Customize`	Reserved for future use. This action is not checked at runtime.
ADF bounded task flow	`Grant`	Reserved for future use. This action is not checked at runtime.
ADF bounded task flow	`Personalize`	Reserved for future use. This action is not checked at runtime.
ADF page definition	`View`	The `View` action controls who can view the page. Page-level security is checked for pages that have an associated page definition binding file *only* if the page is accessed in the process of an unbounded task flow. There is a one-to-one relationship between the **page definition file** and the web page it secures.
ADF Business Components entity objects	`read`	The `read` action controls who can view a row of the bound collection.
ADF Business Components entity objects	`update`	The `update` action controls who can update any attribute of the bound collection.
ADF Business Components entity objects	`delete`	The `delete` action controls who can delete a row from the bound collection. This action corresponds to the entity object `removeCurrentRow` operation.
ADF Business Components attributes of entity objects	`update`	The `update` action controls who can update a specific attribute of the bound collection.

D

Most Commonly Used ADF Business Components Methods

This appendix lists the most commonly used methods in the interfaces and classes of the ADF Business Components layer of Oracle ADF.
This appendix contains the following sections:

- Methods for Creating Your Own Layer of Framework Base Classes
- Methods Used in the Client Tier
- Methods Used in the Business Service Tier

Methods for Creating Your Own Layer of Framework Base Classes

You can create custom framework classes that extend ADF's base Business Components classes and that your own business components definitions use or extend. This is true for application modules as well.

Before you begin to develop application-specific business components, you can create a layer of classes that extend all of the **ADF Business Components** framework base implementation classes described in this appendix. An example of a customized framework base class for **application module** components might look like this:

```
package com.yourcompany.adfextensions;
import oracle.jbo.server.ApplicationModuleImpl;
public class CustomApplicationModuleImpl extends ApplicationModuleImpl {
  /*
   * We might not yet have any custom code to put here yet, but
   * the first time we need to add a generic feature that all of
   * our company's application modules need, we will be very happy
   * that we thought ahead to leave ourselves a convenient place
   * in our class hierarchy to add it so that all of the application
   * modules we have created will instantly benefit by that new feature,
   * behavior change, or even perhaps, bug workaround.
   */
}
```

A common set of customized framework base classes in a package name of your own choosing like `com.yourcompany.adfextensions`, each importing the `oracle.jbo.server.*` package, would consist of the following classes:

- `public class CustomEntityImpl extends EntityImpl`
- `public class CustomEntityDefImpl extends EntityDefImpl`
- `public class CustomViewObjectImpl extends ViewObjectImpl`
- `public class CustomViewRowImpl extends ViewRowImpl`
- `public class CustomApplicationModuleImpl extends ApplicationModuleImpl`

- `public class CustomDBTransactionImpl extends DBTransactionImpl2`
- `public class CustomDatabaseTransactionFactory extends DatabaseTransactionFactory`

For completeness, you may also want to create customized framework classes for the following classes as well:

- `public class CustomViewDefImpl extends ViewDefImpl`
- `public class CustomEntityCache extends EntityCache`
- `public class CustomApplicationModuleDefImpl extends ApplicationModuleDefImpl`

Overriding anything in these classes would be a fairly rare requirement.

Methods Used in the Client Tier

The client tier contains code that runs on the client and with which an ADF user interacts. There are several interface methods in the client tier for the key ADF Business Components.

All of the interfaces described in this section are designed so that you may expose method for use in the client tier. These interface methods part of the `oracle.jbo.*` package.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components interfaces.

> **Note:**
>
> The corresponding implementation classes for these `oracle.jbo.*` interfaces are intentionally designed to *not* be directly accessed by client code. Methods Used in the Business Service Tier shows that the implementation classes reside in the `oracle.jbo.server.*` package and generally have the suffix `Impl` in their name to help remind you not to use them in your client-layer code.

ApplicationModule Interface

An application module is a business service component that acts as a transactional container for other ADF components and coordinates *with* them to implement a number of Java EE design patterns important to business application developers. These design pattern implementations enable your client code to work easily with updatable collections of value objects, based on fast-lane reader SQL queries that retrieve only the data needed by the client, in the way the client wants to view it. Changes made to these value objects are automatically coordinated with your persistent business domain objects in the business service tier to enforce business rules consistently and save changes back to the database. Table D-1 describes the operations that you can perform on an application module using the `ApplicationModule` interface.

Note:

For the complete list of design patterns that ADF Business Components implements, see ADF Business Components Java EE Design Pattern Catalog.

Table D-1 ApplicationModule Interface

If you want to...	Call this ApplicationModule interface method
Access an existing **view object instance** using the assigned instance name (for example, `MyVOInstanceName`)	`findViewObject()`
Create a new view object instance from an existing definition	`createViewObject()`
Create a new view object instance from a SQL Statement	`createViewObjectFromQueryStmt()` **Notes:** This incurs runtime overhead to describe the "shape" of the dynamic query's `SELECT` list. Use this method only when you cannot know the `SELECT` list for the query at design time. Furthermore, if you are creating the dynamic query based on some kind of custom runtime repository, you can follow the steps to create (both read-only and updatable) dynamic view objects without the runtime-describe overhead, as described in Creating a View Object with Multiple Updatable Entities. If only the `WHERE` needs to be dynamic, create the view object at design time, then set the `WHERE` clause dynamically as needed using `ViewObject` APIs.
Access a nested **application module instance** by name	`findApplicationModule()`
Create a new nested application module instance from an existing definition	`createApplicationModule()`
Find a view object instance in a nested application module using a dot-notated name (for example, `MyNestedAMInstanceName.OneOfItsVONames`)	`findViewObject()` **Notes:** You can use this method to find an instance of a view object belonging to a nested application module in a single method call. This way you do not need to first call `findApplicationModule()` to find the nested application module, before calling `findViewObject()` on that nested application module.
Access the current transaction object	`getTransaction()`

In addition to generic application module access, JDeveloper can generate a custom *`YourApplicationModuleName`* interface containing service-level custom methods that you've chosen to expose to the client. You use the **Client Interface** page of the Edit

Application Module dialog to select the methods that you want to appear in your client interface.

Transaction Interface

The `Transaction` interface exposes methods allowing the client to manage pending changes in the current transaction. Table D-2 describes the operations that you can perform on the transaction using the `Transaction` interface.

Table D-2 Transaction Interface

If you want to...	Call this Transaction interface method
Commit pending changes	`commit()`
Roll back pending changes	`rollback()`
Execute a one-time database command or block of PL/SQL	`executeCommand()` **Notes:** Do not use this command with methods that require retrieving `OUT` parameters and that will be executed more than once, or that could benefit from using bind variables. Instead, expose a custom method on your application module.
Validate all pending invalid changes in the transaction	`validate()`
Change the default locking mode	`setLockingMode()` **Notes:** You can set the locking mode in your configuration by setting the property `jbo.locking.mode` to one of the four supported values: `none`, `optimistic`, `pessimistic`, `optupdate`. If you don't explicitly set the locking mode, it will default to `optimistic`. For Fusion web applications, use `optimistic` or `optupdate` modes.
Decide whether to use bundled exception reporting mode or not	`setBundledExceptionMode()` **Notes:** The **ADF Controller** layer support sets this parameter to `true` automatically for Fusion web applications.
Decide whether entity caches will be cleared upon a successful commit of the transaction	`setClearCacheOnCommit()` **Notes:** Default is `false`.
Decide whether entity caches will be cleared upon a rollback of the transaction	`setClearCacheOnRollback()` **Notes:** Default is `true`.
Clear the entity cache for a specific **entity object**	`clearEntityCache()`

ViewObject Interface

A view object is a component that encapsulates a database query and simplifies working with the row set of results it produces. You use view objects to project, filter, join, or sort business data using SQL from one or more tables to cast the data into exactly the format that the user should see on the page or panel. You can create "master-detail" hierarchies of any depth or complexity by connecting view objects together using view links. View objects can produce read-only query results, or when associated with one or more entity objects at design time, can be fully updatable. Updatable view objects can support insertion, modification, and deletion of rows in the result collection, with automatic delegation to the correct business domain objects.

Every view object contains a "default row set" for simplifying the 90 percent of use cases where you work with a single row set of results for the view object's query. A view object implements all the methods on the `RowSet` interface by delegating them to this default `RowSet`. That means you can invoke any `RowSet` methods on any view object as well.

Every view object implements the `StructureDef` interface to provide information about the number and types of attributes in a row of its row sets. So you can call `StructureDef` methods directly on any view object.

Table D-3 describes the operations that you can perform on a view object using the `ViewObject` interface

Table D-3 ViewObject Interface

If you want to...	Call this ViewObject interface method
Set an additional runtime `WHERE` clause on the row set	`setWhereClause()` **Notes:** This `WHERE` clause augments any `WHERE` clause specified at design time in the base view object. It does not replace it.
Set a dynamic `ORDER BY` clause	`setSortBy()`
Create a Query-by-Example criteria collection	`createViewCriteria()` **Notes:** You then create one or more `ViewCriteriaRow` objects using the `createViewCriteriaRow()` method on the `ViewCriteria` object you created. Then you `add()` these **view criteria** rows to the view criteria collection and apply the criteria using the `applyViewCriteria()` method.
Apply a Query-by-Example criteria collection	`applyViewCriteria()`
Set a query optimizer hint	`setQueryOptimizerHint()`
Access the attribute definitions for the key attributes in the view object	`getKeyAttributeDefs()`
Add a dynamic attribute to rows in this view object's row sets	`addDynamicAttribute()`
Clear all row sets produced by a view object	`clearCache()`

Table D-3 (Cont.) ViewObject Interface

If you want to...	Call this ViewObject interface method
Remove a view object instance and its resources	`remove()`
Set an upper limit on the number of rows that the view object will attempt to fetch from the database	`setMaxFetchSize()` **Notes:** Default is -1, which means to impose no limit on how many rows would be retrieved from the database if you iterated through them all. By default, as you iterate through them, they are fetched lazily.

In addition to generic `ViewObject` access, JDeveloper can generate you a custom *`YourViewObjectName`* interface containing view object-level custom methods that you've chosen to expose to the client. You use the **Client Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

RowSet Interface

A row set is an object that contains a set of rows, typically produced by executing a view object's query.

Every `RowSet` aggregates a "default **row set iterator**" for simplifying the 90 percent of use cases where you need only a single iterator over the row set. A `RowSet` object implements all the methods on the `RowSetIterator` interface by delegating them to this default `RowSetIterator`. This means you can invoke any `RowSetIterator` method on any `RowSet` object (or view object, since it implements `RowSet`, as well for its default `RowSet`).

Table D-4 describes the operations that you can perform on a row set using the `RowSet` interface.

Table D-4 RowSet Interface

If you want to...	Call this RowSet interface method
Set a `WHERE` clause bind variable value	`setWhereClauseParams()` **Notes:** Bind variable ordinal positions are zero-based.
Avoid view object row caching if data is being read only once	`setForwardOnly()`

Table D-4 (Cont.) RowSet Interface

If you want to...	Call this RowSet interface method
Force a row set's query to be (re)executed (in the case of exclusive view object instances) or potentially executed (in the case of shared view object instances)	`executeQuery()` **Notes:** The behavior of this method differs depending on whether the view object belongs to a **shared application module** or not. When reexecuting the query for an exclusive view object (not an instance of a shared module), a new query collection is created. Before executing the query for a shared view object instance, a check is performed to determine whether the results already exist. Already cached results will be reused for the shared view object instance instead of reexecuting the query. If you want to ensure that the results for a shared view object instance are refreshed, you can invoke the `forceExecuteQueryOfSharedVO()` method. However, if at the time of invoking force execute a user is iterating over the collection of a shared view object instance, then the behavior is undefined and exceptions may result.
Estimate the number of rows in a view object's query result	`getEstimatedRowCount()`
Produce an XML document for rows in a view object row set	`writeXML()`
Process all rows from an incoming XML document	`readXML()`
Set whether a row set will automatically see new rows based on the same entity object created through other row sets	`setAssociationConsistent()`
Create a secondary iterator to use for programmatic iteration	`createRowSetIterator()` **Notes:** If you plan to find and use the secondary iterator by name later, then pass in a string name as the argument; otherwise, pass `null` for the name and make sure to close the iterator when done iterating by calling its `closeRowSetIterator()` method.

RowSetIterator Interface

A row set iterator is an iterator over the rows in a row set. By default it allows you to iterate both forward and backward through the rows. Table D-5 describes the operations that you can perform on a row set using the `RowSetIterator` interface.

Table D-5 RowSetIterator Interface

If you want to...	Call this RowSetIterator interface method
Get the first row of the iterator's row set	`first()`
Test whether there are more rows to iterate	`hasNext()`
Get the next row of an iterator's row set	`next()`
Find a row in this iterator's row set with a given key value	`findByKey()` **Notes:** It's important that the `Key` object that you pass to `findByKey` be created using the *exact* same data types as the attributes that comprise the key of the rows in the view object you're working with.
Create a new row to populate for insertion	`createRow()` **Notes:** The new row will already have default values set for attributes which either have a static default value supplied at the entity object or view object level, or if the values have been populated in an overridden `create()` method of the underlying entity object(s).
Create a view row with an initial set of foreign key and/or discriminator attribute values	`createAndInitRow()` **Notes:** You use this method when working with view objects that can return one of a "family" of entity object subtypes. By passing in the correct discriminator attribute value in the call to create the row, the framework can create you the correct matching entity object subtype underneath.
Insert a new row into the iterator's row set	`insertRow()` **Notes:** It's a good habit to always immediately insert a newly created row into the rowset. That way you will avoid a common gotcha of creating the row but forgetting to insert it into the rowset.
Get the last row of the iterator's row set	`last()`
Get the previous row of the iterator's row set	`previous()`
Reset the current row pointer to the slot before the first row	`reset()`
Close an iterator when done iterating	`closeRowSetIterator()`
Set a given row to be the current row	`setCurrentRow()`
Remove the current row	`removeCurrentRow()`
Remove the current row to later insert it at a different location in the same iterator	`removeCurrentRowAndRetain()`
Remove the current row from the current collection but do not remove it from the transaction.	`removeCurrentRowFromCollection()`

Table D-5 (Cont.) RowSetIterator Interface

If you want to...	Call this RowSetIterator interface method
Set/change the number of rows in the range (a "page" of rows the user can see)	`setRangeSize()`
Scroll to view the *n*th page of rows (1-based)	`scrollToRangePage()`
Scroll to view the range of rows starting with row number *n*	`scrollRangeTo()`
Set row number *n* in the range to be the current row	`setCurrentRowAtRangeIndex()`
Get all rows in the range as a row array	`getAllRowsInRange()`

Row Interface

A row is generic value object. It contains attributes appropriate in name and Java type for the view object that it is related to. Table D-6 describes the operations that you can perform on a view object row using the `Row` interface.

Table D-6 Row Interface

If you want to...	Call this Row interface method
Get the value of an attribute by name	`getAttribute()`
Set the value of an attribute by name	`setAttribute()`
Produce an XML document for a single row	`writeXML()`
Eagerly validate a row	`validate()`
Read row attribute values from XML	`readXML()`
Remove the row	`remove()`
Flag a newly created row as temporary (until updated again)	`setNewRowState(Row.STATUS_INITIALIZED)`
Retrieve the attribute structure definition information for a row	`getStructureDef()`
Get the `Key` object for a row	`getKey()`

In addition to generic `Row` access, JDeveloper can generate a custom *`YourViewObjectName`*`Row` interface containing your type-safe attribute getter and setter methods, as well as any desired row-level custom methods that you've chosen to expose to the client. You use the **Client Row Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

StructureDef Interface

The `StructureDef` interface provides access to runtime metadata about the structure of a `Row` object.

In addition, for convenience every view object implements the `StructureDef` interface as well, providing access to metadata about the attributes in the resulting view rows that its query will produce.

Table D-7 describes the operations that you can perform on a view object row using the `StructureDef` interface.

Table D-7 StructureDef Interface

If you want to...	Call this StructureDef interface method
Access attribute definitions for all attributes in the view object row	`getAttributeDefs()`
Find an attribute definition by name	`findAttributeDef()`
Get attribute definition by index	`getAttributeDef()`
Get number of attributes in a row	`getAttributeCount()`

AttributeDef Interface

The `AttributeDef` interface provides attribute definition information for any attribute of a view object row or entity object instance like attribute name, Java type, and SQL type. It also provides access to custom attribute-specific metadata properties that can be inspected by generic code you write, as well as UI hints that can assist in rendering an appropriate user interface display for the attribute and its value. Table D-8 describes the operations that you can perform on an attribute using the `AttributeDef` interface.

Table D-8 AttributeDef Interface

If you want to...	Call this AttributeDef interface method
Get the Java type of the attribute	`getJavaType()`
Get the SQL type of the attribute	`getSQLType()` **Notes:** The `int` value corresponds to constants in the JDBC class `java.sql.Types`.
Determine the kind of attribute	`getAttributeKind()` **Notes:** A simple attribute is one that returns one of the constants `ATTR_PERSISTENT`, `ATTR_SQL_DERIVED`, `ATTR_TRANSIENT`, `ATTR_DYNAMIC`, `ATTR_ENTITY_DERIVED`. If the attribute is a 1-to-1 or many-to-1 association/viewlink accessor, it returns `ATTR_ASSOCIATED_ROW`. If the attribute is a 1-to-many or many-to-many association/viewlink accessor, it returns `ATTR_ASSOCIATED_ROWITERATOR`
Get the Java type of elements contained in an `Array`-valued attribute	`getElemJavaType()`
Get the SQL type of elements contained in an `Array`-valued attribute	`getElemSQLType()`
Get the name of the attribute	`getName()`
Get the index position of the attribute	`getIndex()`

Table D-8 (Cont.) AttributeDef Interface

If you want to...	Call this AttributeDef interface method
Get the precision of a numeric attribute or the maximum length of a string attribute	`getPrecision()`
Get the scale of a numeric attribute	`getScale()`
Get the underlying column name corresponding to the attribute	`getColumnNameForQuery()`
Get attribute-specific custom property values	`getProperty()`, `getProperties()`
Get the UI `AttributeHints` object for the attribute	`getUIHelper()`
Test whether the attribute is mandatory	`isMandatory()`
Test whether the attribute is queriable	`isQueriable()`
Test whether the attribute is part of the primary key for the row	`isPrimaryKey()`

AttributeHints Interface

The `AttributeHints` interface exposes UI hint information that you can use to render an appropriate user interface display for the attribute and its value. Table D-9 describes the operations that you can perform on an attribute using the `AttributeHints` interface.

Table D-9 AttributeHints Interface

If you want to...	Call this AttributeHints interface method
Get the UI label for the attribute	`getLabel()`
Get the tooltip for the attribute	`getTooltip()`
Get the formatted value of the attribute, using any format mask supplied	`getFormattedAttribute()`
Get the display hint for the attribute	`getDisplayHint()` **Notes:** The display hint will have a string value of either `Display` or `Hide`.
Get the preferred control type for the attribute	`getControlType()`
Parse a formatted string value using any format mask supplied for the attribute	`parseFormattedAttribute()`

Methods Used in the Business Service Tier

The Business Service tier contains the business logic. There are several methods in the business service tier for the key ADF Business Components.

The implementation classes corresponding to the `oracle.jbo.*` interfaces, as described in Methods Used in the Client Tier, are intentionally designed to *not* be directly accessed by client code. They reside in a different package named oracle.jbo.server.* and have the Impl suffix in their name to help remind you not to use them in your client-layer code.

In your business service tier implementation code, you can use any of the same methods that are available to clients, but in addition you can also:

- Safely cast any oracle.jbo.* interface to its oracle.jbo.server.* package implementation class and use any methods on that Impl class as well.
- Override any of the public or protected methods for the base framework implementation classes and write custom code in your component subclass before or after calling super.*methodName*() to augment or change the default functionality.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components classes.

Controlling Custom Java Files for Your Components

Before examining the specifics of individual classes, it's important to understand how you can control which custom Java files each of your components will use. When you don't need a customized subclass for a given component, you can just let the base framework class handle the implementation at runtime.

Each business component you create comprises a single XML component descriptor, and zero or more related custom Java implementation files. Each component that supports Java customization has a Java page in its component overview editor in the JDeveloper IDE. By selecting or deselecting the different Java classes, you control which ones will be created for your component. If none of the classes is specified, then your component will be an XML-only component, which simply uses the base framework class as its Java implementation. Otherwise, tick the checkbox of the related Java classes for the current component that you need to customize. JDeveloper will create a custom *subclass* of the framework base class in which you can add your code.

Note:

You can set up global IDE preferences for the Java classes to be generated by default for each ADF business component type by choosing **Tools** > **Preferences** > **Business Components** and ticking the checkboxes to indicate what you want your defaults to be.

A best practice is to *always* generate entity object and view row classes, even if you don't require any custom code in them other than the automatically generated getter and setter methods. These getter and setter methods offer you compile-time type checking that prevents errors surfacing at runtime in response to an attribute having been set to an incorrect kind of value.

ApplicationModuleImpl Class

The ApplicationModuleImpl class is the base class for application module components. Since the application module is the ADF component used to implement a business service, think of the application module class as the place where you can write your service-level application logic. The application module coordinates with view object instances to support updatable collections of value objects that are automatically "wired" to business domain objects. The business domain objects are implemented as ADF entity objects.

Methods You Typically Call on ApplicationModuleImpl

Table D-10 describes the operations that you can perform on an application module using the `ApplicationModuleImpl` class.

Table D-10 Methods You Typically Call on ApplicationModuleImpl

If you want to...	Call this method of the ApplicationModuleImpl class
Perform any of the common application module operations from inside your class, which can also be done from the client	For a list of these methods, see ApplicationModule Interface.
Access a view object instance that you added to the application module's data model at design time	`get`*`ViewObjectInstanceName`*`()` **Notes:** JDeveloper generates this type-safe view object instance getter method for you to reflect each view object instance in the application module's design time data model.
Access the current `DBTransaction` object	`getDBTransaction()`
Access a nested application module instance that you added to the application module at design time	`get`*`AppModuleInstanceName`*`()` **Notes:** JDeveloper generates this type-safe application module instance getter method for you to reflect each nested application module instance added to the current application module at design time.

Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass

Table D-11 describes the operations that you can perform on an application module using your custom `ApplicationModuleImpl` class.

Table D-11 Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass

If you want to...	Write a method like this in your custom ApplicationModuleImpl class
Invoke a database stored procedure	*`someCustomMethod`*`()` **Notes:** Use the appropriate method on the `DBTransaction` interface to create a JDBC `PreparedStatement`. If the stored procedure has `OUT` parameters, then create a `CallableStatement` instead. For sample code that demonstrates encapsulating a call to a PL/SQL stored procedure inside your application module, see Invoking Stored Procedures and Functions.
Expose custom business service methods on your application module	*`someCustomMethod()`* **Notes:** Select the method name on the **Client Interface** page of the Edit Application Module dialog to expose it for client access if required.

JDeveloper can generate a custom *`YourApplicationModuleName`* interface containing service-level custom methods that you've chosen to expose to the client. You can use the **Client Interface** page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.

Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

Table D-12 describes the operations that you can override on an application module using your custom `ApplicationModuleImpl` class.

Table D-12 Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

If you want to...	Override this method in your custom ApplicationModuleImpl class
Perform custom setup code the first time an application module is created and each subsequent time it gets used by a different client session.	`prepareSession()` **Notes:** This is the method you'd use to set up per-client context info for the current user in order to use Oracle's Virtual Private Database (VPD) features. It can also be used to set other kinds of PL/SQL package global variables, whose values might be client-specific, on which other stored procedures might rely. This method is also useful to perform setup code that is specific to a given view object *instance* in the application module. If instead of the view object setup code being instance-specific, you want it to be initialized for every instance ever created of that view object component, then put the setup logic in an overridden `create()` method in your `ViewObjectImpl` subclass instead.
Perform custom setup code after the application module's transaction is associated with a database connection from the connection pool.	`afterConnect()` **Notes:** Can be a useful place to write a line of code that uses `getDBTransaction().executeCommand()` to perform an `ALTER SESSION SET SQL TRACE TRUE` to enable database SQL trace logging for the current application connection. These logs can then be processed with the TKPROF utility to study the SQL statements being performed and the query optimizer plans that are getting used. For details about working with the `TKPROF` utility, see section "Understanding SQL Trace and TKPROF" in the "Performing Application Tracing" chapter of the *Oracle Database SQL Tuning Guide*.

Table D-12 (Cont.) Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

If you want to...	Override this method in your custom ApplicationModuleImpl class
Perform custom setup code before the application module's transaction releases its database connection back to the database connection pool.	`beforeDisconnect()` **Notes:** If you have set `jbo.doconnectionpooling` to `true`, then the connection is released to the database connection pool each time the application module is returned to the **application module pool**. In order to clear custom database state when the Application Module returns to the Application Module pool, applications should override the `beforeDisconnect()`method. The method `resetState()` is not recommended for this purpose since Application Modules may participate in transaction sharing. Cleaning up database state in `resetState()` from one Application Module while others are still referencing the same DB Transaction can lead to issues.
Write custom application module state to the state management XML snapshot.	`passivateState()`
Read and restore custom application module state from the state management XML snapshot.	`activateState()`

DBTransactionImpl2 Class

The `DBTransactionImpl2` class — which extends the base `DBTransactionImpl` class, and is constructed by the `DatabaseTransactionFactory` class — is the base class that implements the `DBTransaction` interface, representing the unit of pending work in the current transaction.

Methods You Typically Call on DBTransaction

Table D-13 describes the operations that you can perform on a transaction using the `DBTransaction` class.

Table D-13 Methods You Typically Call on DBTransaction

If you want to...	Call this method on the DBTransaction class
Commit the transaction	`commit()`
Roll back the transaction	`rollback()`
Eagerly validate any pending invalid changes in the transaction	`validate()`

Table D-13 (Cont.) Methods You Typically Call on DBTransaction

If you want to...	Call this method on the DBTransaction class
Create a JDBC `PreparedStatement` using the transaction's `Connection` object	`createPreparedStatement()`
Create a JDBC `CallableStatement` using the transaction's `Connection` object	`createCallableStatement()`
Create a JDBC `Statement` using the transaction's `Connection` object	`createStatement()`
Add a warning to the transaction's warning list	`addWarning()`

Methods You Typically Override in Your Custom DBTransactionImpl2 Subclass

Table D-14 describes the operations that you can perform on a transaction using your custom `DBTransactionImpl2` subclass.

Table D-14 Methods You Typically Override in Your Custom DBTransactionImpl2 Subclass

If you want to...	Override this method in your custom DBTransactionImpl2 class
Perform custom code before or after the transaction commit operation	`commit()`
Perform custom code before or after the transaction rollback operation	`rollback()`

In order for your custom `DBTransactionImpl2` subclass to be used at runtime, there are you must follow these steps:

1. Create a custom subclass of `DatabaseTransactionFactory` that overrides the create method to return an instance of your custom `DBTransactionImpl2` subclass like this:

```
package com.yourcompany.adfextensions;
import oracle.jbo.server.DBTransactionImpl2;
import oracle.jbo.server.DatabaseTransactionFactory;
import com.yourcompany.adfextensions.CustomDBTransactionImpl;
public class CustomDatabaseTransactionFactory
       extends DatabaseTransactionFactory {
  /**
   * Return an instance of our custom CustomDBTransactionImpl class
   * instead of the default implementation.
   *
   * @return An instance of our custom DBTransactionImpl2 implementation.
   */
  public DBTransactionImpl2 create() {
    return new CustomDBTransactionImpl();
  }
}
```

2. Tell the framework to use your custom transaction factory class by setting the value of the `TransactionFactory` configuration property to the fully qualified class

name of your custom transaction factory. As with other configuration properties, if not supplied in the configuration XML file, it can be provided alternatively as a Java system parameter of the same name.

EntityImpl Class

The `EntityImpl` class is the base class for entity objects, which encapsulate the data, validation rules, and business behavior for your business domain objects.

Methods You Typically Call on EntityImpl

Table D-15 describes the operations that you can perform on an entity object using the `EntityImpl` class.

Table D-15 Methods You Typically Call on EntityImpl

If you want to...	Call this method in the EntityImpl class
Get the value of an attribute	`get`*`AttributeName`*`()` **Notes:** This code-generated getter method calls `getAttributeInternal()`, but provides compile-time type checking.
Set the value of an attribute	`set`*`AttributeName`*`()` **Notes:** This code-generated setter method calls `setAttributeInternal()`, but provides compile-time type checking.
Get the value of an attribute by name	`getAttributeInternal()`
Set the value of an attribute by name	`setAttributeInternal()`
Eagerly perform entity object validation	`validate()`
Refresh the entity from the database	`refresh()`
Populate the value of an attribute without *marking* it as being changed, but sending *notification* of its being changed so that the UI refreshes the value on the screen/page	`populateAttributeAsChanged()`
Access the `Definition` object for an entity	`getDefinitionObject()`
Get the `Key` object for an entity	`getKey()`
Determine the state of the entity instance, irrespective of whether it has already been posted (but not yet committed) in the current transaction	`getEntityState()` **Notes:** This method will return one of the constants `STATUS_UNMODIFIED`, `STATUS_INITIALIZED`, `STATUS_NEW`, `STATUS_MODIFIED`, `STATUS_DELETED`, or `STATUS_DEAD`, indicating the status of the entity instance in the current transaction.

Table D-15 (Cont.) Methods You Typically Call on EntityImpl

If you want to...	Call this method in the EntityImpl class
Determine the state of the entity instance	`getPostState()` **Notes:** This method is typically relevant only if you are programmatically using the `postChanges()` method to post but not yet commit, entity changes to the database and need to detect the state of an entity with regard to its posting state.
Get the value originally read from the database for a given attribute	`getPostedAttribute()`
Get the metadata for a view object or entity object	`getStructureDef()` **Notes:** Downcasting the return value of `EntityImpl.getStructureDef()` method invocation to `EntityCache` is not supported. To obtain the instance of `EntityCache` invoke an existing `getEntityCache()`method on the `EntityImpl` object.
Eagerly lock the database row for an entity instance	`lock()`
Copy the values from `masterRow` that are relevant for the entity object to a newly created row.	`masterRow.findOrCreateAssociationAccessorRS(accessorName)` **Note:** This API returns a `RowSet` and follow the familiar pattern of `createRow` and `insertRow`.

Methods You Typically Write in Your Custom EntityImpl Subclass

Table D-16 describes the operations that you can perform on an entity object using your custom `EntityImpl` subclass.

Table D-16 Methods You Typically Write in Your Custom EntityImpl Subclass

If you want to...	Write a method like this in your custom EntityImpl subclass
Perform attribute-specific validation	`public boolean validate`*`Something`*`(`*`AttrType`*`value)` **Notes:** Register the attribute validator method by adding a MethodValidator rule on the correct attribute in the **Validation** page of the Edit Entity Object dialog.
Perform entity-level validation	`public boolean validate`*`Something`*`()` **Notes:** Register the entity-level validator method by adding a MethodValidator rule on the entity in the **Validation** panel of the Edit Entity Object dialog.
Calculate the value of a transient attribute	Add your calculation code to the generated `get`*`AttributeName`*`()` method.

Methods You Typically Override in Your Custom EntityImpl Subclass

Table D-17 describes the operations that you can override on an entity object using your custom `EntityImpl` subclass.

Table D-17 Methods You Typically Override in Your Custom EntityImpl Subclass

If you want to...	Override this method in your EntityImpl subclass
Set calculated default attribute values, including programmatically populating the primary key attribute value of a new entity instance	`create()` **Notes:** After calling `super.create()`, call the appropriate `set`*`AttrName`*`()` method(s) to set the default values for the attributes.
Modify attribute values before changes are posted to the database	`prepareForDML()`
Augment or change the standard `INSERT`, `UPDATE`, or `DELETE` DML operation that the framework will perform on your entity object's behalf to the database	`doDML()` **Notes:** This method checks the value of the operation flag to the constants `DML_INSERT`, `DML_UPDATE`, or `DML_DELETE` to test what DML operation is being performed.
Perform complex, SQL-based validation after all entity instances have been posted to the database but before those changes are committed	`beforeCommit()` **Notes:** This method is invoked for each entity row in the transaction.

Table D-17   (Cont.) Methods You Typically Override in Your Custom EntityImpl Subclass

If you want to...	Override this method in your EntityImpl subclass
Perform custom processing after all entity instances have been committed to the database	`afterCommit()` **Notes:** This method is invoked for each entity row in the transaction list of pending changes.
Insure that a related, newly created, parent entity gets posted to the database *before* the current child entity on which it depends	`postChanges()` **Notes:** If the parent entity is related to this child entity via a composition association, then the framework already handles posting the changes automatically. If they are only associated (but not composed), then you need to override `postChanges()` to force a newly created parent entity to post before the current, dependent child entity. For an example of the code you typically write in your overridden `postChanges()` method to accomplish this, see Overriding postChanges() to Control Post Order.
Programmatically define default attribute values or to perform custom initialization before a modified row is refreshed back to its initialization state or after the row is first created	`initDefaultExpressionAttributes()` **Notes:** This method is invoked just before the end of the initialization cycle, which makes it suitable for executing custom code.

Note:

It is possible to write attribute-level validation code directly inside the appropriate `set`*`AttributeName`* method of your `EntityImpl` class; however, adopting the `MethodValidator` approach suggested in Table D-16 conveniently places all the validations in effect on the **Validation Rules** page of the overview editor for the attributes of the entity object.

> **WARNING:**
>
> It is also possible to override the `validateEntity()` method to write entity-level validation code; however, if you want to maintain the benefits of the ADF bundled exception mode — where the framework collects and reports a *maximal* set of validation errors back to the client user interface — use the `MethodValidator` approach suggested in Table D-16. This allows the framework to automatically collect all of your exceptions that your validation methods throw without your having to understand the bundled exception implementation mechanism. Overriding the `validateEntity()` method directly shifts the responsibility onto your *own* code to correctly catch and bundle the exceptions that **Oracle ADF** would have caught by default, which is nontrivial and a chore to remember and hand-code each time.

EntityDefImpl Class

The `EntityDefImpl` class is a singleton, shared metadata object for all entity objects of a given type in a single Java VM. For instance, if the Java VM contains two instances of the `EntityDefImpl` class, one with the customers XML data and one with the orders, there would only ever be one instance of each. This class defines the structure of the entity instances and provides methods to create new entity instances and find existing instances by their primary key.

Methods You Typically Call on EntityDefImpl

Table D-18 describes the operations that you can perform on an entity object using the `EntityDefImpl` class.

Table D-18 Methods You Typically Call on EntityDefImpl

If you want to...	Call this method in the EntityDefImpl class
Find an entity object of a given type by its primary key	`findByPrimaryKey()` **Notes:** For a tip about getting `findByPrimaryKey()` to find entity instances of subtype entities as well, see Subtype Entity Objects and the findByPrimaryKey() Method.
Access the current `DBTransaction` object	`getDBTransaction()`
Find any `EntityDefImpl` object by its fully qualified name	`findDefObject()` (static method)
Retrieve the value of an entity object's custom property	`getProperty()`, `getProperties()`
Set the value of an entity object's custom property	`setProperty()`

Table D-18 (Cont.) Methods You Typically Call on EntityDefImpl

If you want to...	Call this method in the EntityDefImpl class
Create a new instance of an entity object	`createInstance2()` **Notes:** Alternatively, you can expose custom `create`*`XXX`*`()` methods with your own expected signatures in that same custom `EntityDefImpl` subclass. See Methods You Typically Write in Your Custom EntityDefImpl Class for details.
Iterate over the entity instances in the cache of this entity type	`getAllEntityInstancesIterator()`
Access an array list of entity definition objects for entities that extend the current one.	`getExtendedDefObjects()`

Methods You Typically Write in Your Custom EntityDefImpl Class

Table D-19 describes the operations that you can perform on an entity object using your custom `EntityDefImpl` class.

Table D-19 Methods You Typically Write on EntityDefImpl

If you want to...	Write a method like this in your custom EntityDefImpl class
Allow other classes to create an entity instance with an initial type-safe set of attribute values or setup information	`create`*`XXX`*`(`*`Type1arg1`*`,...,` *`TypeNargN`*`)` **Notes:** Internally, using this method would create and populate an instance of a `NameValuePairs` object (which implements `AttributeList`) and call the protected method `createInstance()`, passing that `NameValuePairs` object. Make sure that the method is `public` if other classes need to be able to call it.

Methods You Typically Override in Your Custom EntityDefImpl

Table D-20 describes the operations that you can perform on an entity object using the `EntityDefImpl` class.

Table D-20 Methods You Typically Override on EntityDefImpl

If you want to...	Override this method in your custom EntityDefImpl class
Perform custom metadata initialization when this singleton metaobject is loaded	`createDef()`

Table D-20 (Cont.) Methods You Typically Override on EntityDefImpl

If you want to...	Override this method in your custom EntityDefImpl class
Avoid using the `RETURNING INTO` clause to support refresh-on-insert or refresh-on-update attributes	`isUseReturningClause()` **Notes:** Set this method to return `false` to disable the use of `RETURNING INTO`, necessary sometimes when your entity object is based on a view with `INSTEAD OF` triggers that don't support `RETURNING INTO` at the database level.
Control whether the `UPDATE` statements issued for this entity update only changed columns or for all columns	`isUpdateChangedColumns()` **Notes:** Defaults to `true`.
Find any `EntityDefImpl` object by its fully qualified name	`findDefObject()` **Notes:** Static method.
Set the value of an entity object's custom property	`setProperty()`
Allow other classes to create a new instance of an entity object without doing so implicitly via a view object	`createInstance()` **Notes:** If you don't write a custom create method as noted in Methods You Typically Write in Your Custom EntityDefImpl Class, you'll need to override this method and widen the visibility from `protected` to `public` to allow other classes to construct an entity instance.

ViewObjectImpl Class

The `ViewObjectImpl` class is the base class for view objects.

Methods You Typically Call on ViewObjectImpl

Table D-21 describes the operations that you can perform on a view object using the `ViewObjectImpl` class.

Table D-21 Methods You Typically Call on ViewObjectImpl

If you want to...	Call this method in the ViewObjectImpl class
Perform any of the common view object, row set, or row set iterator operations from inside your class, which can also be done from the client	For more information about operations at the view object, row set, or row set iterator level , see ViewObject Interface, RowSet Interface, and RowSetIterator Interface.
Search a view instance's in-memory row set without changing the default row set	`findByViewCriteria()`

Table D-21 (Cont.) Methods You Typically Call on ViewObjectImpl

If you want to...	Call this method in the ViewObjectImpl class
Fetch *all* the rows from the database and then determine the total row count in the view object row set	`getRowCount()` **Notes:** Use this method carefully: Performance may be affected when a large number of rows is involved.
Determine the total number of rows in view object row set after *each* invocation by the client	`getQueryHitCount()`
Determine the total number of rows in the view object row set	`getEstimatedRowCount()` **Notes:** This is the preferred way to find row count since it requires only one database query (after the count is obtained, it will be maintained as rows are added and removed).
Execute a count query but with a cap argument to manage execution in the case where a large number of rows may affect performance	`getCappedQueryHitCount()`
Define a named bind parameter	`defineNamedWhereClauseParam()`
Remove a named bind parameter	`removeNamedWhereClauseParam()`
Set bind variable values on the default row set by name	`setNamedWhereClauseParam()` **Notes:** Only works when you have formally defined named bind variables on your view object.
Set bind variable values on the default row set	`setWhereClauseParams()` **Notes:** Use this method for view objects with binding style of "Oracle Positional" or "JDBC Positional" when you have not formally defined named bind variables.
Retrieve a subset of rows in a view object's row set based on evaluating an in-memory filter expression	`getFilteredRows()`
Retrieve a subset of rows in the current range of a view object's row set based on evaluating an in-memory filter expression	`getFilteredRowsInRange()`
Override the runtime display of criteria items that appear inside an ADF query component. Subclasses may override to return custom `AttributeHints` implementation for the given criteria item. Returns null by default.	`getCriteriaItemAttributeHints()`

Table D-21 (Cont.) Methods You Typically Call on ViewObjectImpl

If you want to...	Call this method in the ViewObjectImpl class
Set the number of rows that will be fetched from the database per roundtrip for this view object	`setFetchSize()` **Notes:** The default fetch size is a single row at a time. This is definitely not optimal if your view object intends to retrieve many rows, so you should either set the fetch size higher at design time on the **Tuning** page of the Edit View Object dialog, or set it at runtime using this method.
Force a row set's query to be (re)executed specifically on a lookup view object instance in a shared application module	`forceExecuteQueryOfSharedVO()` **Notes:** Reexecuting the query forces a new query collection and will prevent the application module cache from being used. You should only use this method when you are sure that you are accessing the shared application module during setup and not during runtime. This method when used during normal runtime may have unintended side-effects that disrupt the navigation of users accessing the collection concurrently. If you want to refresh the collection from the cache without creating a new query collection, call `executeQuery()` instead.

Methods You Typically Write in Your Custom ViewObjectImpl Subclass

Table D-22 describes the operations that you can perform on a view object using your custom `ViewObjectImpl` subclass.

Table D-22 Methods You Typically Write in Your Custom ViewObjectImpl Subclass

If you want to...	Write a method like this in your custom ViewObjectImpl subclass
Provide clients with type-safe methods to set bind variable values without exposing positional details of the bind variables themselves	`*someMethodName*(*Type1arg1*,...,*TypeNargN*)` **Notes:** Internally, this method would call the `setWhereClauseParams()` method to set the correct bind variables with the values provided in the type-safe method arguments.

JDeveloper can generate a custom *`YourViewObjectName`* interface containing view object custom methods that you've chosen to expose to the client. You can use the **Client Interface** page of the Edit View Object to select the methods that you want to appear in your client interface.

Methods You Typically Override in Your Custom ViewObjectImpl Subclass

Table D-23 describes the operations that you can perform on a view object using your custom `ViewObjectImpl` subclass.

Table D-23 Methods You Typically Override in Your Custom ViewObjectImpl Subclass

If you want to...	Override this method in your custom ViewObjectImpl subclass
Initialize custom view object class members (not row attributes) when the view object instance is created for the first time	`create()` **Notes:** This method is useful to perform set up logic that is applicable to every instance of a view object that will ever get created, in the context of any application module. If instead of *generic* view object setup logic, you need to perform logic specific to a given view object *instance* in an application module, then override the `prepareSession()` method of your application module's `ApplicationModuleImpl` subclass and perform the logic there after calling `findViewObject()` to find the view object instance whose properties you want to set.
Write custom view object instance state to the state management XML snapshot	`passivateState()`
Read and restore custom view object instance state from the state management XML snapshot	`activateState()`

Table D-23 (Cont.) Methods You Typically Override in Your Custom ViewObjectImpl Subclass

If you want to...	Override this method in your custom ViewObjectImpl subclass
Customize the execution of the view object query to utilize an alternative data source	`executeQueryForCollection()` **Notes:** By default view objects read their data from the database and automate the task of working with the JDBC layer to process the database result sets. However, by overriding appropriate methods in its custom Java class, you can create a view object that programmatically retrieves data from alterative data sources, as described in Using Programmatic View Objects for Alternative Data Sources. It is not correct to override `executeQueryForCollection()` to make changes to `WHERE` clauses and parameters. By the time the method is called, ADF Business Components assumes that the parameters are already calculated and that row filters are constructed. If you change the query before it gets executed each time, ADF Business Components could never reuse an existing cached statement handle. Instead, when you want to specify bind parameters before the query is executed, you can override `prepareRowSetForQuery()` on `ViewObjectImpl` since it provides access to the row set that is being executed.
Customize the programmatic view object to utilize an alternative data source and determine whether the query collection has more rows to fetch from the query execution	`hasNextForCollection()`
Customize the programmatic view object to utilize an alternative data source and log bind parameter names and values used in the query	`bindParametersForCollection()`
Customize the programmatic view object to utilize an alternative data source and populate each row of the retrieved data	`createRowFromResultSet()`
Customize the programmatic view object to utilize an alternative data source and return a count of the number of rows that will be retrieved	`getQueryHitCount()`
Customize the programmatic view object to utilize an alternative data source and to determine whether the query would return more rows than the capped value specified by a global row fetch limit.	`getCappedQueryHitCount()`

Table D-23 (Cont.) Methods You Typically Override in Your Custom ViewObjectImpl Subclass

If you want to...	Override this method in your custom ViewObjectImpl subclass
Customize the programmatic view object to access the row set that is being executed and change the view object WHERE clause and specify bind parameter values before the query is executed. This is the recommended hook point for overriding query and setting bind parameters. This method is invoked by the framework every time a row set is about to be executed.	`prepareRowSetForQuery()`
Customize the programmatic view object to utilize an alternative data source and release any resources that may be associated with a row set that is being closed	`releaseUserDataForCollection()`
Change or augment the way that the `ViewCriteria` collection of `ViewCriteriaRows` is converted into a Query-by-Example `WHERE` clause	`getViewCriteriaClause(boolean)`
Customize the programmatic view object to implement range paging.	`buildRangePagingQuery()`
Customize the programmatic view object to implement range paging and pass in parameters to control the range start and size for the current range of rows to fetch from a data source.	`bindRangePagingParams()`

ViewRowImpl Class

The `ViewRowImpl` class is the base class for view row objects.

Methods You Typically Call on ViewRowImpl

Table D-24 describes the operations that you can perform on a view object row using your custom `ViewRowImpl` class.

Table D-24 Methods You Typically Call on ViewRowImpl

If you want to...	Call this method in your custom ViewRowImpl class
Perform any of the common view row operations from inside your class, which can also be done from the client	For more information about the row-level operations, see Row Interface.
Get the value of an attribute	get*AttrName*()
Set the value of an attribute	set*AttrName*()

Table D-24 (Cont.) Methods You Typically Call on ViewRowImpl

If you want to...	Call this method in your custom ViewRowImpl class
Access the underlying entity instance to which this view row is delegating attribute storage	`getEntityUsageAliasName()` **Notes:** You can change the name of the entity usage alias name on the **Entity Objects** page of the Edit View Object dialog.
Copy the values from `masterRow` that are relevant for the view link to a newly created row.	`masterRow.findOrCreateViewLinkAccessorRS(accessorName)` **Note:** This API returns a `RowSet` and follow the familiar pattern of `createRow` and `insertRow`.

Methods You Typically Write in Your Custom ViewRowImpl Class

Table D-25 describes the operations that you can perform on a view object row using your custom `ViewRowImpl` class.

Table D-25 Methods You Typically Write on ViewRowImpl

If you want to...	Write a method like this in your custom ViewRowImpl class
Calculate the value of a view object-level transient attribute	`getAttrName()` **Notes:** JDeveloper generates the skeleton of the method for you, but you need to write the custom calculation logic inside the method body.
Perform custom processing of the setting of a view row attribute	`setAttrName()` **Notes:** JDeveloper generates the skeleton of the method for you, but you need to write the custom logic inside the method body if required.
Determine the updateability of an attribute in a conditional way	`isAttributeUpdateable()`

Table D-25   (Cont.) Methods You Typically Write on ViewRowImpl

If you want to...	Write a method like this in your custom ViewRowImpl class
Expose logical operations on the current row, optionally callable by clients	`doSomething()` **Notes:** Often these view-row-level custom methods simply turn around and delegate to a method call on the underlying entity object related to the current row.

JDeveloper can generate a custom *`YourViewObjectName`*`Row` interface containing view row custom methods that you've chosen to expose to the client. You can use the **Client Row Interface** page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

Methods You Typically Override in Your Custom ViewRowImpl Subclass

Table D-26 describes the operations that you can perform on a view object row using your custom `ViewRowImpl` subclass.

Table D-26   Methods You Typically Override in Your Custom ViewRowImpl Subclass

If you want to...	Write a method like this in your ViewRowImpl subclass
Determine the updateability of an attribute in a conditional way	`isAttributeUpdateable()`

E

ADF Business Components Java EE Design Pattern Catalog

This appendix summarizes the Java Platform, Enterprise Edition (Java EE) design patterns that **ADF Business Components** implements for you.
By using the Oracle Application Development Framework's business components building-blocks and related design time extensions to JDeveloper, you get a prescriptive architecture for building richly functional and cleanly layered Java EE business services with great performance.

Table E-1 provides a brief overview of the numerous design patterns that the ADF Business Components layer implements for you. Some are the familiar patterns from Sun's Java EE BluePrints and some are design patterns that ADF Business Components adds to the list. For details about Java EE BluePrints, see the BluePrints page at the Oracle Technology Network website at `http://www.oracle.com/technetwork/java/index-jsp-136701.html`.

Table E-1 Java EE Design Patterns Implemented by ADF Business Components

Pattern Name and Description	How ADF Business Components Implements It
Model/View/Controller Cleanly separates the roles of data and presentation, allowing multiple types of client displays to work with the same business information.	The ADF **application module** provides a generic implementation of a Model/View/Controller "application object" that simplifies exposing the application data model for any application or service, and facilitates declaratively specifying the boundaries of a logical unit of work. Additional UI-centric frameworks and tag libraries provided in JDeveloper help you implement the view and controller layers.
Interface / Implementation Separation Cleanly separates the API or Interface for components from their implementation class.	ADF Business Components enforces a logical separation of client-tier accessible functionality (via interfaces) and its business tier implementation. JDeveloper handles the creation of custom interfaces and client proxy classes automatically.
Service Locator Abstracts the technical details of locating a service so that the client can use it more easily.	ADF application modules are looked up using a simple configuration object which hides the low-level details of finding the service instance behind the scenes. For Fusion web applications, it also hides the implementation of the **application module pool** usage, a lightweight pool of service components that improves application scalability.

Table E-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components

Pattern Name and Description	How ADF Business Components Implements It
Inversion of Control A containing component orchestrates the lifecycle of the components it contains, invoking specific methods that you can override at the appropriate times, so as to be able to focus more on what the code should do, instead of when it should be executed.	ADF components contain a number of easy-to-override methods that the framework invokes as needed during the course of application processing.
Dependency Injection Simplifies application code, and increases configuration flexibility by deferring component configuration and assembly to the container.	ADF Business Components configures all its components from externalized XML metadata definition files. At runtime, the framework automatically injects dependent objects like **view object instances** into your application module service component and entity objects into your view rows, implementing lazy loading. It supports runtime factory substitution of components by any customized subclass of that component to simplify onsite application customization scenarios. Much of the ADF Business Components functionality is implemented via dynamic injection of validator and listener subscriptions that coordinate the framework interactions depending on what declarative features have been configured for each component in their XML metadata.
Active Record Avoids the complexity of "anything to anything" object/relational mapping, by providing an object that wraps a row in a database table or view, encapsulates the database access, and adds domain logic on that data.	ADF entity objects handle the database mapping functionality you use most frequently, including inheritance, association, and composition support, so you don't have to focus on object/relational mapping. They also provide a place to encapsulate both declarative business rules and one-off programmatic business domain.
Data Access Objects Prevents unnecessary marshalling overhead by implementing dependent objects as lightweight, persistent classes instead of each as an individual enterprise bean. Isolates persistence details into a single, easy-to-maintain class.	ADF view objects automate the implementation of data access for reading data using SQL statements. ADF entity objects automate persistent storage of lightweight business entities. ADF view objects and entity objects cooperate to provide a sophisticated, performant data access objects layer, where any data queried through a view object can optionally be made fully updatable without requiring that you write any "application plumbing" code.
Session Facade Prevents inefficient client access of entity beans and inadvertent exposure of sensitive business information by wrapping entity beans with a session bean.	ADF application modules are designed to implement a coarse-grained "service facade" architecture in any of their supported deployment modes. When deployed as a service interface, they provide an implementation of the Session Facade pattern automatically.

Table E-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components

Pattern Name and Description	How ADF Business Components Implements It
Value Object Prevents unnecessary network roundtrips by creating one-off "transport" objects to group a set of related attributes needed by a client program.	ADF Business Components provides an implementation of a generic `Row` object, which is a metadata-driven container of any number and kind of attributes that need to be accessed by a client. The developer can work with the generic `Row` interface and do late-bound `getAttribute("Price")` and `setAttribute("Quantity")`calls, or optionally generate early-bound row interfaces like `OverdueOrdersRow`, to enable type-safe method calls like `getPrice()` and `setQuantity()`. Smarter than just a simple "bag 'o attributes", the ADF `Row` object can be introspected at runtime to describe the number, names, and types of the attributes in the row, enabling sophisticated, generic solutions to be implemented.
Page-by-Page Iterator Prevents sending unnecessary data to the client by breaking a large collection into page-sized "chunks" for display.	ADF Business Components provides an implementation of a generic `RowSet` interface which manages result sets produced by executing view object SQL queries. The `RowSet` interface allows you to set a desired page size, for example 10 rows, and page up and down through the query results in these page-sized chunks. Since data is retrieved lazily, only data the user actually visits will ever be retrieved from the database on the backend, and in the client tier the number of rows in the page can be returned over the network in a single roundtrip.
Fast-Lane Reader Prevents unnecessary overhead for read-only data by accessing JDBC APIs directly. This allows an application to retrieve only the attributes that need to be displayed, instead of finding all of the attributes by primary key when only a few are required by the client. Typically, implementations of this pattern sacrifice data consistency for performance, since queries performed at the raw JDBC level do not "see" pending changes made to business information represented by enterprise beans.	ADF view objects read data directly from the database for best performance; however, they give you a choice regarding data consistency. If updateability and/or consistency with pending changes is desired, you need only associate your view object with the appropriate entity objects whose business data is being presented. If consistency is not a concern, view objects can simply perform the query with no additional overhead. In either case, you never have to write JDBC data access code. You need only provide appropriate SQL statements in XML descriptors.
(Bean) Factory Allows runtime instantiation and configuration of an appropriate subclass of a given interface or superclass based on externally configurable information.	All ADF component instantiation is done based on XML configuration metadata through factory classes allowing runtime substitution of specialized components to facilitate application customization.

Table E-1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components

Pattern Name and Description	How ADF Business Components Implements It
Entity Facade Provides a restricted view of data and behavior of one or more business entities.	ADF view objects can surface any set of attributes and methods from any combination of one or more underlying entity objects to furnish the client with a single, logical value object to work with.
Value Messenger Keeps client value object attributes in sync with the middle-tier business entity information that they represent in a bidirectional fashion.	The ADF Business Components value object implementation coordinates with a client-side value object cache to batch attribute changes to the EJB tier and receive batch attribute updates which occur as a result of middle-tier business logic. The ADF Value Messenger implementation is designed to not require any kind of asynchronous messaging to achieve this effect.
Continuations Gives you the simplicity and productivity of a stateful programming model with the scalability of a stateless web solution.	ADF Business Components application module pooling and state management functionality combine to deliver this value-add. Application module pooling eliminates the need to dedicate application server tier resources to individual users and supports a "stateless with user affinity" optimization that you can tune.

F

ADF Equivalents of Common Oracle Forms Triggers

This appendix provides a summary of how basic tasks performed with the most common Oracle Forms triggers are accomplished using Oracle ADF.

This appendix includes the following sections:

- Validation and Defaulting (Business Logic)
- Query Processing
- Database Connection
- Transaction "Post" Processing (Record Cache)
- Error Handling

Validation and Defaulting (Business Logic)

You will learn how Oracle Forms Validation and Defaulting Triggers are performed using Oracle ADF equivalents.

Table F-1 ADF Equivalents for Oracle Forms Validation and Defaulting Triggers

Forms Trigger	ADF Equivalent
`WHEN-VALIDATE-RECORD` Execute validation code at the record level	In the custom `EntityImpl` class for your entity object, write a public method returning a `boolean` type with a method name like `validate`*`XXXX`*`()` and have it return `true` if the validation succeeds or `false` if the validation fails. Then, add a Method validator for this validation method to your entity object at the entity level. When doing that, you can associate a validation failure message with the rule.
`WHEN-VALIDATE-ITEM` Execute validation code at the field level	In the custom `EntityImpl` class for your entity object, write a public method returning a `boolean` type and accepting a single argument of the same data type as your attribute, having a method name like `validate`*`XXXX`*`()`. Have it return `true` if the validation succeeds or `false` if the validation fails. Then, add a Method validator for this validation method to the entity object at the attribute level for the appropriate attribute. When doing that, you can associate a validation failure message with the rule.
`WHEN-DATABASE-RECORD` Execute code when a row in the data block is marked for insert or update	Override the `addToTransactionManager()` method of your entity object. Write code after calling the super.

Table F-1 (Cont.) ADF Equivalents for Oracle Forms Validation and Defaulting Triggers

Forms Trigger	ADF Equivalent
`WHEN-CREATE-RECORD` Execute code to populate complex default values when a new record in the data block is created, without changing the modification status of the record	Override the `create()` method of your entity object and after calling the super, use appropriate `set`*`AttrName`*`()` methods to set default values for attributes as necessary. To immediately set a primary key attribute to the value of a sequence, construct an instance of the `SequenceImpl` helper class and call its `getSequenceNumber()` method to get the next sequence number. Assign this value to your primary key attribute. If you want to wait to assign the sequence number until the new record is saved, but still without using a database trigger, you can use this technique in an overridden `prepareForDML()` method in your entity object. If instead you want to assign the primary key from a sequence using your own `BEFOREINSERTFOREACHROW` database trigger, then use the special data type called `DBSequence` for your primary key attribute instead of the regular `Number` type.
`WHEN-REMOVE-RECORD` Execute code whenever a row is removed from the data block	Override the `remove()` method of your entity object and write code either before or after calling the super.

Query Processing

You will learn how Oracle Forms Query Processing Triggers are performed using Oracle ADF equivalents.

Table F-2 ADF Equivalents for Oracle Forms Query Processing Triggers

Forms Trigger	ADF Equivalent
`PRE-QUERY` Execute logic before executing a query in a data block, typically to set up values for Query-by-Example criteria in the "example record"	Override the `executeQueryForCollection()` method on your **view object** class and write code before calling the super.
`ON-COUNT` Override default behavior to count the query hits for a data block	Override the `getQueryHitCount()` method in your view object and do something instead of calling the super.

Table F-2 (Cont.) ADF Equivalents for Oracle Forms Query Processing Triggers

Forms Trigger	ADF Equivalent
`POST-QUERY` Execute logic after retrieving each row from the data source for a data block.	Generally instead of using a `POST-QUERY` style technique to fetch descriptions from other tables based on foreign key values in the current row, in ADF it's more efficient to build a view object that has multiple participating entity objects, joining in all the information you need in the query from the main table, as well as any auxiliary or lookup-value tables. This way, in a single roundtrip to the database you get all the information you need. If you still need a per-fetched-row trigger like `POST-QUERY`, override the `createInstanceFromResultSet()` method in your view object class.
`ON-LOCK` Override default behavior to attempt to acquire a lock on the current row in the data block	Override the `lock()` method in your entity object class and do something instead of calling the super.

Database Connection

You will learn how Oracle Forms Database Connection Triggers are performed using Oracle ADF equivalents.

Table F-3 ADF Equivalents for Oracle Forms Database Connection Triggers

Forms Trigger	ADF Equivalent
`POST-LOGON` Execute logic after logging into the database	Override the `afterConnect()` method on your custom application module. Since an **application module instance** can stay connected while serving different logical client sessions, you can override the `prepareSession()` method, which is fired after initial login, as well as after any time the application module is accessed by a user that was different from the one that accessed it last time.
`PRE-LOGOUT` Execute logic before logging out of the database	Override the `beforeDisconnect()` method on your custom application module class.

Transaction "Post" Processing (Record Cache)

You will learn how Oracle Forms Transactional Processing Triggers are performed using Oracle ADF equivalents.

Table F-4 ADF Equivalents for Oracle Forms Transactional Triggers

Forms Trigger	ADF Equivalent
`PRE-COMMIT` Execute code before commencing processing of the changed rows in all data blocks in the transaction	Override the `commit()` method in a custom `DBTransactionImpl` class and write code before calling the super. **Note:** For an overview of creating and using a custom `DBTransaction` implementation, see Creating a Custom Database Transaction Framework Extension Class.
`PRE-INSERT` Execute code before a new row in the data block is inserted into the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_INSERT`, then write code *before* calling the super.
`ON-INSERT` Override default processing for inserting a new row into the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_INSERT`, then write code *instead of* calling the super.
`POST-INSERT` Execute code after new row in the data block is inserted into the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_INSERT`, then write code *after* calling the super.
`PRE-DELETE` Execute code before a row removed from the data block is deleted from the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_DELETE`, then write code *before* calling the super.
`ON-DELETE` Override default processing for deleting a row removed from the data block from the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_DELETE`, then write code *instead of* calling the super.
`POST-DELETE` Execute code after a row removed from the data block is deleted from the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_DELETE`, then write code *after* calling the super.
`PRE-UPDATE` Execute code before a row changed in the data block is updated in the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_UPDATE`, then write code *before* calling the super.
`ON-UPDATE` Override default processing for updating a row changed in the data block from the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_UPDATE`, then write code *instead of* calling the super.
`POST-UPDATE` Execute code after a row changed in the data block is updated in the database during "post" processing	Override the `doDML()` method in your entity class, and if the `operation` equals `DML_UPDATE`, then write code *after* calling the super.

Table F-4 (Cont.) ADF Equivalents for Oracle Forms Transactional Triggers

Forms Trigger	ADF Equivalent
`POST-FORMS-COMMIT` Execute code after Forms has "posted" all necessary rows to the database, but before issuing the data commit to end the transaction	If you want a single block of code for the whole transaction, you can override the `doCommit()` method in a custom `DBTransactionImpl` object and write code before calling the super. To execute entity-specific code before commit for each affected entity in the transaction, override the `beforeCommit()` method on your entity object, and write code there.
`POST-DATABASE-COMMIT` Execute code after database transaction has been committed	Override the `commit()` method in a custom `DBTransactionImpl` class, and write code *after* calling the super.

Error Handling

You will learn how Oracle Forms Error Handling Triggers are performed using Oracle ADF equivalents.

Table F-5 ADF Equivalents for Oracle Forms Error Handling Triggers

Forms Trigger	ADF Equivalent
`ON-ERROR` Override default behavior for handling an error	Install a custom error handler (`DCErrorHandler`) on the ADF `BindingContext`.

G

Performing Common Oracle Forms Tasks in Oracle ADF

This appendix describes how common Oracle Forms tasks are implemented in Oracle ADF. In Oracle Forms, you do some tasks in the data block, and others in the UI. For this reason, the appendix is divided into two sections: tasks that relate to data, and tasks that relate to the UI.
This appendix includes the following sections:

Concepts Familiar to Oracle Forms Developers

ADF Business Components provide components that implement functionality similar to what you are used to in the Java world, with responsibilities divided along the cleanly-separated functional lines.

ADF Business Components implements all of the data-centric aspects of Oracle Forms runtime functionality, but in a way that is independent of the user interface. Responsibilities between the querying and entity-related functions are cleanly separated, resulting in better reuse, as described in Table G-1.

Table G-1 Concepts for Oracle Forms Developers

This concept	Maps to Oracle ADF	With these similarities
Headless Form Module	Application Module	The **application module** component is the "data portion" of the form. The application module is a smart data service containing a data model of master-detail-related queries that your client interface needs to work with. It also provides a transaction and database connection used by the components it contains. It can contain form-level procedures and functions, referred to as service methods, that are encapsulated within the service implementation. You can decide which of these procedures and functions should be private and which ones should be public.
Forms Record Manager	Entity Object	The entity object component implements the "validation and database changes" portion of the data block functionality. In the Forms runtime, this duty is performed by the record manager. The record manager is responsible for keeping track of which of the rows in the data block have changed, for firing the block-level and item-level validation triggers when appropriate, and for coordinating the saving of changes to the database. This is exactly what an entity object does for you. The entity object is a component that represents your business domain entity through an underlying database table. The entity object gives you a single place to encapsulate business logic related to validation, defaulting, and database modification behavior for that business object.

Table G-1 (Cont.) Concepts for Oracle Forms Developers

This concept	Maps to Oracle ADF	With these similarities
Data Block	View Object	The **view object** component performs the "data retrieval" portion of the data block functionality. Each view object encapsulates a SQL query, and at runtime each one manages its own query result set. If you connect two or more view objects in a **master-detail relationship**, that coordination is handled automatically. While defining a view object, you can link any of its query columns to underlying entity objects. By capturing this information, the view object and entity object can cooperate automatically for you at runtime to enforce your domain business logic, regardless of the "shape" of the business data required by the user's task.

Performing Tasks Related to Data

In Oracle Forms, you perform some tasks in the data block, and others in the UI. You will learn how tasks that are particularly related to data are performed.

In Oracle Forms, tasks that relate solely to data are performed in the data block. In **Oracle ADF**, these tasks are done on the business components that persist data (entity objects) and on the objects that query data (view objects).

How to Retrieve Lookup Display Values for Foreign Keys

In Oracle Forms, an editable table often has foreign key lookup columns to other tables. The user-friendly display values corresponding to the foreign key column values exist in related tables. You often need to present these related display values to the user.

In Oracle Forms, this was a complicated task that required adding nondatabase items to the data block, adding a block-level `POST-QUERY` trigger to the data block, and writing a SQL select statement for each foreign key attribute. Additionally, if the user changed the data, you needed to sync the foreign key values with an item-level `WHEN-VALIDATE-ITEM` trigger. This process is much easier in Oracle ADF.

Implementation of the task in Oracle ADF

1. Create a view object that includes the following:
   - The main, editable entity object as the primary entity usage
   - Secondary "reference" entity usages for the one or more associated entities whose underlying tables contain the display text

   For more information, see How to Create Joins for Entity-Based View Objects.
2. Select the desired attributes (at least the display text) from the secondary entity usages as described in How to Select Additional Attributes from Reference Entity Usages.

   At runtime, the data for the main entity and all related lookup display fields is retrieved from the database in a single join.

   If the user can change the data, no additional steps are required. If the user changes the value of a foreign key attribute, the reference information is automatically retrieved for the new, related row in the associated table.

How to Get the Sysdate from the Database

In Oracle Forms, when you wanted to get the current date and time, you retrieved the `sysdate` from the database. In Oracle ADF, you also have the option of getting the system date using a Java method or a Groovy expression.

Implementation of the task in Oracle ADF

To get the system date from the database, you can use the following Groovy expression at the entity level:

```
DBTransaction.currentDbTime
```

Note:

The `DBTransaction` reference is for entity-level Groovy expressions only.

If you want to assign a default value to an attribute using this Groovy expression, see How to Define a Default Value Using an Expression.

To get the system date from Java, you call the `getCurrentDate()` method. For more information, see Accessing the Current Date and Time.

How to Implement an Isolation Mode That Is Not Read Consistent

In Oracle Forms, you might have been concerned with *read consistency*, that is, the ability of the database to deliver the state of the data at the time the SQL statement was issued.

Implementation of the task in Oracle ADF

If you use an entity-based view object, the query sees the changes currently in progress by the current user's session in the pending transaction. This is the default behavior, and the most accurate.

If instead, you want a snapshot of the data on the database without considering the pending changes made by the current user, you can use a read-only view object and reexecute the query to see the latest committed database values. For more information on read-only view objects, see How to Create a Custom SQL Mode View Object.

How to Implement Calculated Fields

Calculated fields are often used to show the sum of two values, but they could also be used for the concatenated value of two or more fields, or the result of a method call.

Implementation of the task in Oracle ADF

Calculated attributes are usually not stored in the database, as their values can easily be obtained programmatically. Attributes that are used in the middle tier, but that are not stored in the database are called *transient attributes*. Transient attributes can be defined at the entity object level or the view object level.

If a transient attribute will be used by more than one view object that might be based on an entity object, then define the attribute at the entity object level. Otherwise, define the transient attribute at the view object level for a particular view object.

To define transient attributes at the entity object level, see Adding Transient and Calculated Attributes to an Entity Object. To define transient attributes at the view object level, see Adding Calculated and Transient Attributes to a View Object.

How to Implement Mirrored Items

In Oracle Forms, you may be used to using mirrored items to show two or more fields that share identical values.

Implementation of the task in Oracle ADF

There is no need to have mirrored items in Oracle ADF, because the UI and data are separated. The same view object can appear on any number of pages, so you don't need to create mirrored items that have the same value. Likewise, a form could have the same field represented in more than one place and it would not have to be mirrored.

How to Use Database Columns of Type CLOB or BLOB

If you are used to working with standard database types, you may be wondering how to use the `CLOB` and `BLOB` types in Oracle ADF.

Implementation of the task in Oracle ADF

In Oracle ADF, use the built-in data types `ClobDomain` or `BlobDomain`. These are automatically created when you reverse-engineer entity objects or view objects from existing tables with these column types. For more information, see How to Set Database and Java Data Types for an Entity Object Attribute.

Performing Tasks Related to the User Interface

In Oracle Forms, you perform some tasks in the data block, and others in the UI. You will learn how tasks particularly related to the UI are performed.

In Oracle ADF, common UI-related tasks (such as master-detail screens, popup list of values, and page layout) are handled quite differently than they were in Oracle Forms.

How to Lay Out a Page

Oracle Forms is based on an absolute pixel or point-based layout, as compared to the container-based approach of JSF.

Implementation of the task in Oracle ADF

See *Developing Web User Interfaces with Oracle ADF Faces* for information on how to lay out a page in Oracle ADF.

How to Stack Canvases

In Oracle Forms, stacked canvases were often used to hide and display areas of the screen.

Implementation of the task in Oracle ADF

The analog of stacked canvases in Oracle ADF is panels (layout containers) with the rendered property set to `true` or `false`. See *Developing Web User Interfaces with Oracle ADF Faces* for more information.

How to Implement a Master-Detail Screen

Master-detail relationships in Oracle ADF are coordinated through a view link. A view link is conceptually similar to an Oracle Forms *relation*.

Implementation of the task in Oracle ADF

For information on how create view links, see Working with Multiple Tables in a Master-Detail Hierarchy. Once you have established a relationship between two view objects with a view link, see How to Enable Active Master-Detail Coordination in the Data Model.

How to Implement an Enter Query Screen

In Oracle Forms, another common task was creating an *enter query screen*. That is, a screen that starts in Find mode.

Implementation of the task in Oracle ADF

In Oracle ADF, this accomplished with a search form. Complete information on how to create a search form is covered in Creating ADF Databound Search Forms. In particular, you may want to look at How to Set Search Form Properties on the View Criteria.

How to Implement an Updatable Multi-Record Table

In Oracle Forms, you may be used to creating tables where you can edit and insert many records at the same time. This can be slightly more complicated when using a JSF page in Oracle ADF, because the operations to edit an existing record and to create a new record are not the same.

Implementation of the task in Oracle ADF

In Oracle ADF, this is done using an input table. To create an input table, see Creating an Input Table.

How to Create a Popup List of Values

In Oracle Forms, it was simple to create a **list of values (LOV)** object and then associate that object with a field in a declarative manner. This LOV would display a popup window and provide the following capabilities:

- Selection of modal values
- Query area at the top of the LOV dialog
- Display of multiple columns
- Automatic reduction of LOV contents, possibly based on the contents of the field that launched the LOV

- Automatic selection of the list value when only one value matches the value in the field when the LOV function is invoked
- Validation of the field value based on the values cached by the LOV
- Automatic popup of the LOV if the field contents are not valid

Implementation of the task in Oracle ADF

To implement a popup list in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Input Text with List of Values** as the style for its UI hint. For a description of how to do this, see Working with List of Values (LOV) in View Object Attributes.

How to Implement a Dropdown List as a List of Values

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement an LOV (lookup-value) screen with a search item, usable for a lookup field with many possible values.

Implementation of the task in Oracle ADF

To implement a dropdown list in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Input Text with List of Values** as the style for its UI hint. For a description of how to do this, see Working with List of Values (LOV) in View Object Attributes.

How to Implement a Dropdown List with Values from Another Table

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement a dropdown list with string values from a different table. These string values populate the field with an id code that is valid input in the table that the screen is based on.

Implementation of the task in Oracle ADF

To implement a dropdown list of this type in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select **Choice List** as the style for its UI hint. For a description of how to do this, see Working with List of Values (LOV) in View Object Attributes.

How to Implement Immediate Locking

In Oracle ADF, you can lock a record in the database at the first moment it is obvious that the user is going to change a specific record.

Implementation of the task in Oracle ADF

Immediate row locking can be configured in ADF Business Components, although it is not the default and is typically not used in web application scenarios. For web applications, use the default configuration setting `jbo.locking.mode=optimistic`. For more information, see How to Confirm That Fusion Web Applications Use Optimistic Locking.

How to Throw an Error When a Record Is Locked

When a record has been locked by a user, it's helpful to throw an error to let other users know that the record is not currently updatable.

Implementation of the task in Oracle ADF

Locking rows and throwing an exception if the row is already locked is built-in ADF Business Components functionality. There are a couple of different ways that you can handle the error message, depending on whether you want a static error message or a custom message with information about the current row.

- To throw a static message, register a custom message bundle in your data model project to substitute the default `RowAlreadyLockedException`'s error message with something more meaningful or user-friendly.
- To throw a message that contains information about the row, override the `lock()` method on the entity object, using a try/catch block to catch the `RowAlreadyLocked` exception. After you catch the exception, you can throw an error message that might contain more specific information about the current row.

H

Deploying ADF Applications to GlassFish

This appendix describes how to deploy Oracle ADF applications to a GlassFish application server. It describes how to create deployment profiles, how to create deployment descriptors, and how to deploy the application.
This appendix includes the following sections:

- About Deploying ADF Applications to GlassFish Server
- Running an ADF Application in Integrated WebLogic Server
- Preparing the Application
- Deploying the Application
- Testing the Application and Verifying Deployment

About Deploying ADF Applications to GlassFish Server

In order to run an ADF application, it must be first deployed on an application server such as GlassFish Server. Deployment in the context of web applications is the act of installing the application on a server that allows requests to be handled and so on.

Deployment is the process of packaging application files as an archive file and transferring that file to a target GlassFish application server. You can use JDeveloper to deploy ADF applications directly to the GlassFish Server, or indirectly to an archive file as the deployment target, and then install this archive file to the target GlassFish Server. For application development, you can also use JDeveloper to run an application in Integrated WebLogic Server.

You can use JDeveloper to:

- Run applications in Integrated WebLogic Server

  You can run and debug applications using Integrated WebLogic Server and then deploy to standalone GlassFish Server.
- Deploy directly to the standalone GlassFish Server

  You can deploy applications directly to the standalone GlassFish Server by creating a connection to the server and choosing the name of that server as the deployment target.
- Deploy to an archive file

  You can deploy applications indirectly by choosing an EAR file as the deployment target. The archive file can subsequently be installed on the target GlassFish Server.

Developing Applications with Integrated WebLogic Server

If you are developing an application in JDeveloper and you want to run the application in Integrated WebLogic Server, you do not need to perform the tasks required for deploying directly to Oracle WebLogic Server or to an archive file.

JDeveloper has a default connection to Integrated WebLogic Server and does not require any deployment profiles or descriptors. Integrated WebLogic Server has a preconfigured domain that includes the ADF libraries, as well as the -Djps.app.credential.overwrite.allowed=true setting, that are required to run ADF applications. You can run an application by choosing **Run** from the JDeveloper main menu.

You debug the application using the features described in Testing and Debugging ADF Components.

Developing Applications to Deploy to Standalone GlassFish Server

Typically, for deployment to standalone application servers, you test and develop your application by running it in Integrated WebLogic Server. You can then test the application further by deploying it to standalone GlassFish Server.

In general, you use JDeveloper to prepare the application or project for deployment by:

- Creating a connection to the target GlassFish Server
- Creating deployment profiles (if necessary)
- Creating deployment descriptors that are specific to GlassFish
- Updating application.xml and web.xml to be compatible with the GlassFish Server (if required)

You must already have an installed GlassFish Server. For instructions on obtaining and installing GlassFish, see https://javaee.github.io/glassfish/download.

> **Note:**
>
> For information about the GlassFish Server version supported by JDeveloper and ADF, see the Certification Information link for your JDeveloper release on OTN at http://www.oracle.com/technetwork/developer-tools/jdev/documentation/index.html.

You must also prepare the GlassFish Server for ADF application deployment. For more information, see Configuring GlassFish Server in *Administering Oracle ADF Applications*.

- Installing the ADF runtime into the GlassFish Server installation:
- Setting JVM cache size and simple option
- Enabling Secure Admin on the GlassFish Server to allow for remote logins and remote connections in order for JDeveloper to run on a different machine than GlassFish.
- Creating a global JDBC data source for applications that require a connection to a data source

After the application and the GlassFish Server have been prepared, you can:

- Use JDeveloper to:
  - Directly deploy to the GlassFish Server using the deployment profile and the application server connection.

  - Deploy to an EAR file using the deployment profile. For ADF applications, WAR files can be deployed only as part of an EAR file.
- Use the GlassFish Server's administration tools to deploy the EAR file created in JDeveloper.

Running an ADF Application in Integrated WebLogic Server

In order to test run an ADF application during development, you can use JDeveloper to run an application in Integrated WebLogic Server. You do not have to manually complete many of the steps that are necessary for deployment to a standalone server.

JDeveloper is installed with Integrated WebLogic Server which you can use to test and develop your application. For most development purposes, Integrated WebLogic Server will suffice. When your application is ready to be tested, you can select the run target and then choose the **Run** command from the main menu.

> **Note:**
>
> The first time you run an application in Integrated WebLogic Server, the Create Default Domain dialog appears for you to define an administrative password for the new domain.

When you run the application target, JDeveloper detects the type of Java EE module to deploy based on artifacts in the projects and workspace. JDeveloper then creates an in-memory deployment profile for deploying the application to Integrated WebLogic Server. JDeveloper copies project and application workspace files to an "exploded EAR" directory structure. This file structure closely resembles the EAR file structure that you would have if you were to deploy the application to an EAR file. JDeveloper then follows the standard deployment procedures to register and deploy the "exploded EAR" files into Integrated WebLogic Server. The "exploded EAR" strategy reduces the performance overhead of packaging and unpackaging an actual EAR file.

In summary, when you select the run target and run the application in Integrated WebLogic Server, JDeveloper:

- Detects the type of Java EE module to deploy based on the artifacts in the project and application
- Creates a deployment profile in memory
- Copies project and application files into a working directory with a file structure that would simulate the "exploded EAR" file of the application.
- Performs the deployment tasks to register and deploy the simulated EAR into Integrated WebLogic Server

> **Note:**
>
> JDeveloper ignores the deployment profiles that were created for the application when you run the application in Integrated WebLogic Server.

The application will run in the base domain in Integrated WebLogic Server. This base domain has the same configuration as a base domain in a standalone WebLogic Server instance. In other words, this base domain will be the same as if you had used the Oracle Fusion Middleware Configuration Wizard to create a base domain with the default options in a standalone WebLogic Server instance.

JDeveloper will extend this base domain with the necessary domain extension templates, based on the JDeveloper technology extensions. For example, if you have installed JDeveloper Studio, JDeveloper will automatically configure the Integrated WebLogic Server environment with the ADF runtime template (JRF Fusion Middleware runtime domain extension template).

You can explicitly create a default domain for Integrated WebLogic Server. You can use the default domains to run and test your applications. Open the Application Servers window, right-click **IntegratedWebLogicServer** and choose **Create Default Domain**.

How to Run an Application in Integrated WebLogic Server

You can test an application by running it in Integrated WebLogic Server. You can also set breakpoints and then run the application within the ADF Declarative Debugger.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you run an application in Integrated WebLogic Server. For more information, see Running an ADF Application in Integrated WebLogic Server.

To run an application in Integrated WebLogic Server:

1. In the Applications window, select the project, unbounded task flow, JSF page, or file as the run target.
2. Right-click the run target and choose **Run** or **Debug**.

   The Create Default Domain dialog displays the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

Preparing the Application

Once your application is developed, you must perform some essential tasks to deploy the ADF application to a standalone GlassFish Server. You also need to configure GlassFish-specific security within the ADF application.

Before you deploy an ADF application to a standalone GlassFish Server, you must perform prerequisite tasks within JDeveloper to prepare the application for deployment.

The tasks are:

- How to Create a Connection to the Target Application Server
- How to Create Deployment Profiles
- How to Create and Edit Deployment Descriptors
- How to Enable JDBC Data Source for GlassFish

- How to Change Initial Context Factory

> **Note:**
>
> ADF Security is not supported on ADF Essentials for GlassFish. You should configure GlassFish-specific security within the ADF application. For information about configuring GlassFish security, see `http://docs.oracle.com/cd/E18930_01/html/821-2418/beabg.html#scrolltoc`.

How to Create a Connection to the Target Application Server

You can deploy applications to the GlassFish Server via JDeveloper application server connections.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an application server connection. For more information, see Preparing the Application.

You will need to complete this task:

Install the GlassFish Server.

To create a connection to an application server:

1. Launch the Application Server Connection wizard.

   You can:

   - In the Application Servers window, right-click **Application Servers** and choose **New Application Server**.
   - In the New Gallery, expand **General**, select **Connections** and then **Application Server Connection**, and click **OK**.
   - In the Resources window, choose **New** > **IDE Connections > Application Server**.
2. In the Create Application Server Connection dialog, on the Usage page, select **Standalone Server**.
3. On the Name and Type page, enter a connection name.
4. In the **Connection Type** dropdown list, choose:
   - **GlassFish 3.1** to create a connection to the GlassFish Server
5. Click **Next**.
6. On the Authentication page, enter a user name and password for the administrative user authorized to access the GlassFish Server.
7. Click **Next**.
8. On the Configuration page, enter the information for the GlassFish Server:
   - **Host Name**: Enter the name of the machine where the GlassFish Server is running. If no name is entered, the name defaults to localhost.

- **RMI Port**: If necessary, change to the RMI port number for the server. The default is 8686.
- **HTTP Port**: By default, GlassFish listens to port 8080 for HTTP requests. If necessary, you can change the port number here.
- **Admin HTTP Port:** By default, GlassFish uses port 4848 for administration. If necessary, you can change the port number here.
- **Secure Admin Enabled**: select if you want GlassFish to allow remote logins and remote connections

> **Note:**
>
> If you are using GlassFish 3.1.2 and you are running JDeveloper on a different machine than GlassFish, you need to enable Secure Admin in GlassFish to allow remote logins. You do not need to enable Secure Admin if both JDeveloper and GlassFish are on the same machine.

9. Click **Next**.
10. On the Test page, click **Test Connection** to test the connection.

    JDeveloper performs several types of connections tests. The JSR-88 test must pass for the application to be deployable. If the test fails, return to the previous pages of the wizard to fix the configuration.
11. Click **Finish**.

How to Create Deployment Profiles

A **deployment profile** defines the way the application is packaged into the archive that will be deployed to the target environment. The deployment profile:

- Specifies the format and contents of the archive file that will be created
- Lists the source files, deployment descriptors, and other auxiliary files that will be packaged
- Describes the type and name of the archive file to be created
- Highlights dependency information, platform-specific instructions, and other information

You need a WAR deployment profile for each web user interface project that you want to deploy in your application. You need an application-level EAR deployment profile and you must select the projects (such as WAR profiles) to include from a list. When the application is deployed, the EAR file will include all the projects that were selected in the deployment profile.

> **Note:**
>
> If you create your project or application using the ADF Fusion Web Application template, JDeveloper automatically creates default WAR and EAR deployment profiles. Typically, you would not need to edit or create deployment profiles manually.

For ADF applications, you can deploy the application only as an EAR file. The WAR files that are part of the application should be included in the EAR file when you create the deployment profile.

Creating a WAR Deployment Profile

You will need to create a WAR deployment profile for each web-based project you want to package into the application. Typically, the WAR profile will include the dependent data model projects it requires.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a WAR deployment profile. For more information, see Preparing the Application.

You will need to complete this task:

Create web-based projects. If you used the ADF Fusion Web Application template, you should already have a default WAR deployment profile.

To create WAR deployment profiles for an application:

1. In the Applications window, right-click the web project that you want to deploy and choose **New** and then **From Gallery**.

   You will create a WAR profile for each web project.

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **WAR File**, and click **OK**.

   If you don't see **Deployment Profiles** in the **Categories** tree, click the **All Features** tab.

3. In the Create Deployment Profile -- WAR File dialog, enter a name for the project deployment profile and click **OK**.

4. In the Edit WAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog. Note that some items list below may not be in your particular application.

   - Ensure that **ADF Faces Runtime 11**, **JSTL 1.2,** and the ADFm, ADFc, and ADFv libraries are marked deployed in the **WEB-INF/lib/Contributors** panel.
   - Select **File Groups > Web Files > Filters > WEB-INF** and deselect **weblogic.xml**.
   - Select **File Groups > Web Files/Classes > Filters > META-INF** and deselect **ejb-jar.xml**.
   - Select **File Groups > Web Files/Classes > Filters > path** and deselect **serviceinterface**.
   - Select **File Groups > Web Files/Classes > Filters > path** and deselect **server**.
   - You might also want to change the Java EE web context root setting. To do so, choose **General** in the left pane.

     By default, when **Use Project's Java EE Web Context Root** is selected, the associated value is set to the project name, for example, `Application1-`

`Project1-context-root`. You need to change this if you want users to use a different name to access the application.

- Select **Glassfish 3.1** as the **Platform**

5. Click **OK** to exit the Deployment Profile Properties dialog.
6. Click **OK** again to exit the Project Properties dialog.
7. Repeat Steps 1 through 6 for all web projects that you want to deploy.

Creating an Application-Level EAR Deployment Profile

The EAR file contains all the necessary application artifacts for the application to run in the application server. If you used the ADF Fusion Web Application template, you should already have a default EAR deployment profile. For more information about the EAR file, see What You May Need to Know About EAR Files and Packaging.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an application-level EAR deployment profile. For more information, see Preparing the Application.

You will need to complete this task:

> Create the WAR deployment profiles, as described in Creating a WAR Deployment Profile.

To create an EAR deployment profile for an application:

1. In the Applications window, right-click the application and choose **New** and then **From Gallery**.

   You will create an EAR profile for the application.

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **EAR File,** and click **OK**.

   If you don't see **Deployment Profiles** in the Categories tree, click the **All Features** tab.

3. In the Create Deployment Profile -- EAR File dialog, enter a name for the application deployment profile and click **OK**.
4. In the Edit EAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.
   - Select **File Groups > Application Descriptors > Filters** and deselect **weblogic-application.xml**.
   - Select **Application Assembly** and then in the **Java EE Modules** list, select all the project profiles that you want to include in the deployment, including any **WAR** profiles.
   - Select **Platform**, select the application server you are deploying to, and then select the target application connection from the **Target Connection** dropdown list. For GlassFish, select **GlassFish 3.1**.
5. Click **OK** again to exit the Edit EAR Deployment Profile Properties dialog.
6. Click **OK** again to exit the Application Properties dialog.

> **Note:**
>
> To verify that your customization classes are put correctly in the EAR class path, you can deploy the EAR profile to file system. Then you can examine the EAR to make sure that the customization class JAR is available in the EAR class path (the `EAR/lib` directory) and not available in the WAR class path (the `WEB-INF/lib` and `WEB-INF/classes` directories).

Viewing and Changing Deployment Profile Properties

After you have created a deployment profile, you can view and change its properties.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you view and change deployment profile properties. For more information, see Preparing the Application.

To view, edit, or delete a project's deployment profile:

1. In the Applications window, right-click the project and choose **Project Properties**.
2. In the Project Properties dialog, click **Deployment**.

   The **Deployment Profiles** list displays all profiles currently defined for the project.
3. In the list, select a deployment profile.
4. To edit or delete a deployment profile, click **Edit** or **Delete**.

How to Create and Edit Deployment Descriptors

Deployment descriptors are server configuration files that define the configuration of an application for deployment and that are deployed with the Java EE application as needed. The deployment descriptors that a project requires depend on the technologies the project uses and on the type of the target application server. Deployment descriptors are XML files that can be created and edited as source files, but for most descriptor types, JDeveloper provides dialogs or an overview editor that you can use to view and set properties. If you cannot edit these files declaratively, JDeveloper opens the XML file in the source editor for you to edit its contents.

In addition to the standard Java EE deployment descriptors (for example, `application.xml` and `web.xml`), you can also have deployment descriptors that are specific to your target application server.

Creating Deployment Descriptors

JDeveloper automatically creates many of the required deployment descriptors for you. If they are not present, or if you need to create additional descriptors, you can use JDeveloper to create them.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create deployment descriptors. For more information, see Preparing the Application.

You will need to complete this task:

Check to see whether JDeveloper has already generated deployment descriptors.

To create a deployment descriptor:

1. In the Applications window, expand the user interface project, select **WEB-INF** and click **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, choose **XML Document** and click **OK**.
3. In the Create XML File dialog, enter a name for your descriptor and click **OK**.

   For instance, you may want to create a `glassfish-web.xml` to define GlassFish-specific information.
4. In the overview editor, add entries for GlassFish.

   The following example shows a sample `glassfish-web.xml` descriptor.

   The `glassfish-web.xml` descriptor can be used to add additional settings that are not defined in `web.xml` or to modify the settings that are already defined in `web.xml`. For instance, you can override the `jdbc/Connections1DS` setting defined in `web.xml` by adding the entries `res-ref-name` and `jndi-name` to `glassfish-web.xml` as shown below. After setting `glassfish-web.xml`, `jdbc/NewConnections1DS` will be used instead of `jdbc/Connections1DS`. Note that the `res-ref-name` section is optional.

```
<glassfish-web-app>
    <context-root>DeptApp-ViewController-context-root</context-root>
    <resource-ref>
        <res-ref-name>jdbc/Connection1DS</res-ref-name>
        <jndi-name>jdbc/NewConnection1DS</jndi-name>
    </resource-ref>
    <class-loader delegate="false"/>
    <property value="true" name="useBundledJsf"/>
</glassfish-web-app>
```

Note:

For EAR files, do not create more than one deployment descriptor file of the same type per application or workspace. These files can be assigned to projects, but have application workspace scope. If multiple projects in an application have the same deployment descriptor, the one belonging to the launched project will supersede the others. This restriction applies to `application.xml`.

The best place to create an application-level descriptor is in the **Descriptors** node of the Application Resources panel in the Applications window. This ensures that the application is created with the correct descriptors.

Application-level descriptors created in the project will be ignored at runtime. Only the application resources descriptors or descriptors generated at the EAR level will be used by the runtime.

Viewing or Modifying Deployment Descriptor Properties

After you have created a deployment descriptor, you can change its properties by using JDeveloper dialogs or by editing the file in the source editor. The deployment descriptor is an XML file (for example, `application.xml`) typically located under the Application Sources node.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you view or modify deployment descriptors. For more information, see Preparing the Application.

To view or change deployment descriptor properties:

1. In the Applications window or in the Application Resources panel, double-click the deployment descriptor.
2. In the overview editor, select either the **Overview tab** or the **Source tab**, and configure the descriptor by setting property values.

   If the overview editor is not available, JDeveloper opens the file in the source editor.

Configuring the application.xml File for Application Server Compatibility

You may need to configure your `application.xml` file to be compliant with your Java EE 1.5.

> **Note:**
>
> Typically, your project has an `application.xml` file that is compatible and you would not need to perform this procedure.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you configure the `application.xml` file. For more information, see Preparing the Application.

To configure the application.xml file:

1. In the Applications window, right-click the application and choose **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor Wizard**, and click **OK**.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select **application.xml** and click **Next**.
4. On the Select Version page, select **5.0** to be compatible with Java EE 5.0 or higher and click **Next**.
5. On the Summary page, click **Finish**.
6. Edit the `application.xml` file with the appropriate values.

Configuring the web.xml File for GlassFish Server Compatibility

You may need to configure your `web.xml` file to be compliant with your Java EE version).

The following example shows a `web.xml` file with a setting for a JDBC connection. For more information and other settings that are required, see web.xml.

```
<resource-ref>
      <description>DB Connection</description>
      <res-ref-name>jdbc/Connection1DS</res-ref-name>
      <res-type>javax.sql.DataSource</res-type>
      <res-auth>Container</res-auth>
</resource-ref>
```

> **Note:**
>
> Typically, your project has a `web.xml` file that is compatible and you would not need to perform this procedure. JDeveloper creates a starter `web.xml` file when you create a project.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you configure the `web.xml` file. For more information, see Preparing the Application.

To configure the web.xml file:

1. In the Applications window, right-click the project and choose **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor**, and click **OK**.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select **web.xml** and click **Next**.
4. On the Select Version page, select the version you want to use and click **Next**.

   Version 3.0 is compatible with Java EE 6.0 or higher, and version 2.5 is compatible with Java EE 5.0.
5. On the Summary page, click **Finish**.
6. Open the `web.xml` file in the overview editor.
7. Select the **Filters** tab and remove **JpsFilter**.

How to Enable JDBC Data Source for GlassFish

If you are using **ADF Business Components** in your application, you may need to check that the data source defined for the ADF Business Components as part of the application matches the data source defined in the GlassFish container.

You can configure the ADF application to use a JDBC Data Source in the application by editing the application's `bc4j.xcfg` file.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you configure JDBC. For more information, see Preparing the Application.

To configure the bc4j.xcfg file to enable JDBC data source:

1. In the Applications window, expand the model project and click the application module.
2. In the overview editor for the application module, choose **Configurations** and click **bc4j.xcfg**.
3. In the overview editor for `bc4j.xcfg`, select the **Source** tab.
4. Check that the `Custom JDBCDataSource` entry defined in the file matches the JDBC datasource defined for the GlassFish Server as described in Configuring GlassFish Server in *Administering Oracle ADF Applications*.

   For instance, the following example shows the `JDBCDataSource` property defined in the `bc4j.xcfg` file:

   ```
   <BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/
   configuration">
      <AppModuleConfigBag ApplicationName="model.AppModule">
         <AppModuleConfig name="AppModuleLocal" jbo.project="model.Model"
            ApplicationName="model.AppModule" DeployPlatform="LOCAL">
            <Database jbo.TypeMapEntries="OracleApps"/>
            <Security AppModuleJndiName="model.AppModule"/>
            <Custom ns0:JDBCDataSource="jdbc/OracleDS"
              xmlns:ns0="http://xmlns.oracle.com/bc4j/configuration"/>
         </AppModuleConfig>
         <AppModuleConfig name="AppModuleShared" jbo.project="model.Model"
            ApplicationName="model.AppModule" DeployPlatform="LOCAL">
            <AM-Pooling jbo.ampool.maxpoolsize="1"
             jbo.ampool.isuseexclusive="false"/>
            <Database jbo.TypeMapEntries="OracleApps"/>
            <Security AppModuleJndiName="model.AppModule"/>
            <Custom ns0:JDBCDataSource="jdbc/OracleDS"
              xmlns:ns0="http://xmlns.oracle.com/bc4j/configuration"/>
         </AppModuleConfig>
      </AppModuleConfigBag>
   </BC4JConfig>
   ```

How to Change Initial Context Factory

If your application requires JNDI lookup, such as in EJB-based applications, you need to change the initial context factory class name to the GlassFish context factory.

To change the initial context factory:

1. In the Applications window, expand the model project and double-click the **DataControls.dcx** file
2. In the overview editor, click the **Source** tab.
3. Edit the `initial-context-factory` entry to be `initial-context-factory="com.sun.enterprise.naming.SerialInitContextFactory"`

Deploying the Application

Once the target environment is set up and the ADF application is prepared for deployment, the final step is to deploy the application to the target environment.

You can use JDeveloper to deploy ADF applications directly to the GlassFish Server or you can create an archive file and use other tools to deploy to the application server.

> **Note:**
>
> Before you begin to deploy applications that use **Oracle ADF** to the standalone application server, you need to prepare the GlassFish Server environment by performing tasks such as installing the ADF runtime libraries and setting configuration values. See Configuring GlassFish Server in *Administering Oracle ADF Applications*.

Table H-1 describes some common deployment techniques that you can use during the application development and deployment cycle. The deployment techniques are listed in order from deploying on development environments to deploying on production environments. It is likely that in the production environment, the system administrators deploy applications by using the GlassFish Administration Console or scripts.

Table H-1 Deployment Techniques for Development or Production Environments

Deployment Technique	Environment	When to Use
Run directly from JDeveloper	Test or Development	When you are developing your application. You want deployment to be quick because you will be repeating the editing and deploying process many times. JDeveloper contains Integrated WebLogic Server, on which you can run and test your application. Note that you are testing your application in an integrated WebLogic Server and not in an Integrated GlassFish Server. After testing on the Integrated WebLogic Server, you can test further by deploying to the standalone GlassFish Server.
Use JDeveloper to directly deploy to the target GlassFish Server	Test or Development	When you are ready to deploy and test your application on an application server in a test environment. You can also use the test environment to develop your deployment scripts, for example, using Ant.
Use JDeveloper to deploy to an EAR file, then use the target GlassFish Server's tools for deployment	Test or Development	When you are ready to deploy and test your application on an application server in a test environment. As an alternative to deploying directly from JDeveloper, you can deploy to an EAR file and then use other tools to deploy to the application server. You can also use the test environment to develop your deployment scripts, for example, using Ant.

Table H-1 (Cont.) Deployment Techniques for Development or Production Environments

Deployment Technique	Environment	When to Use
Use GlassFish `asadmin` commands or GlassFish Administration Console.	Production	When your application is in a test and production environment. In production environments, system administrators usually use GlassFish `asadmin` commands or the GlassFish Administration Console.

How to Deploy to the Application Server from JDeveloper

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you deploy to the application server from JDeveloper. For more information, see Preparing the Application.

You will need to complete this task:

Create an application-level deployment profile that deploys to an EAR file.

To deploy to the target application server from JDeveloper:

1. In the Applications window, right-click the application and choose **Deploy >** ***deployment profile***.

   Make sure you choose a GlassFish deployment profile.

2. In the Deploy wizard, on the Deployment Action page, select **Deploy to Application Server** and click **Next**.
3. On the Select Server page, select the application server connection, and click **Next**.
4. Click **Finish**.

   During deployment, you can see the process steps displayed in the deployment Log window. You can inspect the contents of the modules (archives or exploded EAR) being created by clicking on the links that are provided in the log window. The archive or exploded EAR file will open in the appropriate editor or directory window for inspection.

   > **Note:**
   >
   > If you are deploying a Java EE application, click the application menu next to the Java EE application in the Applications window.

   For more information on creating application server connections, see How to Create a Connection to the Target Application Server.

What You May Need to Know About Deploying from JDeveloper

When you deploy an application using the EAR deployment profile created for GlassFish, JDeveloper:

- Inserts the required ADF Model, ADF Controller, and ADF View library JARs into the EAR file.
- Inserts `adf-share-glassfish.jar` into the WAR.
- Inserts an entry for the GlassFish application lifecycle listener `ADFGlassFishAppLifeCycleListener` into the `web.xml` file.
- Removes the other listener entries, `ADFConnectionLifeCycleCallBack`, `ADFConfigLifeCycleCallBack`, and `BC4JConfigLifeCycleCallBack`, from the `web.xml` files.

How to Create an EAR File for Deployment

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using GlassFish Administration Console.

Although an ADF application is encapsulated in an EAR file (which usually includes WAR components), it may have parts that are not deployed with the EAR.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an EAR file for deployment. For more information, see Preparing the Application.

You will need to complete this task:

Create an application-level deployment profile that deploys to an EAR file.

To create an EAR archive file:

- In the Applications window, right-click the application containing the deployment profile, and choose **Deploy > *deployment profile* > to EAR file**.

  If an EAR file is deployed at the application level, and it has dependencies on a JAR file in the data model project and dependencies on a WAR file in the user interface project, then the files will be located in the following directories by default:

  - *ApplicationDirectory*/deploy/*EARdeploymentprofile*.EAR
  - *ApplicationDirectory*/*ModelProject*/deploy/*JARdeploymentprofile*.JAR
  - *ApplicationDirectory*/*ViewControllerProject*/deploy/*WARdeploymentprofile*.WAR

> **Tip:**
>
> Choose **View** >**Log** to see messages generated during creation of the archive file.

What You May Need to Know About ADF Libraries

An ADF Library is a JAR file that contains JAR services registered for ADF components such as ADF task flows, pages, or application modules. If you want the ADF components in a project to be reusable, you create an ADF Library deployment profile for the project and then create an ADF Library JAR based on that profile.

An application or project can consume the ADF Library JAR when you add it using the Resources window or manually by adding it to the library classpath. When the ADF Library JAR is added to a project, it will be included in the project's WAR file if the **Deployed by Default** option is selected.

For more information, see Reusing Application Components.

What You May Need to Know About EAR Files and Packaging

When you package an ADF application into an EAR file, it can contain the following:

- WAR files: Each web-based view controller project should be packaged into a WAR file.
- ADF Library JAR files: If the application consumes ADF Library JARs, these JAR files may be packaged within the EAR.
- Other JAR files: The application may have other dependent JAR files that are required. They can be packaged within the EAR.

How to Deploy to the Application Server using asadmin Commands

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you deploy to the application server from JDeveloper. For more information, see Preparing the Application.

To deploy to the target application server using asadmin command:

1. Start an `asadmin` shell for GlassFish Server.
2. Invoke the `deploy` command.

   For instance, the following command deploys `application1.ear` to the GlassFish Server.

   ```
   deploy \--target=server \--force /path/application1.ear
   ```

How to Deploy the Application Using Scripts and Ant

You can deploy the application using commands and automate the process by putting those commands in scripts. The `ojdeploy` command can be used to deploy an application without JDeveloper. You can also use Ant scripts to deploy the application. JDeveloper has a feature to help you build Ant scripts. Depending on your requirements, you may be able to integrate regular scripts with Ant scripts.

For more information about commands, scripts, and Ant, see Deploying Using Scripting Commands and Deploying Using Scripts and Ant in *Administering Oracle ADF Applications*.

Testing the Application and Verifying Deployment

In order to ensure the deployment of the ADF application has been successful, you should test-run the application.

After you deploy the application, you can test it from the application server. To test-run your ADF application, open a browser window and enter a URL:

- For non-Faces pages: `http://<host>:port/<context root>/<page>`
- For Faces pages: `http://<host>:port/<context root>/faces/<view_id>`

  where `<view_id>` is the view ID of the ADF task flow view activity.

> **Tip:**
>
> The context root for an application is specified in the user interface project settings by default as *`ApplicationName`*/*`ProjectName`*/`context-root`. You can shorten this name by specifying a name that is unique across the target application server. Right-click the user interface project, and choose **Project Properties**. In the Project Properties dialog, select **Java EE Application** and enter a unique name for the context root.

> **Note:**
>
> `/faces` has to be in the URL for Faces pages. This is because JDeveloper configures your `web.xml` file to use the URL pattern of `/faces` in order to be associated with the Faces Servlet. The Faces Servlet does its per-request processing, strips out `/faces` part in the URL, then forwards the URL to the JSP. If you do not include the `/faces` in the URL, then the Faces Servlet is not engaged (since the URL pattern doesn't match). Your JSP is run without the necessary JSF per-request processing.
