Placeholder data controls can be used in many situations. In addition to being used for design review and development, they can be used to develop realistic runtime mock-ups for usability studies, or for proof-of-concept requirements. They can be used to create demos when the data model is not yet ready.

19.1.2 Additional Functionality for Placeholder Data Controls

You may find it helpful to understand some data access features before you start working with placeholder data controls. Following are links to other functionality that may be of interest.

- After your initial design with placeholder data controls, when the final data controls are available, you can simply rebind the components. For more information about rebinding components, see Chapter 28, "Creating a Basic Databound Page" and Chapter 29, "Creating ADF Databound Tables."

- A placeholder data type attribute can be configured to be a list of values (LOV). For more information about LOVs, see Section 5.12, "Working with List of Values (LOV) in View Object Attributes."

- You can create master-detail relationships between placeholder data types, similar to the master-detail data collections in a standard data control. For more information on master-detail forms and tables, see Chapter 31, "Displaying Master-Detail Data."

- When you define placeholder data types in a master-detail hierarchy, JDeveloper creates view links that define that relationship. For more information about view links, see Section 6.2, "Working with Multiple Tables in a Master-Detail Hierarchy."

- Placeholder data controls can be used for the development of search forms. For more information about query search forms, see Chapter 33, "Creating ADF Databound Search Forms."

- You might want to package placeholder data controls into reusable components as ADF Library JARs. For more information about reusable components and the ADF Library, see Chapter 44, "Reusing Application Components."
19.2 Creating Placeholder Data Controls

You add placeholder data controls to a project using the New Gallery. After the placeholder data control has been created, it appears as a node in the Data Controls panel. It has a different icon than do standard data controls. Instead of an Operations node, the placeholder data control has a Built-in Operations node. Although the Built-in Operations node contains Commit and Rollback operations, these operations do not perform commits or rollbacks because there is not an actual data source for the data.

When a data control is initially created, it does not have any data types associated with it. You will need to manually create the data types as described in section Section 19.3, "Creating Placeholder Data Types."

19.2.1 How to Create a Placeholder Data Control

Placeholder data controls are defined at the project level in JDeveloper. You must already have created a project before you can create placeholder data controls.

Before you begin:
It may be helpful to have an understanding of the options you have for creating placeholder data controls. For more information, see Section 19.2, "Creating Placeholder Data Controls."

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Section 19.1.2, "Additional Functionality for Placeholder Data Controls."

To create a placeholder data control:
1. In the Applications window, right-click the project to which you want to add a placeholder data control and choose New > From Gallery.
2. In the New Gallery, expand Business Tier, select Data Controls and then Placeholder Data Control, and click OK.
3. In the Placeholder Data Control dialog, as shown in Figure 19–1, enter:
   - Name: The name of the placeholder data control.
   - Package: The package name that will be used to reference the placeholder data control.
   - Description: Optional description of the placeholder data control.
4. Click OK.

19.2.2 What Happens When You Create a Placeholder Data Control

When you create a placeholder data control, the package you selected to contain the data control appears under the project node in the Applications window. A data control XML file *PlaceholderDataControl.xml* appears under the package, where *PlaceholderDataControl* is the name of the placeholder data control. Example 19–1 shows a sample file called *Placeholder01.xml*, which was created when the *Placeholder01* data control was created.

**Example 19–1 Sample placeholder01.xml file**

```xml
<?xml version='1.0' encoding='windows-1252' ?>
<AppModule
  xmlns="http://xmlns.oracle.com/placeholder"
  Name="Placeholder01">
</ AppModule>
```

JDeveloper also creates a *DataControls.dcx* file if it has not yet been defined, and adds entries for the placeholder data control, as shown in Example 19–2.

**Example 19–2 Placeholder Data Control entry in DataControls.dcx**

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<DataControlConfigs xmlns="http://xmlns.oracle.com/adfm/configuration" version="12.1.2" id="DataControls"
  Package="model">
  <PlaceholderDataControl SupportsTransactions="true" SupportsFindMode="true"
    SupportsResetState="true" SupportsRangesize="true"
    SupportsSortCollection="true"
    FactoryClass='oracle.adf.model.placeholder.DataControlFactoryImpl'
    id='Placeholder01'
    xmlns="http://xmlns.oracle.com/adfm/datacontrol"
    Package="model.prototype"/>
</ DataControlConfigs>
```

In the Data Controls panel, the placeholder data control appears alongside other data controls in the root tree. A placeholder data control that does not yet have data types
defined will have only the Commit and Rollback built-in operations available, as shown in Figure 19–2.

Figure 19–2 Applications Window and Data Controls Panel

19.3 Creating Placeholder Data Types

A standard data control obtains its data collections and attributes from its underlying data source in the model or business service layer. For example, an application module data control obtains its data collections from the view objects and associated database tables.

For a placeholder data control, instead of data collections, it has placeholder data types. A placeholder data type is analogous to a data collection. It can be dropped onto a page to create complex components such as forms, tables, and trees. It also has a set of attributes that can be dropped onto pages as individual components such as input text, output text, and select choice. Some attributes may be defined as LOVs.

When you first create a placeholder data control, it is devoid of any data types because there are no underlying database tables for the placeholder data control to reference. You must declaratively create one or more placeholder data types. For each data type, you specify attribute names, types, default UI components, and other options. You can create multiple data types for a data control, similar to the multiple data collections in an application module.

After you have created a placeholder data type, it appears as a child node of the placeholder data control. It also has a Built-in operations node with the standard set of operations. It has a Named Criteria node that contains an All Queriable Attributes item that is analogous to the named view criteria of a view object in a standard data control. You can drag and drop the All Queriable Attributes item onto a page to create a query or quick query search form. In a standard data control, you can create multiple view criteria on a view object. Because there is no real view object in a placeholder data type, only one All Queriable Attributes item is available. For more information about query search forms, see Chapter 33, “Creating ADF Databound Search Forms.”

You can create master-detail relationships between placeholder data types, similar to the master-detail data collections in a standard data control. You can drop
Creating Placeholder Data Types

Master-detail data types onto pages to create master-detail forms and tables. For more information on master-detail forms and tables, see Chapter 31, "Displaying Master-Detail Data."

JDeveloper allows you to reuse placeholder data types created for other placeholder data controls in the same project. When you are creating a data type, you can select an option to load existing data types from another placeholder data control. If you select the Import From: Existing Data Type option, the attributes from the imported data type will be added to the list of attributes.

You can also select an option to import the sample data associated with the imported data type when the attributes are added.

---

**Note:** Although you do not need sample data until you run the application, you should add sample data to provide a consistent design time rendering of the components.

---

### 19.3.1 How to Create a Placeholder Data Type

After you have created a placeholder data control, you can proceed to create data types. You define a name for the data type, and define each of its individual attributes. For each attribute, you then define its type, format, default UI component, and whether or not it should be an LOV.

In order to simplify the process of creating placeholder data types, you can select from a list of four of the most common types: String, Boolean, Date, and Number. Because placeholder attributes are typed, you can create column labels and include UI control hints in the design.

If you have a sample data file in comma-separated value (CSV) format, you can create all the attributes and load sample data using the sample data file import function. You do not need to create the attributes. JDeveloper will create them for you from the format of the CSV file, which can optionally contain a list of column headings as the first row. The attributes default to type String. You can manually reset each attribute to another type as required. For instructions to import sample data, see Section 19.3.2.3, "How to Import Attributes and Sample Data to a Placeholder Data Type."

**Before you begin:**

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Section 19.3, "Creating Placeholder Data Types."

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Section 19.1.2, "Additional Functionality for Placeholder Data Controls."

Additionally, you must first create the placeholder data control, as described in Section 19.2.1, "How to Create a Placeholder Data Control."

**To create a placeholder data type:**

1. In the Applications window, double-click the placeholder data control to which you want to add a placeholder data type.

2. In the overview editor, in the Data Types section, select the placeholder data control and click the New Placeholder Data Type icon.
3. In the Create Placeholder Data Type dialog, enter a file name and package for the placeholder data type.

4. If you have an existing placeholder data type or a .csv file, from which you want to import attributes and data, select Import From and select either .CSV File or Existing Data Type, and then specify the options for the import.

   To import from a .csv file:
   a. In the File Name field, specify the file from which you want to import, or click the Browse icon to navigate to and select the file.
   b. From the Character Set dropdown list, select the character set that the file uses.
   c. If your file has a header row with the names of the columns, select First row of the file contains Attribute names to import.

   To import from an existing placeholder data type:
   a. Expand the tree to locate and select an existing placeholder data type.
   b. If the existing data type contains data that you want to import, select Also Import Sample Data.

5. Click OK.

The placeholder data type is created and opened in the overview editor.
6. In the overview editor, click the **Attributes** navigation tab to view, add, and edit attributes for the placeholder data type.

7. Click the **Data** navigation tab to view, add, and edit sample data for the placeholder data type.

   You need sample data for runtime and for a consistent design time.

### 19.3.2 How to Add Attributes and Sample Data to a Placeholder Data Type

If you intend to run an application using the placeholder data control, you will need to add sample data to be displayed during execution. You can add sample data to the placeholder data type attributes manually or by importing the data from another placeholder data type or CSV file. Although having sample data is necessary only at runtime, you should add sample data for a consistent design time rendering of the components.

If you did not import attributes when you created your placeholder data type, you can add them using the Attributes page of the overview editor. Also, you can use the Data page of the overview editor to add sample data to be displayed during execution. Both the Attributes page and the Data page have an Import button that opens the Import Placeholder Data Type dialog, which allows you to import attributes and sample data.

Before you begin to add sample data to a placeholder data type, you should have already created a placeholder data control and a placeholder data type. If you are entering the data manually, you should have the data ready. If you are loading the data from a CSV file, you need to have the location of the file. If you are importing from another placeholder data type, you must have already created the other data type.

#### 19.3.2.1 Manually Adding Attributes to a Placeholder Data Type

Using the Attributes page of the overview editor, you can add and configure attributes to a placeholder data type.

**Before you begin:**

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Section 19.3, "Creating Placeholder Data Types."

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Section 19.1.2, "Additional Functionality for Placeholder Data Controls."

Additionally, you must first create the placeholder data control, as described in Section 19.2.1, "How to Create a Placeholder Data Control," and create the placeholder data type, as described in Section 19.3.1, "How to Create a Placeholder Data Type."

**To manually add a placeholder data type attribute:**

1. In the Applications window, double-click the placeholder data type to which you want to add attributes.

2. In the overview editor, click the **Attributes** navigation tab.

3. On the Attributes page, click the **Add** icon.

4. In the Insert View Attributes dialog, enter a name for the attribute, and click **OK**.

5. After adding attributes, select an attribute and use the fields beside the attributes list to configure the selected attribute.
- **Name**: Enter a name for the attribute.
- **Data Type**: Select a type for the attribute from the dropdown list. The supported types are String, Boolean, Date, and Number.
- **Default Component**: Select a default component for the attribute from the dropdown list. For an LOV, select Combo Box List of Values. Then click the Edit icon to configure the LOV. For more information, see Section 19.3.4, "How to Configure a Placeholder Data Type Attribute to Be a List of Values."
- **Default Value**: Enter the initial value for the attribute.
- **Label**: Enter a label for the attribute. The label will be used when the component is displayed.
- **Tooltip**: Enter text to be displayed as a tooltip for the attribute.
- **Format Type**: This field is enabled only when the type is Date or Number. Select a format type from the dropdown list.
- **Format**: This field is enabled only when a format mask has been defined for that format type.
- **Display Width**: Enter the character width to be used by the control that displays this attribute.
- **Searchable**: Select this checkbox to make the attribute searchable.

Click the Add icon to add more attributes.

### 19.3.2.2 Adding Sample Data Manually

You can use the Sample Data page of the Edit Placeholder Data Type dialog to manually enter sample data for your placeholder data control.

**Before you begin:**
It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Section 19.3, "Creating Placeholder Data Types."

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Section 19.1.2, "Additional Functionality for Placeholder Data Controls."

Before you add sample data to a placeholder data type, you need to perform the following tasks:

- Create a placeholder data type, as described in Section 19.3.1, "How to Create a Placeholder Data Type."
- Have your list of sample data ready.

**To add sample data to a placeholder data type manually:**

1. In the Data Controls panel, right-click the placeholder data type to which you want to add sample data, and choose Open.
2. In the overview editor, click the Data navigation tab.
3. In the Data page, click the Add icon to add a row to the data table, and enter a value for each attribute. Repeat as necessary until you have entered adequate sample data.
19.3.2.3 How to Import Attributes and Sample Data to a Placeholder Data Type

As an alternative to manually entering attributes and sample data for a placeholder data type, you can import them in a single operation. Using the Attributes page of the overview editor, you can import attributes from an existing placeholder data type or from a .csv file.

A .csv (comma-separated values) file is a plain text file containing rows of attribute values, delimited by commas. A .csv file can optionally have a header row that defines the names of each attribute.

In the overview editor for a placeholder data type, both the Attributes page and the Data page have an Import button that opens the Import Placeholder Data Type dialog, which allows you to import attributes and sample data.

Before you begin:

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Section 19.3, "Creating Placeholder Data Types."

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Section 19.1.2, "Additional Functionality for Placeholder Data Controls."

Additionally, you must first create the placeholder data control, as described in Section 19.2.1, "How to Create a Placeholder Data Control," and create the placeholder data type, as described in Section 19.3.1, "How to Create a Placeholder Data Type."

To import attributes into a placeholder data type:

1. In the Applications window, double-click the placeholder data type to which you want to add attributes.

2. In the overview editor, click the Attributes navigation tab.

3. If you are importing attributes as well as sample data, you must delete any existing attributes in the placeholder data type.

   If you do not remove the existing attributes, JDeveloper imports only the first columns of data for the number of defined attributes. For example, if you have two attributes defined in your data type and four columns of sample data in your CSV file, JDeveloper will import only the first two columns of data.

4. On the Attributes page, click Import.

5. In the Import Placeholder Data Type dialog, specify where you want to import attributes from.

   To use a .csv file:

   a. Select Import from .CSV File.

   b. In the File Name field, enter the full path and name of the file, or click the Browse icon to navigate to and select it.

   c. From the Character Set dropdown list, select the character set represented in the specified .csv file.

   d. If the .csv file has a header row that contains the names of the attributes, select First row of the file contains Attribute names to import.

   To use an existing placeholder data type:

   a. Select Import from an Existing Placeholder Data Type.
b. Expand the available placeholder data controls displayed to see the placeholder data types they contain, and select the one you want to copy.

Figure 19–4  Import Placeholder Data Type Dialog

6. Select the Also Import Sample Data checkbox to load sample data from the file or existing placeholder data type.

7. Specify whether you would like to append or overwrite the attributes already defined for the placeholder data type.
   - Select Append to add the imported attributes to the current list of attributes in the placeholder data type
   - Select Overwrite to replace the current attributes with the imported attributes.

8. Click OK.

9. After importing attributes, you can optionally go to the Attributes page and reconfigure the attributes.

19.3.2.4 What Happens When You Add Sample Data

Placeholder sample data, whether added manually added or imported, are stored in message bundle files. Example 19–3 shows a sample message bundle with two rows of five attributes.

Example 19–3  Sample Data Properties File TelevisionMsgBundle.properties

model.prototype.SupplierLocationsDataType.SL_0_0=101
model.prototype.SupplierLocationsDataType.SL_0_1=so
model.prototype.SupplierLocationsDataType.SL_0_2=Houston
model.prototype.SupplierLocationsDataType.SL_0_3=TX
Creating Placeholder Data Types

19.3.3 What Happens When You Create a Placeholder Data Type

When you create a placeholder data type, JDeveloper creates a `PlaceholderDataType.xml` file, where `PlaceholderDataType` is the name of the placeholder data type you had specified.

The `PlaceholderDataType.xml` file has the same format as a view object XML file. It includes the name of the view object and the name and values of each placeholder attribute that was defined.

Example 19–4 shows a `PlaceholderDataType.xml` for a Supplier data type. Two attributes are declaratively defined: `Supplier_Id` and `Supplier_Name`.

**Example 19–4 Sample Placeholder Data Type XML File**

```xml
<?xml version='1.0' encoding='windows-1252' ?>
<ViewObject
    xmlns="http://xmlns.oracle.com/placeholder"
    Name="SuppliersDataType"
    InheritPersonalization="merge"
    BindingStyle="OracleName"
    CustomQuery="true">
    <ViewAttribute
        Name="Supplier_Id"
        Type="oracle.jbo.domain.Number"/>
    <ViewAttribute
        Name="Supplier_Name"
        Type="java.lang.String"/>
</ViewObject>
```

Since a data type is similar to a data collection and is based on a view object, each data type will have a corresponding `PlaceholderDataType.xml` file.

JDeveloper also adds entries for each placeholder data type to the `PlaceholderDataControl.xml` file. For example, after the Suppliers data type is created, the data control XML file includes a new `ViewUsage` entry for the Suppliers data type, as shown in Example 19–5.

**Example 19–5 Sample PlaceholderDataControl.xml File After Addition of Placeholder Data Type**

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<AppModule
    xmlns="http://xmlns.oracle.com/placeholder"
    Name="Placeholder01"
    InheritPersonalization="merge">
    <ViewUsage
        Name="SuppliersDataType"
        ViewObjectName="model.prototype.SuppliersDataType"/>
</AppModule>
```
In the Data Controls panel, a placeholder data type node appears under the placeholder data control. Expanding the node reveals the presence of each of the attributes, the Built-in Operations node, and the Named Criteria node.

Figure 19–5 shows a placeholder data control as it appears in the Data Controls panel.

**Figure 19–5  Data Controls Panel Showing Placeholder Data Control**

### 19.3.4 How to Configure a Placeholder Data Type Attribute to Be a List of Values

A placeholder data type attribute can be configured to be a list of values (LOV). An LOV-formatted attribute binds to UI components that display dropdown lists or list picker dialogs. For more information about LOVs, see Section 5.12, "Working with List of Values (LOV) in View Object Attributes."

When you are configuring a placeholder data type attribute, you can select an option to bring up a dialog to configure that attribute to be an LOV.

If you have only one data source, you can only create a fixed LOV. To create a dynamic LOV, there must be more than one placeholder data type available to be the source.

#### 19.3.4.1 Configuring an Attribute to Be a Fixed LOV

Before you begin, you should determine which attribute you want to be a fixed LOV and which values should be in the fixed list.

**Before you begin:**

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Section 19.3, "Creating Placeholder Data Types."

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Section 19.1.2, "Additional Functionality for Placeholder Data Controls."

Additionally, you must have already created the placeholder data type for your placeholder data control.

**To configure an attribute to be a fixed LOV:**

1. In the Data Controls panel, right-click the placeholder data type and choose **Open**.
2. In the overview editor, click the **Attributes** navigation tab.
3. In the Attributes page, select the attribute you want to configure as an LOV.
4. Click the **Edit LOV Binding** icon next to the **Default Component** pulldown list.
The Configure List of Values dialog appears, as shown in Figure 19–6.

**Figure 19–6 Configure List of Values Dialog for a Fixed LOV**

5. In the dialog, select **Fixed List**.

6. Click the **Add** icon to add an entry to the list of values.

7. For each entry, enter a label and a value.
   When the user selects an item from the list of values, the value entry will be entered into the input field.

8. Specify the maximum number of the most recently used items that will be displayed in the dropdown list.

9. From the **No Selection Item** dropdown list, select an option for how you want the "no selection" item to be displayed.
   For instance, selecting **Blank Item (First of List)** will display the "no selection" item as a blank at the beginning of the list.

10. Click **OK**.

**19.3.4.2 Configuring an Attribute to Be a Dynamic LOV**

Using a placeholder data type to serve as the source, you can configure an attribute to be a dynamic LOV.

**Before you begin:**
It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Section 19.3, "Creating Placeholder Data Types."
You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Section 19.1.2, "Additional Functionality for Placeholder Data Controls."

Also, you should have already created another placeholder data type to serve as the source of the dynamic LOV.

To configure an attribute to be a dynamic LOV:

1. In the Data Controls panel, right-click the placeholder data type and choose Open.
2. In the overview editor, click the Attributes navigation tab.
3. In the Attributes page, select the attribute you want to configure as an LOV.
4. Click the Edit LOV Binding icon next to the Default Component pulldown list.
   The Configure List of Values dialog appears, as shown in Figure 19–7.

   **Figure 19–7 Configure List of Values Dialog for a Dynamic LOV**

5. In the Configure List of Values dialog, select Dynamic List.
6. Select the list data type with the source attribute. You must have a source placeholder data type for this selection to be available.
7. Select the list attribute.
8. Shuttle the desired display attributes from the Available list to the Selected list.
9. Select the maximum number of the most recently used items that will be displayed in the dropdown list.
10. From the **No Selection Item** dropdown list, select an option for how you want the "no selection" item to be displayed. For example, selecting **Blank Item (First of List)** will display the "no selection" item as a blank at the beginning of the list.

11. Click **OK**.

### 19.3.5 How to Create Master-Detail Data Types

You create master-detail relationships between data types in the same way you create master-detail hierarchies between tables. In a standard data control, you can use view links to define source and target view objects that would become the master and the detail objects. For more information about master-detail relationships, see Chapter 31, "Displaying Master-Detail Data."

You first create a master data type and its attributes. Then you create a detail data type as a child of the master data type. You define the source attribute in the master data type that defines the relationship to the detail data type.

**Before you begin:**

It may be helpful to have an understanding of the options you have for creating placeholder data types. For more information, see Section 19.3, "Creating Placeholder Data Types."

You may also find it helpful to understand additional functionality that can be added after using placeholder data controls. For more information, see Section 19.1.2, "Additional Functionality for Placeholder Data Controls."

Before you create a placeholder master-detail hierarchy, you must perform the following tasks:

- Determine the data structure of the master data type and the data structure of the detail data type.
- Determine which attribute in the master will be the source for the detail data type.
- Create a placeholder data type to be the master, as described in Section 19.3.1, "How to Create a Placeholder Data Type."

**To create master-detail hierarchical data types:**

1. In the Data Controls panel, right-click the master placeholder data type and choose **New Child Placeholder Data Type**.

   Figure 19–8 shows the Create Placeholder Data Type dialog for entering detail data type attributes.
2. In the Create Placeholder Data Type dialog, enter a name and package for the detail data type.

3. From the **Join Attribute to Parent** dropdown list, select the attribute from the master data type that will be used to join to the new detail data type.

4. If you have an existing placeholder data type or a .csv file, from which you want to import attributes and data, select **Import From** and select either **.CSV File** or **Existing Data Type**, and then specify the options for the import.

   To import from a .csv file:
   
   a. In the **File Name** field, specify the file from which you want to import, or click the **Browse** icon to navigate to and select the file.
   
   b. From the **Character Set** dropdown list, select the character set that the file uses.
   
   c. If your file has a header row with the names of the columns, select **First row of the file contains Attribute names to import**.

   To import from an existing placeholder data type:
   
   a. Expand the tree to locate and select an existing placeholder data type.
   
   b. If the existing data type contains data that you want to import, select **Also Import Sample Data**.

5. Click **OK**.

The Data Controls panel displays the detail data type as a child of the master data type, as shown in Figure 19–9. If you did not import attributes, you can add them now, as described in Section 19.3.2, "How to Add Attributes and Sample Data to a Placeholder Data Type."
19.3.6 What Happens When You Create a Master-Detail Data Type

A master-detail relationship is implemented in the same way as is a standard master-detail relationship, using view object and view links. When you define placeholder data types in a master-detail hierarchy, JDeveloper creates a DTLink.xml file that contains metadata entries for view links that define that relationship. For more information about view links, see Section 6.2, "Working with Multiple Tables in a Master-Detail Hierarchy." For example, in the relationship between the master data type SuppliersDataType and the detail data type SupplierLocationsDataType associated with a key Supplier_Id, JDeveloper creates a DTLink.xml file in the form of a view link file to define that relationship, as shown in Example 19–6.

Example 19–6  DTLink.xml file for Master-Detail Data Type Relationships

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<ViewLink
  xmlns="http://xmlns.oracle.com/placeholder"
  Name="DTLink"
  InheritPersonalization="merge">
  <ViewLinkDefEnd
    Name="SuppliersDataType"
    Cardinality="1"
    Source="true"
    Owner="model.prototype.SuppliersDataType">
    <AttrArray Name="Attributes">
      <Item Value="model.prototype.SuppliersDataType.Supplier_Id"/>
    </AttrArray>
  </ViewLinkDefEnd>
  <ViewLinkDefEnd
    Name="SupplierLocationsDataType"
    Cardinality="-1"
    Owner="model.prototype.SupplierLocationsDataType">
    <AttrArray Name="Attributes">
      <Item Value="model.prototype.SupplierLocationsDataType.Supplier_Id"/>
    </AttrArray>
  </ViewLinkDefEnd>
</ViewLink>
```

19.4 Using Placeholder Data Controls

You use placeholder data controls in the same way you would use standard data controls. You can drag data types onto pages and use the context menus to drop the data types as forms, tables, trees, graphs, and other components. You can drop
individual attributes onto pages as text, lists of values, single selections, and other
components. You can use any of the built-in operations such as Create, Execute, and
Next by dropping them as buttons, command links, and menu items.

You can work in several ways to take advantage of placeholder data controls:

- Build a page using the placeholder data controls and rebind to real data controls
  later.
- Build a page using components, bind them to placeholder data controls, and
  rebind to real data controls later.
- Build a page using some combination of components from the Components
  window, components from the placeholder data controls, and then bind or rebind
  to the real data controls later.

19.4.1 Limitations of Placeholder Data Controls

You can use placeholder data controls in your application development in many
situations. For most UI design evaluations, placeholder data controls should be able to
fully substitute for real data controls.

There are a few limitations:

- Because data types are not tied to an underlying data source, the Commit and
  Rollback operations do not perform real transactions, nor do they update the
  cache.
- Placeholder data controls can only be created declaratively. You cannot create
  custom methods like you can with a real application module or data control.
- Placeholder data controls cannot be used when there is a need either for custom
data or for filtering or custom code to fetch data. Placeholder data controls will
disable those operations.

19.4.2 Creating Layout

Use the drag-and-drop feature to create the page using the placeholder data controls,
any available real data controls, and components from the Components window. If
you intend to run a page or application that requires real data, enter sample data for
your placeholder data types. If you have a large amount of sample data, you may be
able to create CSV files from the data source and load them into the data type. You
may also use spreadsheets and other tools to create CSV sample data files.

19.4.3 Creating a Search Form

In a standard data control, you can create view criteria on view objects to modify the
query. These view criteria are also used for drag-and-drop creation of query and quick
query search forms. The named view criteria items appear under the Named Criteria
node for a data collection. For more information about query and quick query search
forms, see Chapter 33, "Creating ADF Databound Search Forms."

For placeholder data controls, there is also a Named Criteria node under each data
type node. An automatically created All Queriable Attributes item appears under this
node and can be used to drag and drop onto pages to create the query or quick query
search forms.
19.4.4 Binding Components

Instead of building the page using the data controls, for instance, if you are unsure of the shape of your data, you can lay out the page first using the Components window and later bind it to the data types, attributes, or operations of the placeholder data controls.

19.4.5 Rebinding Components

After the final data controls are available, you can simply rebinding the components. You can select the component in the Structure window and use the context menu to open the relevant rebind dialog. You can also drag and drop the data control item onto the UI component to initiate a rebinding editor. The rebinding procedures are the same whether the component was originally bound to a placeholder data control or a standard data control.

For more information about rebinding components, see Chapter 28, "Creating a Basic Databound Page" and Chapter 29, "Creating ADF Databound Tables."

19.4.6 Packaging Placeholder Data Controls to ADF Library JARs

A useful feature of placeholder data controls is that they allow parallel development and division of labor among developers and designers. You may be able to leverage that further by packaging placeholder data controls into reusable components as ADF Library JARs. ADF Libraries are JARs that have been packaged to contain all the necessary artifacts of an ADF component. For more information about reusable components and the ADF Library, see Chapter 44, "Reusing Application Components."

You can create libraries of placeholder data controls and distribute them to multiple designers working on the same UI project. Because they are lightweight, you can even use them in place of available real data controls for the earlier phases of UI design.
Part IV

Creating ADF Task Flows

Part IV contains the following chapters:

- Chapter 20, "Getting Started with ADF Task Flows"
- Chapter 21, "Working with Task Flow Activities"
- Chapter 22, "Using Parameters in Task Flows"
- Chapter 23, "Using Task Flows as Regions"
- Chapter 24, "Creating Complex Task Flows"
- Chapter 25, "Using Dialogs in Your Application"
This chapter describes getting started with ADF tasks flows that you can create in your Fusion web application. In addition to describing how to create ADF task flows, key ADF task flow features such as activities, control flows, control flow rules, memory scopes, and bounded and unbounded task flows are described. The chapter also describes how to refactor, test, and run a finished task flow.

This chapter includes the following sections:

- Section 20.1, "About ADF Task Flows"
- Section 20.2, "Creating a Task Flow"
- Section 20.3, "Adding Activities to a Task Flow"
- Section 20.4, "Adding Control Flow Rules to Task Flows"
- Section 20.5, "Testing Task Flows"
- Section 20.6, "Refactoring to Create New Task Flows and Task Flow Templates"

### 20.1 About ADF Task Flows

*ADF task flows* provide a modular approach for defining control flow in a Fusion web application. Instead of representing an application as a single large JSF page flow, you can break it up into a collection of reusable task flows. Each task flow contains a portion of the application’s navigational graph. The nodes in the task flows are activities. An *activity node* represents a simple logical operation such as displaying a page, executing application logic, or calling another task flow. The transitions between the activities are called *control flow cases*.

*Figure 20–1* shows two view activities called *Create* and *Confirm*. These view activities are similar to page nodes within a JSF page flow.

*Figure 20–1 ADF Task Flow*

The are two types of ADF task flow:

- Unbounded task flow: A set of activities, control flow rules, and managed beans that interact to allow a user to complete a task. The unbounded task flow consists...
of all activities and control flows in an application that are not included within a bounded task flow.

- **Bounded task flow:** A specialized form of task flow that, in contrast to the unbounded task flow, has a single entry point (an entry point is a view activity that can be directly requested by a browser) and zero or more exit points. It contains its own set of private control flow rules, activities, and managed beans. A bounded task flow allows reuse, parameters, transaction management, reentry, and can render within an ADF region in a JSF page.

For a description of the activity types that you can add to an unbounded or bounded task flow see Chapter 21, "Working with Task Flow Activities."

By default, JDeveloper proposes the following file name for the source file of a bounded task flow:

```
task-flow-definitionN.xml
```

where \( N \) is a number that increments each time that you create a new bounded task flow. You can choose a file name for the bounded task flow. For example, you might use `checkout-task-flow.xml` if the purpose of the bounded task flow is to allow customers to check out from a shopping application.

The source file contains the metadata for the bounded task flow. Multiple bounded task flows can be included within the same source file using the following metadata:

```
<task-flow-definition id="TaskFlowID1">
  ...
</task-flow-definition>
<task-flow-definition id="TaskFlowID2">
  ...
</task-flow-definition>
```

However, as JDeveloper’s visual editors show one bounded task flow per file, it makes the modification of bounded task flows easier if you do not include more than one bounded task flow within the same source file.

A typical application is a combination of the unbounded task flow and one or more bounded task flows. For example, JDeveloper, by default, creates an empty unbounded task flow (source file name is `adfc-config.xml`) when you create an application using the Fusion Web Application template. At runtime, the Fusion web application can call bounded task flows from activities that you added to the unbounded task flow.

As shown in Figure 20–2, the first activity to execute in an application is often a view activity within the unbounded task flow. A view activity represents a JSF page that displays as part of the application. The activity shown in Figure 20–2 starts with the Home view activity and then calls a bounded task flow. The `calltoLogin_taskFlow` activity calls a bounded task flow that enables a user to log into the application.

*Figure 20–2  Unbounded Task Flow Calling a Bounded Task Flow*
You can also design an application in which all application activities reside within the unbounded flow. This mimics a JSF application, but does not take advantage of bounded task flow functionality. To take full advantage of task flow functionality, use bounded task flows.

Table 20–1 describes the advantages that the control flow provided by ADF task flows offers over the control flow offered by JSF page flow. In certain scenarios you may need to use JSF page flow. For example, using phase listeners, as described in Section 27.4, "Customizing the ADF Page Lifecycle," involves using the JSF page flow’s faces-config.xml configuration file. In general, it is not recommended that you mix JSF page flow and ADF task flows in your application.

<table>
<thead>
<tr>
<th>JSF Page Flow</th>
<th>ADF Task Flow</th>
</tr>
</thead>
<tbody>
<tr>
<td>The entire application must be represented in a single page navigation file</td>
<td>The application can be broken up into a series of modular flows that call one another.</td>

<td>After you break up your application into task flows, you may decide to reuse task flows containing common functionality.</td>
</tr>
<tr>
<td></td>
<td>For more information, see Chapter 44, &quot;Reusing Application Components.&quot;</td>
</tr>
<tr>
<td>There is no shared memory scope between multiple requests except for session scope.</td>
<td>Shared memory scope (for example, page flow scope) enables data to be passed between activities within the task flow. Page flow scope defines a unique storage area for each instance of a bounded task flow.</td>
</tr>
</tbody>
</table>

20.1.1 About Unbounded Task Flows

A Fusion web application always contains an ADF unbounded task flow, which contains the entry point or points to the application. An entry point is a view activity that can be directly requested by a browser. A Fusion web application only has one unbounded task flow. By default, the source file for the unbounded task flow is the adfc-config.xml file. Although you can create additional source files for unbounded task flows, the application combines all source files at runtime into the adfc-config.xml file. Figure 20–3 displays the diagram for an unbounded task flow from an application. This task flow contains a number of view activities that are all entry points to the application.
You typically use the unbounded task flow instead of a bounded task flow if:

- You want to take advantage of ADF Controller features not offered by bounded task flows, such as bookmarkable view activities. For more information, see Section 21.2.2, "Bookmarking View Activities."
- The task flow will not be called by another task flow.
- The application has multiple points of entry. In Figure 20–3, the task flow can be entered through any of the pages represented by the view activity icons on the unbounded task flow.

The unbounded task flow cannot declaratively specify parameters. In addition, it cannot contain a default activity, an activity designated as the first to run in the unbounded task flow. This is because the unbounded task flow does not have a single point of entry. To perform any of these requires a bounded task flow.

In order to take advantage of completely declarative ADF Controller transaction and reentry support, use a bounded task flow rather than the unbounded task flow.

### 20.1.2 About Bounded Task Flows

An ADF bounded task flow is used to encapsulate a reusable portion of an application. A bounded task flow is similar to a Java method in that it:

- Has a single entry point
- May accept input parameters
- May generate return values
- Has its own collection of activities and control flow rules
- Has its own memory scope and managed bean lifespan (a page flow scope instance)

For more information about memory scopes, see Section 20.2.4, "What You May Need to Know About Memory Scope for Task Flows."

- Can determine whether or not it has an isolated data control frame

For more information about access to data control frames, see Section 24.2, "Sharing Data Controls Between Task Flows."

- Can define an activity as an exception handling activity
For more information about exception handling in bounded task flows, see Section 24.5, "Handling Exceptions in Task Flows."

The `createOrder` activity in Figure 20–3 is a call to a bounded task flow. The unbounded task flow can call a bounded task flow, but cannot be called by another task flow. A bounded task flow can call another bounded task flow, which can call another and so on. There is no limit to the depth of the calls.

Figure 20–4 shows a bounded task flow.

**Figure 20–4 Bounded Task Flow**

The reasons for creating a bounded task flow are:

- The bounded task flow always specifies a default activity, a single point of entry that must execute immediately upon entry of the bounded task flow.

  In Figure 20–4, this is the method call activity labeled `reconcileOrders`. Because it is the default activity, the method call activity is always invoked before the bounded task flow renders the page referenced by the `order` view activity.

- It is reusable. For example, it can be included in other applications requiring a process to manage or check out orders. The bounded task flow can also be reused within the same application.

- Any managed beans you use within a bounded can be specified in page flow scope, so are isolated from the rest of the application. These managed beans (with page flow scope) are automatically released when the task flow completes.

Table 20–2 summarizes the main features of a bounded task flows.
### Table 20–2 Bounded Task Flow Features

<table>
<thead>
<tr>
<th>Feature</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Well-defined boundary</td>
<td>A bounded task flow consists of its own set of private control flow rules, activities, and managed beans. A caller requires no internal knowledge of page names, method calls, child bounded task flows, managed beans, and control flow rules within the bounded task flow boundary. Input parameters can be passed into the bounded task flow, and return values can be passed out on exit of the bounded task flow. Data controls can be shared between task flows.</td>
</tr>
<tr>
<td>Single point of entry</td>
<td>A bounded task flow has a single point of entry, a default activity that executes before all other activities in the task flow. For more information, see Section 20.2.3, &quot;What You May Need to Know About the Default Activity in a Bounded Task Flow.&quot;</td>
</tr>
<tr>
<td>Page flow memory scope</td>
<td>You can specify page flow scope as the memory scope for passing data between activities within the bounded task flow. Page flow scope defines a unique storage area for each instance of a bounded task flow. Its lifespan is the bounded task flow, which is longer than request scope and shorter than session scope. For more information, see Section 20.2.4, &quot;What You May Need to Know About Memory Scope for Task Flows.&quot;</td>
</tr>
<tr>
<td>Addressable</td>
<td>You can access a bounded task flow by specifying its unique identifier within the XML source file for the bounded task flow and the file name of the XML source file. For more information, see Section 21.6.8, &quot;What Happens When You Add a Task Flow Call Activity.&quot;</td>
</tr>
<tr>
<td>Reuse</td>
<td>You can identify an entire group of activities as a single entity, a bounded task flow, and reuse the bounded task flow in another application within an ADF region. You can also reuse an existing bounded task flow simply by calling it. For example, one task flow can call another bounded task flow using a task flow call activity or a URL. In addition, you can use task flow templates to capture common behaviors for reuse across different bounded task flows. For more information, see Section 24.9, &quot;Creating Task Flow Templates.&quot;</td>
</tr>
<tr>
<td>Parameters and return values</td>
<td>A caller can pass input parameters to a bounded task flow and accept return values from it. For more information, see Section 22.3, &quot;Passing Parameters to a Bounded Task Flow.&quot; In addition, you can share data controls between bounded task flows. For more information, see Section 24.2, &quot;Sharing Data Controls Between Task Flows.&quot;</td>
</tr>
<tr>
<td>Transaction management</td>
<td>A bounded task flow can represent a transactional unit of work. You can declaratively specify options on the bounded task flow that determine whether, when entering the task flow, the task flow creates a new transaction, joins an existing one or is not part of the existing transaction. For more information, see Section 24.3, &quot;Managing Transactions in Task Flows.&quot;</td>
</tr>
<tr>
<td>Reentry</td>
<td>You can specify options on the bounded task flow that determine whether or not it can be reentered. For more information, see Section 24.4, &quot;Reentering Bounded Task Flows.&quot;</td>
</tr>
<tr>
<td>On-demand loading of metadata</td>
<td>Bounded task flow metadata is loaded on demand when entering a bounded task flow.</td>
</tr>
</tbody>
</table>
Understanding the assumptions and constraints listed in Table 20–3 will help you successfully use ADF task flows, activities and other associated ADF Controller features.

Table 20–3  ADF Controller Features Assumptions and Constraints

<table>
<thead>
<tr>
<th>Feature Area</th>
<th>Assumption/Constraint</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADF Controller objects and diagram UI</td>
<td>JSF view layer</td>
<td>ADF Controller operates in a JSF environment. Oracle’s web-based Fusion web application strategy focuses on JSF as the sole view layer technology.</td>
</tr>
<tr>
<td>Dependent on Oracle</td>
<td>ADF Faces</td>
<td>ADF Controller extensions are implemented on top of Oracle ADF Faces. They are dependent on the ADF Faces libraries, but ADF Controller can run against any JSF implementation, providing these libraries are present.</td>
</tr>
<tr>
<td>Navigation and state</td>
<td>ADF Controller</td>
<td>ADF Controller encapsulates both navigation and, to some extent, state management. JSF and the Servlet API are still available for the basic management of state at the application, session, and request levels.</td>
</tr>
<tr>
<td>Model layer</td>
<td>ADF Model layer</td>
<td>ADF Model layer is used to implement the application’s model layer.</td>
</tr>
<tr>
<td>Dependent on MDS</td>
<td>ADF Controller</td>
<td>ADF Controller metadata is stored in MDS. However, MDS is currently not capable of loading faces-config.xml. If the customization features that MDS provides are required, you should use ADF task flows exclusively in order to define managed beans and control flow rules.</td>
</tr>
<tr>
<td>No supported migration path from struts or model 1</td>
<td>There is no support for a migration from Struts or Model 1 to the ADF Controller. However, you can create a new bounded task flow based on selected pages in a JSF page flow. For more information, see Section 20.6.3, “How to Create a Task Flow from JSF Pages.”</td>
<td></td>
</tr>
</tbody>
</table>
About ADF Task Flows

### 20.1.3 About Control Flows

A task flow consists of activities and control flow cases that define the transitions between activities. Figure 20–5 shows a control flow rule, labeled toView2, that defines the transition between the ViewActivity1 and ViewActivity2 view activities. The ViewActivity1 view activity displays before the ViewActivity2 view activity when the task flow in Figure 20–5 executes.

---

**Table 20–3 (Cont.) ADF Controller Features Assumptions and Constraints**

<table>
<thead>
<tr>
<th>Feature Area</th>
<th>Assumption/Constraint</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bounded task flow</td>
<td>Exposed as page flow-scoped state</td>
<td>ADF Controller manages implementation of a page flow scoped-state. Any auto-management functions provided by the framework, such as back button support and state cleanup function, assume page flow-scoped data. In order for an application to fully implement such functions for all of its pages, the entire application should be exposed as an ADF bounded task flow, using nested bounded task flows as needed. The application should store any state requiring versioning within the page flow scope.</td>
</tr>
<tr>
<td>Page flow scope</td>
<td>Transactional boundaries</td>
<td>The developer will use ADF bounded task flows to manage transaction boundaries.</td>
</tr>
<tr>
<td>Page flow scope</td>
<td>Access availability within ADF lifecycle</td>
<td>An application cannot attempt to access the page flow scope early in the ADF lifecycle before ADF Controller is ready to provide it. Page flow scope is not guaranteed to be available for access until after Before and After listeners have executed on the Restore View phase. ADF Controller uses before and after listeners on the Restore View phase to synchronize the server side state with the request. This is where things such as browser back-button detection and bookmark dereference are handled.</td>
</tr>
<tr>
<td>Navigation</td>
<td>Navigation</td>
<td>When using ADF Controller task flows, perform all application navigation should be performed using ADF Controller control flow rules instead of using navigation rules in faces-config.xml. Although ADF Controller delegates navigation handling when no matching control flow cases are found in ADF Controller metadata, not all ADF Controller functionality is guaranteed to work correctly if navigation is performed by a non-ADF Controller NavigationHandler.</td>
</tr>
</tbody>
</table>
The task flow in Figure 20–5 also contains a method call activity (methodCall1) that invokes after the ViewActivity2 view activity and before the taskflowCall1 task flow call activity. In a task flow, you invoke an activity such as a method call activity before or after a page renders. Invoking a method call activity outside of a particular page can facilitate reuse because you can reuse the page in other contexts that do not require the method (for example, a different task flow). For more information about control flow rules, see Section 20.4, "Adding Control Flow Rules to Task Flows."

A wildcard control flow rule represents a control flow from-activity-id that contains a trailing wildcard (foo*) or a single wildcard character (*). Use the single wildcard character when you want to pass control from any activity in the task flow to the wildcard control flow rule. Alternatively, use a trailing wildcard when you want to constrain the activities that can pass control to the wildcard control flow rule.

In Figure 20–6, the wildcard control flow rule contains a single wildcard character, indicating that control can pass to the activities connected to it in the task flow diagram from any activity within the task flow.

The trailing wildcard in Figure 20–7 indicates that control flow can pass to the loginPage view from any valid source activity whose activity-id begins with the characters summit.
20.1.4 ADF Task Flow Use Cases and Examples

Figure 20–8 shows a screen from the Summit sample application for ADF task flows. End users of the screen invoke a task flow that displays a list of customers. Using controls exposed on the screen, end users can also invoke a task flow that allows them to create or to edit an order.

Task flows can also be used to secure your Fusion web application by reducing the number of access points that you expose to end users. For example, configure an unbounded task flow to display one page that provides navigation to the remaining pages in your application. Use bounded task flows for the remaining pages in the application. By setting the URL Invoke property of these bounded task flows to url-invoke-disallowed, your application has one access point (the page on the unbounded task flow). For more information about the URL Invoke property, see Section 21.6.4, "How to Call a Bounded Task Flow Using a URL." For more information about securing your Fusion web application, see Chapter 41, "Enabling ADF Security in a Fusion Web Application."

20.1.5 Additional Functionality for ADF Task Flows

You may find it helpful to understand other Oracle ADF features before you configure or use ADF task flows. Additionally, you may want to read about what you can do with your task flow configurations. Following are links to other functionality that may be of interest.
Task flows can invoke managed beans. For more information about defining managed beans for use with a task flow, the supported memory scopes, and other related information, see Section 20.2.4, "What You May Need to Know About Memory Scope for Task Flows" and Section 26.4, "Using a Managed Bean in a Fusion Web Application."

Task flows are reusable. For more information about reusing functionality in your application, see Chapter 44, "Reusing Application Components."

Task flows can be secured by defining the privileges that are required for someone to use it. For more information, see Chapter 41, "Enabling ADF Security in a Fusion Web Application."

You can extend the functionality that your task flows implement by writing custom code. For example, you can write a custom exception handler that a task flow passes control to when a task flow activity raises an exception. For more information, see Section 24.5.3, "How to Designate Custom Code as an Exception Handler."

Make sure when you write custom code that you do not import packages that are marked internal, as in the following example:

```java
import oracle.adfinternal.controller.*;
```

For information about the APIs that you can use to write custom code, see the following reference documents:

- Java API Reference for Oracle ADF Controller
- Java API Reference for Oracle ADF Faces

### 20.2 Creating a Task Flow

A task flow is made up of the task flow itself, plus a number of activities with control flow rules between those activities. In most cases, the majority of the activities are view activities which represent the different pages in the flow. When some method or operation needs to be called, for example before a page is rendered, you use a method call activity with a control flow case from that activity to the appropriate next activity. When you want to call another task flow, you use a task flow call activity. If the flow requires some sort of branching, you use a router activity. At the end of a bounded task flow, you use a return activity which allows the flow to exit and control is sent back to the flow that called this bounded task flow.

For more detailed information and procedures regarding the individual activities of a task flow, including the metadata created for each activity and additional configuration that you can set, see Section 20.3, "Adding Activities to a Task Flow."

### 20.2.1 How to Create a Task Flow

The processes for creating bounded and unbounded task flows are similar. The main difference is that you select the Create as Bounded Task Flow checkbox in the Create Task Flow dialog to create a bounded task flow.
Before you begin:

It may be helpful to have an understanding of what constitutes a task flow. For more information, see Section 20.2, "Creating a Task Flow."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

To create a task flow:

1. In the Applications window, right-click the project in which you want to create the task flow and choose New > ADF Task Flow.

2. In the Create Task Flow dialog, the Create as Bounded Task Flow checkbox is selected by default. Deselect it if you want to create a source file that will be incorporated into the application's unbounded task flow.

   Deselecting the checkbox automatically changes the default value in the File Name field. This value will be used to name the XML source file for the task flow you create. The XML source file contains metadata describing the activities and control flow rules in the task flow.

   **Tip:** The default name for the unbounded task flow is adfc-config.xml. The default name for the source file for a bounded task flow matches the value specified in the Task Flow ID field.

   Because a single project can contain multiple task flows, a number may be added to the default value in the File Name field in order to give the source file a unique name, for example, task-flow-definition3.xml.

3. In the Create Task Flow dialog, the Create with Page Fragments checkbox is selected by default.

   Deselect this checkbox if you want the view activities that you add to the task flow to reference JSF pages that render in the main browser window as the root page. Leave the Create with Page Fragments checkbox selected if you want the view activities that you add to the task flow to reference page fragments files (.jsff) that the task flow displays in an ADF region at runtime.

4. Click OK.

   A diagram representing the task flow appears in the editor.

   **Tip:** You can view a thumbnail of the entire task flow diagram by clicking the diagram and then choosing Window > Thumbnail from the main menu.

After you create the task flow, you can update it using the diagram, overview, and source editors. You can also use the Structure window to update the task flow.
5. In the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop an activity onto the diagram.

Normally, you would start with a view activity. For more detailed procedures for adding any type of activity, see Section 20.3.1, "How to Add an Activity to a Task Flow."

- If you drag a view activity onto the diagram, you can double-click it to display the wizard for the JSF page or page fragment that the task flow is configured to invoke. Use the wizard to define characteristics for the page or page fragment. For more information, see Section 21.2, "Using View Activities."

- If you drag a router activity onto the diagram, you can use the Properties window to create an expression whose evaluation determines which control flow rule to follow. For more information, see Section 21.4, "Using Router Activities."

- If you drag a method call activity onto the diagram, you can use the Properties window to configure the method to call. For more information, see Section 21.5, "Using Method Call Activities."

- If you drag a task flow call activity onto the diagram, you can double-click it to display the Create Bounded Task Flow dialog where you can define settings for a new bounded task flow. For more information, see Section 21.6, "Using Task Flow Call Activities."

- If you are creating a bounded task flow, and you drag a task flow return activity onto the diagram, you can use the Properties window to configure the activity. For more information, see Section 21.7, "Using Task Flow Return Activities."

6. Create control flow cases between the activities (for more information and detailed procedures, see Section 20.4.1, "How to Add a Control Flow Rule to a Task Flow"):

   a. In the ADF Task Flow page of the Components window, from the Component panel, in the Control Flow group, choose Control Flow Case.

   b. On the diagram, click a source activity, for example a view, and then click the destination activity. For example in Figure 20–14, two activities have been linked with a control flow. Both the source (view1) and the destination (view2) activities are linked.

   c. In the Properties window, expand the General section, and choose the outcome value using either the From Action attribute (if a method determines the outcome) or the From Outcome attribute (if the outcome can be set as a String).

7. If you are creating a bounded task flow, you may want to designate one of the activities as the default activity. This makes sure that this specific activity executes first whenever the bounded task flow runs. By default, JDeveloper makes the first
activity you add to the task flow the default. To change to a different activity, right-click the appropriate activity in the diagram and choose Mark Activity > Default Activity. For more information, see Section 20.2.3, "What You May Need to Know About the Default Activity in a Bounded Task Flow."

20.2.2 What Happens When You Create a Task Flow

A new XML source file is created every time you create a new unbounded or bounded task flow. By default, the XML source file for the unbounded task flow is called adfc-config.xml.

As shown in Example 20–1, <adfc-config> appears first as the top-level element in all ADF Controller XML source files. Bounded task flows, activities and control flow rules are defined inside the <adfc-config> element. Bounded task flows are identified within the source file by the <task-flow-definition> metadata element.

Example 20–1 Bounded Task Flow XML Source File

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2" id="__1">
  <task-flow-definition id="task-flow-definition">
    <use-page-fragments/>
  </task-flow-definition>
</adfc-config>
```

A bounded task flow is identified by its task flow reference, which is comprised of a unique combination of identifier and document name. Example 20–2 shows a sample task flow reference within a task flow call activity.

Example 20–2 Task Flow Reference

```xml
<adfc-config xmlns="http://xmlns.oracle.com/adf/Controller" version="1.2">
  <task-flow-definition id="task-flow-definition">
    <use-page-fragments/>
    ...
    <task-flow-call id="taskFlowCall">
      <task-flow-reference>
        <document>/WEB-INF/target-task-flow-definition.xml</document>
        <id>my-task-flow</id>
      </task-flow-reference>
    </task-flow-call>
    ...
  </task-flow-definition>
</adfc-config>
```

**Note:** If you use JDeveloper to create the bounded task flow, specify only one ID (indicating one bounded task flow) per document.

You assign both identifier and document name when you create the bounded task flow. As shown in Example 20–2, the identifier is the value in the Task Flow ID field. The document name is the value in the File Name field.
20.2.3 What You May Need to Know About the Default Activity in a Bounded Task Flow

The default activity is the first activity to execute in a bounded task flow. For example, the default activity always executes first when a task flow call activity passes control to the bounded task flow.

Unbounded task flows do not have default activities.

As shown in Figure 20–9, a green circle identifies the default activity in a task flow diagram.

The first activity that you add to a new bounded task flow diagram is automatically identified as the default activity. You can also right-click any activity in the task flow diagram and choose Mark Activity > Default Activity. The default can be any activity type and it can be located anywhere in the control flow of the bounded task flow. To find the default activity, right-click anywhere on the task flow diagram and choose Go to Default Activity.

A bounded task flow can have only one default activity. If you mark a second activity as the default, the first is unmarked automatically. To unmark an activity manually, right-click the activity in the task flow diagram and choose Unmark Activity > Default Activity.

You should not specify a train stop in the middle of a train as a default activity. For more information, see Section 24.8, "Using Train Components in Bounded Task Flows."

Example 20–3 contains sample metadata for a default activity called SurveyPrompt in a bounded task flow:

Example 20–3  Default Activity Metadata in a Bounded Task Flow

```
<task-flow-definition id="survey">
  <default-activity>SurveyPrompt</default-activity>
  <view id="SurveyPrompt">
    <page>/SurveyPrompt.jsff</page>
  </view>
  <use-page-fragments/>
</task-flow-definition>
```

20.2.4 What You May Need to Know About Memory Scope for Task Flows

Each task flow in your Fusion web application defines a pageFlow scope to manage state. The pageFlow scope begins when the task flow begins and ends when the task flow ends. A pageFlow scope defines a unique storage area for each instance of a task flow within an application which is used to pass data values between the activities in the task flow. When one task flow calls another, the calling task flow cannot access the called task flow’s pageFlow scope. This means, for example, that a UI component on a page referenced by a task flow’s view activity cannot access the pageFlow scope of...
another task flow even if this task flow is an ADF region embedded in the same page as the UI component.

You can define multiple managed beans with task flows. Figure 20–10 shows an example from the Summit ADF task flow sample application where a bounded task flow (customers-task-flow-definition.xml) references a managed bean with a backingBean scope. You can determine the scope assigned to a managed bean.

**Figure 20–10  Managed Bean Registered With Task Flow**

![Managed Bean Registered With Task Flow](image)

Table 20–4 lists available scopes for managed beans and describes when it is appropriate to use each scope in a managed bean that you define with a task flow. The table lists the scopes in order of their life span. For example, the application scope has a longer life span than the request scope. For more information about the life span of object scopes, see Section 27.3, "About Object Scope Lifecycles."

**Table 20–4  Memory Scope for ADF Managed Beans**

<table>
<thead>
<tr>
<th>Scope</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>application</td>
<td>The application scope lasts until the application stops. Values that you store in a managed bean with this scope are available to every session and every request that uses the application. Avoid using this scope in a task flow because it persists beyond the life span of the task flow.</td>
</tr>
<tr>
<td>session</td>
<td>The session scope begins when a user first accesses a page in the application and ends when the user’s session times out due to inactivity, or when the application invalidates the session. Use this scope only for information that is relevant to the whole session, such as user or context information. Avoid using it to pass values from one task flow to another. Instead, use parameters to pass values between task flows. Using parameters gives your task flow a clear contract with other task flows that call it or are called by it. Another reason to avoid use of session scope is because it may persist beyond the life span of the task flow. Finally, if an end user opens multiple browser windows within the same session, session scoped values are shared across these browser windows. Conflicts can occur between these browser windows.</td>
</tr>
<tr>
<td>pageFlow</td>
<td>Choose this scope if you want the managed bean to be accessible across the activities within a task flow. A managed bean that has a pageFlow scope shares state with pages from the task flow that access it. A managed bean that has a pageFlow scope exists for the life span of the task flow.</td>
</tr>
</tbody>
</table>
When you define a managed bean with a task flow, JDeveloper generates entries similar to the following in the task flow’s source file:

```xml
<managed-bean id="__15">
  <managed-bean-name id="__16">egBackingBean</managed-bean-name>
  <managed-bean-class id="__13">oracle....egBackingBean</managed-bean-class>
  <managed-bean-scope id="__14">backingBean</managed-bean-scope>
</managed-bean>
```

The `<managed-bean-scope>` element holds the value for the scope of the managed bean (backingBean in the example).

When you bind a UI component to a managed bean, JDeveloper appends `Scope` to the scope name in the EL expression that it generates to reference the managed bean. For example, the binding attribute of a table component that references the managed bean has the following EL expression:

```xml
<af:table id="cartTab">
  ...
  binding='#{backingBeanScope.egBackingBean.table}"
  ...
</af:table>
```

Restrict the scope of the managed bean that you reference through a UI component’s binding attribute to backingBean or request scope. Instances of UI components cannot be serialized. Objects in scopes other than backingBean and request are expected to be serializable. For this reason, you should not bind UI components to managed beans that have a scope other than backingBean or request. Note that JDeveloper defaults the binding attribute for UI components and region fragments to use the backingBean scope.

### Table 20–4 (Cont.) Memory Scope for ADF Managed Beans

<table>
<thead>
<tr>
<th>Scope</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>view</td>
<td>Use this scope for managed bean objects that are needed only within the current view activity and not across view activities. The life span of this scope begins and ends when the current <code>viewId</code> of a view port changes. If you specify view, the application retains managed bean objects used on a page as long as the user continues to interact with the page. These objects are automatically released when the user leaves the page. Both JSF and Oracle ADF have an implementation of this scope. In a Fusion web application, when you use view scope in an EL expression, it resolves to the Oracle ADF implementation.</td>
</tr>
<tr>
<td>request</td>
<td>Use request scope when the managed bean does not need to persist longer than the current request.</td>
</tr>
<tr>
<td>backingBean</td>
<td>A backing bean is a convention to describe a managed bean that stores accessors for UI components and event handling code on a JSF page. It exists for the duration of a request and should not be used to maintain state. Use this scope if it is possible that your task flow appears in two ADF regions on the same JSF page and you want to isolate each instance of ADF region. In scenarios where you have more than one task flow, consider using a naming convention that assigns a unique name to each managed bean. Adopting this approach makes sure that you do not attempt to put two managed beans with the same name from different task flows into backingBean scope.</td>
</tr>
</tbody>
</table>
20.2.5 What You May Need to Know About the Source Files for Task Flows

A single application can have multiple unbounded task flow XML source files and multiple bounded task flow XML source files. The set of files that combine to produce the unbounded task flow is referred to as the application’s *ADF Controller bootstrap configuration files*. The unbounded task flow is assembled at runtime by combining one or more ADF Controller bootstrap configuration files. All activities within the bootstrap configuration files that are not contained within a bounded task flow are considered to be within the unbounded task flow.

The names of the source files within a single application must be different. The example in Figure 20–11 contains two unbounded task flows (`adfc-config`, `adfc-config1`) and a bounded task flow (`task-flow-definition`).

![Figure 20–11  Application with Two Unbounded Task Flow XML Source Files](image)

20.3 Adding Activities to a Task Flow

After you create a task flow, you add activities to the task flow and configure the control flow between the activities. The Components window displays available activities and control flows. You drag and drop the activities and control flows from the Components window to the diagram for the task flow. You then configure control flow between the activities so that the task flow performs the task you want it to perform.

20.3.1 How to Add an Activity to a Task Flow

After you create a task flow, a task flow diagram and the Components window automatically display. The task flow diagram is a visual editor on which you can add the activities and control flows for the task flow. You can add them to the diagram by dragging them from the Components window.
Before you begin:

It may be helpful to have an understanding of what activities you can add to a task flow. For more information, see Section 20.3, "Adding Activities to a Task Flow."

You may also find it helpful to understand functionality that can be added to task flows using other Oracle ADF features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

To add an activity to a task flow:

1. In the Applications window, expand the WEB-INF node and double-click the task flow to which you want to add an activity.

   For example, Figure 20–12 shows the editor and the Components window that automatically appears when you double-click a task flow source file (task-flow-definition.xml).

   Figure 20–12 Task Flow Diagram

2. In the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop an activity onto the diagram.

   - If you drag a view activity onto the diagram, you can double-click it to display the wizard to create a JSF page or page fragment. For more information, see Section 21.2, "Using View Activities."
   
   - If you drag a task flow call activity onto the diagram, you can double-click it to display the Create Bounded Task Flow dialog where you can define settings for a new bounded task flow. For more information, see Section 21.6, "Using Task Flow Call Activities."
**Tip:** Each activity you drag to the task flow diagram can display optional status icons and a tooltip that provides additional information about the activity. For example, after you drag a view activity to the task flow diagram, it may display a warning icon until you associate it with a JSF page.

To turn on the icons, choose **Show** at the top of the task flow diagram, and then choose **Status** and one of the following:

- **Error:** Displays when there is a problem in the task flow metadata which prevents it from running. For example, a view activity in the metadata can contain a `<bookmark>` or `<redirect>` element, but not both.

- **Warning:** Displays when there is a problem in the task flow metadata that does not prevent the task flow from running.

- **Incomplete:** Displays when an activity is incomplete. For example, a view activity that does not have a physical page associated with it or a task flow call that does not have a task flow reference associated with it are both considered incomplete activities. The resulting task flow metadata may prevent it from running.

You can drag your mouse over a secondary icon to read a tooltip describing the icon’s meaning.

### 20.3.2 What Happens When You Add an Activity to a Task Flow

As shown in Figure 20–13, the Components window contains separate sections for components and diagram annotations. The contents of the **Components** section differ slightly depending on whether you are creating a bounded or an unbounded task flow. For example, if you are creating a bounded task flow, the **Components** section contains an additional task flow return activity.

**Figure 20–13** displays the activities you can add to an unbounded task flow.
20.4 Adding Control Flow Rules to Task Flows

An ADF Controller control flow rule defines how control passes from one activity to another in a task flow. A control flow rule can contain one or more control flow cases. A control flow case identifies the activity to which control flow passes. A control case also has options that allow you to configure conditional navigation (using the `<if>` element) and/or limit navigation based on the value of the action from where the control flow originates (using the `from-action` element).

An ADF Controller control flow rules are based on JSF navigation rules, but capture additional information. JSF navigation is always between pages, whereas control flow rules describe transitions between activities. For example, a control flow rule can indicate a transition between a view activity and a subsequent method call activity. Or, it can indicate that control passes from the page (view activity) to another task flow.

The following task flow activities cannot be the source of a control flow rule:

- Save Point Restore
- Task Flow Return
- URL View

The basic structure of a control flow rule mimics a JSF navigation rule. Table 20–5 describes how metadata maps from JSF navigation rules to ADF Controller control flow rules.

Table 20–5 Mapping of JSF Navigation Rules to ADF Controller Control Flow Rules

<table>
<thead>
<tr>
<th>JSF Navigation Rule</th>
<th>ADF Controller Control Flow Rule</th>
</tr>
</thead>
<tbody>
<tr>
<td>Navigation Rule</td>
<td>Control Flow Rule</td>
</tr>
<tr>
<td>From View ID</td>
<td>From Activity ID</td>
</tr>
<tr>
<td>Navigation Case</td>
<td>Control Flow Case</td>
</tr>
<tr>
<td>From Action</td>
<td>From Action</td>
</tr>
<tr>
<td>From Outcome</td>
<td>From Outcome</td>
</tr>
<tr>
<td>If</td>
<td>If</td>
</tr>
<tr>
<td>To View ID</td>
<td>To Activity ID</td>
</tr>
</tbody>
</table>

When using ADF task flows, perform all application navigation using ADF Controller control flow rules instead of using JSF navigation rules in the `faces-config.xml` file. ADF Controller delegates navigation handling when it does not find a matching control flow case in its metadata. However, not all ADF Controller functionality is guaranteed to work correctly if navigation is performed by a non-ADF Controller navigation handler. For more information about how ADF Controller evaluates control flow rules, see Section 20.4.4, "What Happens at Runtime: How Task Flows Evaluate Control Flow Rules."

Use the task flow diagram as a starting point for creating basic control flows between activities. Later, you can edit control flow properties in the Structure window, Properties window or overview editor for the task flow diagram.

**Tip:** You can drag and drop an activity onto an existing control flow. This splits the existing control flow into two, with the activity in the center.
20.4.1 How to Add a Control Flow Rule to a Task Flow

You create a control flow rule by dragging a Control Flow Case from the ADF Task Flow page of the Components window and dropping it on a source task flow activity and a target task flow activity.

**Before you begin:**

It may be helpful to have an understanding of what a control flow rule is. For more information, see Section 20.4, "Adding Control Flow Rules to Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, ‘Additional Functionality for ADF Task Flows.’

**To add a control flow rule to a task flow:**

1. In the Applications window, expand the WEB-INF node and double-click the task flow where you want to add a control flow rule.

2. In the ADF Task Flow page of the Components window, from the Component Panel, in the Control Flow group, select **Control Flow Case**.

3. On the diagram, click a source task flow activity and then click the destination task flow activity.

   In many cases, the source and destination task flow activities will be view activities. In Figure 20–14, two such task flow activities (view1) and (view2) have been linked with a control flow case.

4. To change the value of **From Outcome**, choose the text next to the control flow in the diagram and overwrite the default wildcard * character.

   A useful convention is to cast the control flow rule in the form toDestination or some other form that describes the purpose of the control flow rule. To define the control flow shown in Figure 20–14, for instance, you would overwrite the wildcard with toView2.

5. To change the values of **From Activity ID** (which identifies the source activity) or **To Activity ID** (which identifies the target activity), drag either end of the arrow in the diagram to a new activity.
Tip: After you choose the control flow in the task flow diagram, you can also change its properties in the Properties window or the Structure window. The Structure window is helpful for displaying the relationship between control rules and cases.

You can also click Control Flows on the overview editor for the task flow diagram to add cases, as shown in Figure 20–15. To add a case, make sure that the From Activity (source activity) and the To Activity (target activity) for the rule have already been added to the task flow.

**Figure 20–15 Control Flows on Overview Editor for the Task Flow**

6. Optionally, in the Properties window expand the Behavior section, and write an EL expression in the If field that must evaluate to true before control can pass to the activity identified by To Activity ID.

### 20.4.2 How to Add a Wildcard Control Flow Rule

You can add a wildcard control flow rule to an unbounded or bounded task flow. The steps for adding it are similar to those for adding any activity to a task flow diagram.

**Before you begin:**

It may be helpful to have an understanding of the control flow rule options available to you. For more information, see Section 20.4, "Adding Control Flow Rules to Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

**To add a wildcard control flow rule:**

1. In the Applications window, expand the WEB-INF node and double-click the task flow where you want to add a wildcard control flow rule.

2. In the ADF Task Flow page of the Components window, from the Component panel, in the Control Flow group, drag and drop a Wildcard Control Flow Rule onto the diagram.

3. In the ADF Task Flow page of the Components window, from the Component panel, in the Control Flow group, select Control Flow Case.

4. In the task flow diagram, drag the control flow case from the wildcard control flow rule to the target activity.

   The target can be any activity type.

5. By default, the label below the wildcard control flow rule is *. This is the value for the From Activity ID element. To change this value, select the wildcard control flow rule in the diagram. In the Properties window for the wildcard control flow rule, enter a new value in the From Activity ID field. A useful convention is to cast the wildcard control flow rule in a form that describes its purpose. For
example, enter `project*`. The wildcard must be a trailing character in the new label.

**Tip:** You can also change the From Activity ID value in the overview editor for the task flow diagram.

6. Optionally, in the Properties window expand the Behavior section, and write an EL expression in the If field that must evaluate to `true` before control can pass to the activity identified by To Activity ID.

### 20.4.3 What Happens When You Create a Control Flow Rule

Understanding the elements that define the rules in the source file for the task flow helps when creating control flow rules directly in the task flow diagram, task flow overview editor, or Structure window, or when adding them directly in the XML source file. Example 20–4 shows the general syntax of a control flow rule element in the task flow source file.

**Example 20–4  Control Flow Rule Syntax in the Source File**

```xml
<control-flow-rule>
  <from-activity-id>from-view-activity</from-activity-id>
  <control-flow-case>
    <from-action>actionmethod</from-action>
    <from-outcome>outcome</from-outcome>
    <to-activity-id>destinationActivity</to-activity-id>
    <if>#{myBean.someCondition}</if>
  </control-flow-case>
  <control-flow-case>....</control-flow-case>
</control-flow-rule>
```

Control flow rules can consist of the following metadata:

- **control-flow-rule**: A mandatory wrapper element for control flow case elements.

- **from-activity-id**: The identifier of the activity where the control flow rule originates, for example, `source`.

  A trailing wildcard (*) character in `from-activity-id` is supported. The rule applies to all activities that match the wildcard pattern. For example, `login*` matches any logical activity ID name beginning with the literal `login`. If you specify a single wildcard character in the metadata (not a trailing wildcard), the control flow automatically converts to a wildcard control flow rule activity in the diagram. For more information, see Section 20.4.2, "How to Add a Wildcard Control Flow Rule."

- **control-flow-case**: A mandatory wrapper element for each case in the control flow rule. Each case defines a different control flow for the same source activity. A control flow rule must have at least one control flow case.

- **from-action**: An optional element that limits the application of the rule to outcomes from the specified action method. The action method is specified as an EL binding expression, such as `#{backingBean.cancelButton_action}`.

  In Example 20–4, control passes to `destinationActivity` only if `outcome` is returned from `actionmethod`. 

20-24   Developing Fusion Web Applications with Oracle Application Development Framework
The value in from-action applies only to a control flow originating from a view activity, not from any other activity types. Wildcards are not supported in from-action.

- from-outcome: Identifies a control flow case that will be followed based on a specific originating activity outcome. All possible originating activity outcomes should be accommodated with control flow cases.

If you leave both the from-action and the from-outcome elements empty, the case applies to all outcomes not identified in any other control flow cases defined for the activity, thus creating a default case for the activity. Wildcards are not supported in from-outcome.

- to-activity-id: A mandatory element that contains the complete identifier of the activity to which the navigation is routed if the control flow case is performed. Each control flow case can specify a different to-activity-id.

- if: An optional element that accepts an EL expression as a value. If the EL expression evaluates to true at runtime, control flow passes to the activity identified by the to-activity-id element.

### 20.4.4 What Happens at Runtime: How Task Flows Evaluate Control Flow Rules

At runtime, task flows evaluate control flow rules from the most specific to the least specific match to determine the next transition between activities. Evaluation is based on the following priority, which is similar to that for JSF navigation rules:

1. from-activity-id, from-action, from-outcome
2. from-activity-id, from-outcome
3. from-activity-id

ADF Controller first searches for a match in all three elements: from-activity-id, from-action, and from-outcome. If there is no match, ADF Controller searches for a match in just the from-activity-id and from-outcome elements. Finally, ADF Controller searches for a match in the from-activity-id element alone.

If ADF Controller cannot find a control flow rule within its metadata to match a request, it allows the standard JSF navigation handler to find a match.

The unbounded task flow can have more than one ADF Controller XML source file. Because control flow rules can be defined in more than one ADF Controller XML source file, similar rules may be defined in different files. If there is a conflict in which two or more cases have the same from-activity-id, and the same from-action or from-outcome values, the last case (as listed in the adfc-config.xml, bootstrap, or bounded task flow source file) is used. If the conflict is among rules defined in different source files, the rule in the last source file to be loaded is used.

ADF Controller also implements the following interface with a number of restrictions:

`javax.faces.application.ConfigurableNavigationHandler`

The restrictions are:

- The Map object returned by `getNavigationCases()` is not modifiable. Any runtime changes to control flow rules must be made with the customization features provided with the MDS framework. For more information, see Chapter 45, “Customizing Applications with MDS.”

- Do not invoke the `performNavigation()` method after the JSF Invoke Application phase. This is to make sure that the view ID does not change between the ADF Prepare Render phase and the JSF Render Response phase. For more
Testing Task Flows

The metadata values for a task flow view activity’s Bookmark and Redirect properties populate the corresponding information for the navigation case objects returned by the `getNavigationCases()`.

20.5 Testing Task Flows

The procedure for running and debugging task flows differs depending on whether the task flow is bounded or unbounded, whether it contains pages or page fragments, or whether it accepts input parameters.

JDeveloper and Oracle ADF provides a number of features that facilitate your testing of the task flows that you create. Among these is the ability to set ADF declarative breakpoints on task flow activities. For more information, see Section 42.9.1, "How to Set and Use Task Flow Activity Breakpoints." In addition, you can also modify a task flow’s metadata for an application that is currently executing in the Integrated WebLogic Server. The changes that you make to the task flow can be deployed to the application without stopping the application and redeploying it to the Integrated WebLogic Server (also known as hot reloading). To do this, you invoke the make command on the modified task flow (right-click the task flow and choose Make). This deploys the modified task flow to the application executing in the Integrated WebLogic Server. For more information about hot reloading, see Section 42.4, "Reloading Oracle ADF Metadata in Integrated WebLogic Server."

The Configure Default Domain dialog appears the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

20.5.1 How to Run a Bounded Task Flow That Contains Pages

You can run or debug a bounded task flow that contains view activities that are pages.

For information on running a bounded task flow that contains view activities that are page fragments, see Section 20.5.2, "How to Run a Bounded Task Flow That Uses Page Fragments."

Before you begin:

It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Section 20.5, "Testing Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

To run or debug a bounded task flow that uses pages:

- In the task flow diagram, right-click the task flow and choose either Run or Debug.
- You can also run the task flow directly by entering its URL in the browser. For example:

For more information, see Section 21.6.6, "What You May Need to Know About Calling a Bounded Task Flow Using a URL."

In the Applications window, expand the WEB-INF node, right-click the bounded task flow and choose either Run or Debug.

20.5.2 How to Run a Bounded Task Flow That Uses Page Fragments

Bounded task flows that use page fragments are intended to run only within an ADF region. A page fragment is a JSF document that renders as content in another JSF page. For more information, see Section 23.1.1, "About Page Fragments and ADF Regions."

Before you begin:

It may help to understand what factors affect how you test a task flow. For more information, see Section 20.5, "Testing Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

You will need to complete these tasks:

1. Create a JSF page containing a region that binds to the bounded task flow. JDeveloper automatically creates the region for you in a JSF page when you drop a bounded task flow containing page fragments on a page. For more information about creating regions, see Section 23.2, "Creating an ADF Region."

2. Create a view activity in the project’s unbounded task flow that refers to the page. For more information, see Section 20.3.1, "How to Add an Activity to a Task Flow."

To run or debug a bounded task flow that uses page fragments:

Right-click the view activity in the Applications window or in the task flow diagram and choose Run.

20.5.3 How to Run a Bounded Task Flow That Has Parameters

Before you run a bounded task flow with parameters, you must first run a bounded task flow containing pages. For more information, see Section 20.5.2, "How to Run a Bounded Task Flow That Uses Page Fragments."

When you attempt to run or debug a bounded task flow with input parameters defined, the Set Run Configuration dialog appears, as shown in Figure 20–16. You enter values that you want to pass to the bounded task flow in this dialog and click OK. For more information about how to define input parameters for a bounded task flow, see Chapter 22, "Using Parameters in Task Flows."
Before you begin:
It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Section 20.5, "Testing Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

To run or debug a bounded task flow that has input parameter definitions:
1. In the diagram for the bounded task flow, right-click the task flow and choose either Run or Debug.

2. In the Input Parameters list of the Set Run Configuration dialog, enter values that you want to be passed as input parameters to the task flow. If you do not specify a value, the input parameter is not used when calling the bounded task flow.

   Each required input parameter in the list appears with an asterisk, as shown in Figure 20–16. You must specify the parameter value as a literal string. You cannot specify an EL expression.

3. Click OK.

20.5.4 How to Run a JSF Page When Testing a Task Flow
You can run a JSF page by right-clicking the page in the Applications window and choosing Run. However, if the page contains navigation UI components, such as a button or link, navigation is not guaranteed to work.

Before you begin:
It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Section 20.5, "Testing Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

You will need to complete these tasks:
1. Create a bounded or unbounded task flow.

   For more information, see Section 20.2.1, "How to Create a Task Flow."
2. Add a view activity to the task flow.
   For more information, see Section 20.3.1, "How to Add an Activity to a Task Flow."

**To run a JSF Page with fully functioning navigation:**
1. In the Applications window, drag the JSF page you want to run and drop it onto the view activity in the task flow diagram.
   This associates the view activity with the JSF page.
2. In the diagram, right-click the view activity and choose Run.

### 20.5.5 How to Run an Unbounded Task Flow

To run or debug an unbounded task flow, you choose a specific view activity with which to start the unbounded task flow.

**Before you begin:**
It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Section 20.5, "Testing Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

**To run a view activity in the unbounded task flow:**
- In the task flow diagram, right-click the view activity and choose either Run or Debug.
  The unbounded task flow runs beginning with the selected view activity.
- If you have selected something other than a single view activity (or have nothing selected), you are prompted to choose one in the Set Run Configuration dialog.

### 20.5.6 How to Set a Run Configuration for a Project

A run configuration contains settings that determine how projects run, such as specifying the first activity to run in a task flow. You can define one or more run configurations for a project. Within a run configuration, you can designate an ADF Controller source file as the default run target. When you run the project, the source file is the first to run.

**Before you begin:**
It may be helpful to have an understanding of the factors that affect how you test a task flow. For more information, see Section 20.5, "Testing Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

**To define a default task flow run target:**
1. In the Applications window, right-click the project where you want to define a default task flow run target and choose Project Properties.
2. In the Project Properties dialog, select Run/Debug and click New in the Run Configurations list.
3. In the Create Run Configuration dialog, enter the name for the new run configuration.

4. If you want to base the new configuration on an existing one, choose a configuration in the **Copy Settings From** dropdown list.

5. Click **OK** to exit the Create Run Configuration dialog.

6. In the Run Configurations list, click **Edit**.

7. In the **Default Run Target** field in the Edit Run Configuration dialog, specify a source file for the task flow that should run first when you run the project.

   Once you choose a task flow, you can set a view activity (for the unbounded task flow) or input parameters (for bounded task flows).

8. In the left panel of the Edit Run Configuration dialog, click **ADF Task Flow**.

9. In the **Task Flow** dropdown list, located on the right panel, choose the task flow containing the run target.

10. If you are running the unbounded task flow, the Edit Run Configuration dialog displays the **View Activity** dropdown list where you choose the view activity that runs first in the application, as shown in Figure 20–17.

    ![Edit Run Configuration Dialog](image)

11. Click **OK**.

    The next time you run the project, the saved run configuration will be available in the **Run > Choose Active Run Configuration** menu.

    If you are running a bounded task flow that has been set up to accept input parameters, a dialog displays a section for specifying values for all input parameters defined for the bounded task flow. For more information, see Section 20.5.3, "How to Run a Bounded Task Flow That Has Parameters."

### 20.5.7 What Happens at Runtime: Testing Task Flows

The behavior that you observe when you test a task flow may depend on a number of factors. For example, if you attempt to run or debug a bounded task flow with input parameters defined, the Set Run Configuration dialog appears. Also, if it is the first time that you attempt to test an application in this installation of JDeveloper, the
Configure Default Domain dialog appears so that you can start a new domain in Integrated WebLogic Server.

## 20.6 Refactoring to Create New Task Flows and Task Flow Templates

You can convert existing activities, JSF page flows, and JSF pages into new ADF Controller components such as bounded task flows and task flow templates.

### 20.6.1 How to Extract a Bounded Task Flow from an Existing Task Flow

You can create a new bounded task flow based on activities you choose in an existing bounded or unbounded task flow.

**Before you begin:**

It may be helpful to have an understanding of the factors that affect how you refactor a task flow. For more information, see Section 20.6, "Refactoring to Create New Task Flows and Task Flow Templates."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

To extract a bounded task flow from an existing task flow:

1. In the Applications window, expand the WEB-INF node and double-click the unbounded or bounded task flow containing the activities you want to extract to a new bounded task flow.

2. In the task flow diagram, select one or more activities.

   **Tip:** To select multiple activities in a diagram, click the left mouse button and drag the cursor over the activities.

   You can also press the Ctrl key while selecting each activity.

3. Right-click your selection and choose Extract Task Flow.

4. In the Extract Bounded Task Flow dialog, enter a file name for the new bounded task flow and enter the name of the directory that stores it.

   For more information about creating a bounded task flow, see Section 20.2, "Creating a Task Flow."

### 20.6.2 What Happens When You Extract a Bounded Task from an Existing Task Flow

The new bounded task flow that you extract displays in the task flow diagram. Table 20–6 describes the properties that JDeveloper automatically sets for the new bounded task flow.

<table>
<thead>
<tr>
<th>Property</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Task flow definition ID</td>
<td>Value you entered in the File Name field in the Extract Bounded Task Flow dialog.</td>
</tr>
<tr>
<td>Default activity</td>
<td>Determined as the destination of all incoming control flow cases. If more than one destination exists, an error is flagged and the entire operation is rolled back.</td>
</tr>
</tbody>
</table>
The following changes automatically occur in the originating task flow (the task flow containing the activities you selected as the basis for the new task flow):

- A new task flow call activity is added to the originating task flow. The task flow call activity calls the new bounded task flow.
- The selected activities are removed from the originating task flow.
- Existing control flow cases associated with the activities you selected are removed from the originating task flow. They are replaced with new control flow cases:
  - An incoming control flow case to the old activity is redirected to the new task flow call activity.
  - An outgoing control flow case from the old activity is redirected from the new task flow call activity.

### 20.6.3 How to Create a Task Flow from JSF Pages

You can create a new bounded task flow based on selected pages in a JSF page flow. JDeveloper converts the JSF pages that are part of a flow (that is, those that are linked by JSF navigation cases) to view activities in the new task flow.

**Before you begin:**

It may be helpful to have an understanding of the factors that affect how you refactor a task flow. For more information, see Section 20.6, "Refactoring to Create New Task Flows and Task Flow Templates."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

**To create a new task flow from selected JSF pages in a page flow:**

1. In the Applications window, double-click the page flow containing the pages you want to use in the new bounded task flow.
2. In the task flow diagram, select one or more JSF pages.
   
   **Tip:** To select multiple elements in a diagram, click the left mouse button and drag the cursor over the elements.
   
   You can also press the Ctrl key while selecting each element.
3. Right-click your selection and choose Generate ADF Task Flow.
The Create Task Flow dialog appears, which allows you to create a new unbounded or bounded task flow.

4. In the Create Task Flow dialog, enter a file name and directory for the task flow. Clear the Create as Bounded Task checkbox if you want to create an unbounded task flow.

For more information, see Section 20.2, "Creating a Task Flow."

5. Click OK.

20.6.4 How to Convert Bounded Task Flows

You can convert an existing bounded task flow to an unbounded task flow or change whether the views it contains are pages or page fragments. Table 20–7 describes the results of each conversion.

<table>
<thead>
<tr>
<th>Conversion</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bounded task flow to unbounded task flow</td>
<td>Loses all metadata not valid for unbounded task flows, such as parameter definitions and transactions.</td>
</tr>
<tr>
<td>Bounded task flow to use JSF pages</td>
<td>Converts page fragments associated with any view activities in the task flow to JSF pages. Old page fragments are saved if you select the Keep Page Fragment checkbox. New JSF page names default to the name of the old page fragment.</td>
</tr>
<tr>
<td>Bounded task flow to use page fragments</td>
<td>Converts all pages associated with view activities in the bounded task flow to page fragments. Old pages are saved if you select the Keep Page checkbox. New page fragment names default to the name of the old page</td>
</tr>
</tbody>
</table>

Before you begin:

It may be helpful to have an understanding of the factors that affect how you refactor a task flow. For more information, see Section 20.6, "Refactoring to Create New Task Flows and Task Flow Templates."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 20.1.5, "Additional Functionality for ADF Task Flows."

To convert a bounded task flow:

1. In the Applications window, expand the WEB-INF node and double-click the bounded task flow that you want to convert.

2. In the task flow diagram, right-click anywhere other than on an activity or a control flow.

3. Choose the appropriate menu option:
   - Convert to Unbounded Task Flow
   - Convert to Task Flow with Page Fragments
   - Convert to Task Flow with Pages
Refactoring to Create New Task Flows and Task Flow Templates
This chapter describes how to use activities in the ADF task flows that you create in your Fusion web application. The chapter contains detailed information about each task flow activity type that displays in the Components window in addition to describing the properties that you can configure for each task flow activity type.

This chapter includes the following sections:

- Section 21.1, "About Task Flow Activities"
- Section 21.2, "Using View Activities"
- Section 21.3, "Using URL View Activities"
- Section 21.4, "Using Router Activities"
- Section 21.5, "Using Method Call Activities"
- Section 21.6, "Using Task Flow Call Activities"
- Section 21.7, "Using Task Flow Return Activities"
- Section 21.8, "Using Task Flow Activities with Page Definition Files"

21.1 About Task Flow Activities

An activity represents a piece of work that is performed when the task flow runs. It displays in the task flow’s diagram editor as a node. You can add most activities to both bounded and unbounded task flows, although some activity types can be added only to bounded task flows.

Figure 21–1 shows the emp-reg-task-flow-definition.xml bounded task flow from the Summit sample application for ADF task flows. This task flow contains the following activities:

1. A method call activity that invokes a CreateInsert action
2. A view activity that renders a page fragment where end users can enter general information about the employee to be created
3. A view activity that renders a page fragment where a confirmation message appears if the end user successfully creates the new employee
About Task Flow Activities

Figure 21–1 Bounded Task Flow with Task Flow Activities

A task flow consists of activities and control flow cases that define the transitions between activities. Table 21–1 describes the types of activities and control flows you can add to a task flow by dragging and dropping from the Components window.

Table 21–1 Task Flow Activities and Control Flows

<table>
<thead>
<tr>
<th>Icon</th>
<th>Component Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><img src="image" alt="Method Call" /></td>
<td>Method Call</td>
<td>Invokes a method, typically a method on a managed bean. A method call activity can be placed anywhere within an application’s control flow to invoke application logic based on control flow rules. For more information, see Section 21.5, “Using Method Call Activities.”</td>
</tr>
<tr>
<td><img src="image" alt="Parent Action" /></td>
<td>Parent Action</td>
<td>Allows a bounded task flow to generate outcomes that are passed to its parent view activity. Typically used for a bounded task flow running in an ADF region that needs to trigger navigation of its parent view activity. For more information, see Section 23.7, “Navigating Outside an ADF Region’s Task Flow.”</td>
</tr>
<tr>
<td><img src="image" alt="Router" /></td>
<td>Router</td>
<td>Evaluates an EL expression and returns an outcome based on the value of the expression. For example, a router in a credit check task flow might evaluate the return value from a previous method call and generate success, failure, or retry outcomes based on various cases. These outcomes can then be used to route control to other activities in the task flow. For more information, see Section 21.4, “Using Router Activities.”</td>
</tr>
<tr>
<td><img src="image" alt="Save Point Restore" /></td>
<td>Save Point Restore</td>
<td>Restores a previous persistent save point, including application state and data, in an application supporting save for later functionality. A save point captures a snapshot of the Fusion web application at a specific instance. Save point restore enables the application to restore whatever was captured when the save point was originally created. For more information, see Section 24.7, “Using Save Points in Task Flows.”</td>
</tr>
<tr>
<td><img src="image" alt="Task Flow Call" /></td>
<td>Task Flow Call</td>
<td>Calls a bounded task flow from the unbounded task flow or another bounded task flow. For more information, see Section 21.6, “Using Task Flow Call Activities.”</td>
</tr>
<tr>
<td><img src="image" alt="Task Flow Return" /></td>
<td>Task Flow Return</td>
<td>Identifies when a bounded task flow completes and sends control flow back to the caller. (Available for bounded task flows only). For more information, see Section 21.7, “Using Task Flow Return Activities.”</td>
</tr>
</tbody>
</table>

<td>Note Attachment</td>
<td>Attaches an existing note to an activity or a control flow case in the diagram.</td>
</tr>
</tbody>
</table>

21.1.1 Task Flow Activities Use Cases and Examples

Figure 21–2 shows the diagram for the customer task flow in the Summit ADF task flow sample application. This task flow uses a number of the activities that a bounded task flow supports in order to complete a task. For more information about the Summit ADF sample applications, see Chapter 2, "Introduction to the ADF Sample Application."
21.1.2 Additional Functionality for Task Flow Activities

You may find it helpful to understand other Oracle ADF features before you configure or use task flow activities. Additionally, you may want to read about what you can do with your configured task flows. Following are links to other functionality that may be of interest.

- Task flows can invoke managed beans. For more information about managed beans, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."
- Bounded task flows can be secured by defining the privileges that are required for someone to use them. For more information, see Section 41, "Enabling ADF Security in a Fusion Web Application."
- Bounded task flows can be packaged in ADF Library JARs. For more information, see Section 44.2, "Packaging a Reusable ADF Component into an ADF Library."
- Task flow activities can be associated with page definition files. For more information about page definition files, see Section 17.7, "Working with Page Definition Files."

21.2 Using View Activities

One of the primary types of task flow activity is the view activity. A view activity displays a JSF page or page fragment. A page fragment is a JSF document that renders as content in another JSF page. Page fragments are typically used in bounded task flows that can be added to a JSF page as a region, as described in Section 23.2, "Creating an ADF Region."

Figure 21–3 shows the index view activity in the Summit ADF task flow sample application.
XML metadata in the source file of the task flow associates a view activity with a physical JSF page or page fragment. An id attribute identifies the view activity. The <page> element identifies the page or page fragment's file name. Example 21–1 shows the metadata that corresponds to the view activity in Figure 21–3:

Example 21–1 Metadata for a View Activity

```xml
<view id="index">
  <page>/index.jsf</page>
</view>
```

The view activity ID and page name do not have to be the same.

The steps for adding a view activity to a task flow are the same as those for adding any activity to a task flow diagram. For more information, see Section 20.3.1, "How to Add an Activity to a Task Flow." After you add the view activity, you can double-click it to display a wizard that allows you to create a new page or page fragment. The wizard allows you to choose between one of the following two document types for the JSF page or page fragments that you create:

- Facelets
  The file extension for pages in this document type is .jsf and .jsff for page fragments.

- JSP XML
  The file extension for pages in this document type is .jspx and .jsff for page fragments.

Use one document type only in your task flows. For example, do not use the Facelets document type for view activities in one task flow and the JSP XML document type for view activities in another task flow. For more information about the document types, see Section 1.3.7, "Implementing the User Interface with JSF."

You also use the wizard to choose the page layout for the page or page fragment that you create. For more information about page layouts, see the "Using Quick Start Layouts" section in Developing Web User Interfaces with Oracle ADF Faces. In addition, you can specify whether or not to automatically expose UI components on the page or page fragment in a managed bean. For more information, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

After you complete the wizard, JDeveloper automatically associates the completed page or page fragment with the view activity. As an alternative to using the wizard, you can associate a page or page fragment with a view activity by dragging an existing...
page or page fragment from the Applications window and dropping it on top of an existing view activity. If no view activity exists, drag a page or page fragment to any other location on the diagram. When you drop the page or page fragment, JDeveloper automatically creates a new view activity associated with the page or page fragment. During creation, a default id for the view activity is automatically generated (for example index) based on the name of the page or page fragment.

### 21.2.1 Passing Control Between View Activities

You can configure view activities in your task flow to pass control to each other at runtime. For example, to pass control from one view activity (view activity A) to a second view activity (view activity B), you could configure a command component (a button or a link) on the page associated with view activity A. Set the command component’s **Action** attribute to the control flow case *from-outcome* that corresponds to the task flow activity that you want to invoke (for example, view activity B). At runtime, the end user initiates the control flow case by invoking the command component. You can navigate from a view activity to another activity using either a constant or dynamic value on the **Action** attribute of the UI component.

A constant value of the component’s **Action** attribute is an action outcome, as shown in **Figure 21–4**, that always triggers the same control flow case. When an end user clicks the component, the activity specified in the control flow case is performed. There are no alternative control flows.

**Figure 21–4  Edit Property dialog**

A dynamic value of the component’s **Action** attribute is bound to a managed bean or a method. The value returned by the method binding determines the next control flow case to invoke. For example, a method might verify user input on a page and return one value if the input is valid and another value if the input is invalid. Each of these different action values trigger different navigation cases, causing the application to navigate to one of two possible target pages.

You can also write an EL expression that must evaluate to `true` before control passes to the target view activity. You write the EL expression as a value for the `<if>` child element of the control flow case in the task flow. For more information, see Section 20.4.1, "How to Add a Control Flow Rule to a Task Flow."

#### 21.2.1.1 How to Pass Control Between View Activities

You pass control to a view activity by specifying the value of the control flow case’s *from-outcome* attribute as the value for the *action* attribute of the command component.
Before you begin:
It may be helpful to have an understanding of the options that are available to you when you configure the passing of control between view activities. For more information, see Section 21.2.1, "Passing Control Between View Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

You will need to complete these tasks:
- Create a target view activity to receive control after an end user invokes the command component at runtime
- Create a JSF page that will host a command component for the end user to invoke at runtime

To pass control to a view activity:
1. In the Applications window, double-click the JSF page.
2. In the editor window, use one of the following options to add a UI component to the JSF page:
   - In the ADF Faces page of the Components window, from the General Controls panel, drag a navigation UI component, such as Button or Link, and drop it onto the page.
   - From the Data Controls panel, drag and drop an operation or a method onto the JSF page and, from the context menu, choose ADF Button or ADF Link.
3. In the Properties window, expand the Common section, and select Edit in the dropdown menu that you invoke from the icon that appears when you hover over the Action property field.
4. In the Edit Property: Action dialog, select Action Outcome and choose a value from the associated dropdown list.

The list contains the control flow case already defined for the view activity associated with the page.

Tips: The action attribute of the UI component can be bound either to a literal string to hard code a navigation case, or it can be bound to a method binding expression that points to a method, which takes no arguments and returns a String. It cannot be bound to any other type of EL expression.

21.2.1.2 What Happens When You Pass Control Between View Activities
Example 21–2 contains an example of a control flow case defined in the XML source file for a bounded or unbounded task flow.

Example 21–2 Control Flow Case Defined in XML Source File
<control-flow-rule>
   <from-activity-id>Start</from-activity-id>
   <control-flow-case>
      <from-outcome>toOffices</from-outcome>
      <to-activity-id>WesternOffices</to-activity-id>
   </control-flow-case>
</control-flow-rule>
As shown in Example 21–3, a button on a JSF page associated with the Start view activity specifies `toOffices` as the `action` attribute. When the user clicks the button, control flow passes to the `WesternOffices` activity specified as the `to-activity-id` in the control flow metadata.

Example 21–3  Static Navigation Button Defined in a View Activity

```
<af:button text="Go" id='b1' action='toOffices'>
```

### 21.2.2 Bookmarking View Activities

Bookmarking is available only for view activities within unbounded task flows. When an end user bookmarks a page associated with a view activity, the URL that displays in the browser’s address field for the view is saved as the bookmark. In most cases, this URL cannot be used to redisplay the page associated with the view. For example, the URL may contain state information that cannot be used to redisplay the page.

The bookmark URL should contain information that enables dynamic content on the page to be reproduced. For example, if an end user bookmarks a page displaying a customer's contact information, the bookmark URL needs to contain not only the page but also some identifier for the customer. This enables contact information for the same customer to display when the customer returns to the page using the bookmark.

To make sure that the URL for a page displayed in a browser can be used as a bookmark, identify the view activity associated with the page as bookmarkable.

At runtime, you can identify if a view activity within the unbounded task flow has been designated as bookmarkable using the `isViewBookmarkable()` method. The method is located off the view port context.

After you designate a view activity as bookmarkable, you can optionally specify one or more URL parameters. The value of `url-parameter` is an EL expression. The EL expression specifies where the parameters that will be included in the URL are retrieved when the bookmarkable URL is generated. The EL expression also stores a value from the URL when the bookmarkable URL is dereferenced. The `converter` option identifies a method that performs conversion and validation when parameters are passed via bookmarkable view activity URLs.

In addition, you can specify an optional method that is invoked after updating the application model with submitted URL parameter values and before rendering the view activity. You can use this method to retrieve additional information based on URL parameter key values.

Example 21–4 contains the URL syntax for a bookmarked view activity.

Example 21–4  Unbounded Task Flow View Activity URL Syntax

```
<server root>/<app_context>/faces/<view activity id>?<param name>=<param value>&...
```

The syntax of the URL for the bookmarked view activity is:

- `<server root>`: Provided by customization at site or admin level, for example, http://mycompany.com/internalApp.
- `<app context>`: The web application context root, for example, myapp. The context root is the base path of a web application. For example, `<app_context>` maps to the physical location of the WEB-INF node on the server.
faces: The Faces servlet mapping. The value in faces points to the node containing the faces-config.xml configuration file.

<view activity id>: The identifier for the bookmarked view activity, for example, edit-customers.

<param name>: The name of the bookmarked view activity URL parameter, for example, customer-id.

<param value>: The parameter value, derived from an EL expression, for example, #{pageFlowScope.employee.id}. The value of the EL expression must be capable of being represented as a string.

Example 21–5 contains a sample URL for a bookmarkable view activity in an unbounded task flow.

**Example 21–5  Sample URL for Bookmarkable View Activity**

21.2.2.1 How to Create a Bookmarkable View Activity

To create a bookmarkable view activity, designate a view activity as bookmarkable, specify a URL parameter in the bookmark, and specify a method that is executed after the bookmark is dereferenced.

Before you begin:

It may be helpful to have an understanding of the syntax required to create a bookmarkable view activity. For more information, see Section 21.2.2, "Bookmarking View Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

To designate a view activity as bookmarkable:

1. In the Applications window, expand the WEB-INF node and double-click the unbounded task flow where you want to designate a view activity as bookmarkable.

2. In the diagram for the unbounded task flow, choose the view activity that you want to designate as bookmarkable.

3. In the Properties window, expand the Bookmark section, and select true from the Bookmark dropdown list.

4. Enter an EL expression in the Method field to specify a method to invoke after ADF Controller updates the application model with the corresponding bookmark URL parameter values.

5. To add optional URL parameters to include in the URL for the bookmarked view activity, click Add and enter the URL parameter in the Bookmark URL Parameters list:

   - **Name**: the name for the URL parameter.

   - **Value**: A settable EL expression that, when evaluated, specifies the parameter value, for example, #{pageFlowScope.employeeID}. The value must be capable of being represented as a string.
The value property is where the parameters to include in the URL are retrieved from when the bookmarkable URL is generated. In addition, parameters are stored here when the bookmarkable URL is dereferenced. If the EL expression returns NULL, the parameter is omitted from the bookmarked view activity URL. Example 21-5 shows how name and value are used to append a bookmark parameter to a view activity URL.

- **Converter** (optional) Enter a value binding for the bookmark URL parameter value, for example: #{pageFlowScope.employee.idConverter}.

The object that the EL expression references must implement: oracle.adf.controller.URLParameterConverter

A URL parameter converter's `getAsObject()` method takes a single string value as its input parameter and returns an object of the appropriate type. ADF Controller invokes the converter method on the URL parameters before applying the parameter value to the application's model objects. Similarly, the URL parameter converter's `getAsString()` method takes an object as its input parameter and returns a string representation that is used on the URL.

In a JSF application, data values are converted and validated using the converters and validators specified with the UI components on the submitting page. In a Fusion web application using a bookmarkable URL, there is no submitting page to handle conversion and validation. Therefore, you have the option of designating a converter to use for each URL parameter.

### 21.2.2.2 What Happens When You Designate a View as Bookmarkable

When you designate a view activity as bookmarkable, a bookmark element is added to the metadata for the view activity, as shown in Example 21–6. The bookmark element can optionally contain metadata specifying URL parameters and a method to execute after the bookmark is dereferenced.

**Example 21–6 Sample Metadata for a Bookmarkable View Activity**

```xml
<view id="employee-view">
    <page>/folderA/folderB/display-employee-info.jsf</page>
    <bookmark>
        <url-parameter>
            <name>employee-id</name>
            <value>#{pageFlowScope.employee.id}</value>
            <converter>#{pageFlowScope.employee.validateId}</converter>
        </url-parameter>
        <method>#{pageFlowScope.employee.queryData}</method>
    </bookmark>
</view>
```

### 21.2.3 Specifying HTTP Redirect for a View Activity

You can configure a view activity so that it redirects at runtime to a URL in response to a client request. This causes ADF Controller to create a new browser URL for the view activity. The original URL for the view activity is no longer used. You cannot configure HTTP redirect for a view activity if you have already made the view activity bookmarkable, as described in Section 21.2.2, "Bookmarking View Activities."

#### 21.2.3.1 How to Specify HTTP Redirect for a View Activity

You set a view activity’s `redirect` property to `true`. 
Before you begin:
It may be helpful to have an understanding of the affect of setting a view activity’s redirect property to true. For more information, see Section 21.2.3, "Specifying HTTP Redirect for a View Activity."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

To specify HTTP redirect for a view activity:
1. In the Applications window, expand the WEB-INF node and double-click the task flow.
2. In the task flow diagram, select the view activity.
3. In the Properties window, expand the General section, and in the Redirect dropdown list, select true.

21.2.3.2 What Happens When You Specify HTTP Redirect for a View Activity
The ADF Controller issues an HTTP redirect in response to a view activity request. The redirected request creates a new browser URL for the view activity. The original view URL is no longer used.

When specified, a HTTP redirect occurs in response to a client GET request. For a client GET, the #{bindings} EL scope is invalid until ADF Controller and ADF Model set up a new bindings context for the page. Therefore, you cannot use EL expressions, such as the following, for view activities for which you specified HTTP redirect:

#{bindings.foo}

Note: If you want http://www.mycompany.org/x.html to instead display what is at http://www.mycompany.org/y.html, do not use refresh techniques such as:

<META HTTP-EQUIV=REFRESH CONTENT="1;
URL=http://www.example.org/bar">

This technique could adversely affect back button behavior. If an end user clicks a browser back button, the refresh occurs again, and navigation is forward, not backward as expected.

In this situation, use HTTP redirect instead.

21.3 Using URL View Activities
You can use a URL view activity to redirect the root view port (for example, a browser page) to any URL-addressable resource, even from within the context of an ADF region. URL addressable resources include:

- Bounded task flows
- View activities in the unbounded task flow
- Addresses external to the current web application (for example, http://www.oracle.com)

To display the resource, you specify an EL expression that evaluates at runtime to generate the URL to the resource. In addition, you can specify EL expressions that, when evaluated, are added as parameters and parameter values to the URL.
A URL view activity redirects the client regardless of the view port (root view port or an ADF region) from which it is executed. The \texttt{<redirect>} element of a view activity performs in a similar way, except that it can be used only if the view activity is within the root view port. The \texttt{<redirect>} element is ignored within the context of an ADF region. For more information, see Section 21.2.3, "Specifying HTTP Redirect for a View Activity".

Redirecting elsewhere within the same application using URL view activities (not the \texttt{<redirect>} element) is handled similarly to back button navigation since the task flow stack is cleaned up. Redirecting out of the web application is handled like dereferencing a URL to a site external to the application.

### 21.3.1 How to Add a URL View Activity to a Task Flow

You can add a URL view activity to a bounded or unbounded task flow.

**Before you begin:**

It may be helpful to have an understanding of the effect of adding a URL view to the functionality of a task flow. For more information, see Section 21.3, "Using URL View Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

**To add a URL view activity to a task flow:**

1. In the Applications window, expand the \texttt{WEB-INF} node and double-click the task flow to which you want to add a URL view activity.

2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a \texttt{URL View} onto the diagram.

3. In the Properties window, expand the \texttt{General} section, and enter an ID that identifies the URL view activity in the \texttt{Activity ID} field.

4. In the \texttt{URL} field, enter an EL expression that returns the URL at runtime. Click the icon that appears when you hover over the property field to use the Expression Builder if needed.

   For example, Figure 21–5 shows a URL activity (\texttt{register}) in an application’s \texttt{myorders-task-flow.xml} bounded task flow with an EL expression (\texttt{#{myOrdersBean.registerNav}}) that retrieves a URL at runtime.

**Figure 21–5  URL View Activity**

5. Expand the \texttt{URL Parameters} section to add optional URL parameters to include in the URL:
■ **Name:** A name for the parameter.

■ **Value:** An EL expression that, when evaluated, generates the parameter value.

■ **Converter:** A settable EL expression that, when evaluated, specifies a method to perform conversion and validation when parameters are passed via bookmarkable view activity URLs. For more information, see Section 21.2.2, “Bookmarking View Activities.”

### 21.3.2 What Happens When You Add a URL View Activity to a Task Flow

JDeveloper writes entries similar to those shown in Example 21–7 for the URL view activity in the source file of the task flow.

**Example 21–7 Sample Metadata for URL View Activity**

```xml
<url-view id='register'>
    <url>${myOrdersBean.registerNav}</url>
</url-view>
```

### 21.3.3 What You May Need to Know About URL View Activities

Task flow URL view activities can be used within JSF portlets. Create the URL using one of the following options if you configure a task flow URL view activity for use within a JSF portlet:

■Invoke one of the following methods from the ControllerContext class in the oracle.adf.controller package:
  - `getLocalViewActivityURL()`
  - `getGlobalViewActivityURL()`

Do not invoke the `encodeActionURL()` method from the ADFPortletContainerExternalContext class with the response from the `getLocalViewActivityURL()` or `getGlobalViewActivityURL()` methods before you invoke the `redirect()` method from the ADFPortletContainerExternalContext class. The `getLocalViewActivityURL()` and `getGlobalViewActivityURL()` methods both perform the necessary encoding of the URL.

■ Supply a fully qualified absolute URL.

■ Supply a context path relative URL.

■ Supply a URL relative to the current view.

A task flow URL view activity in a JSF portlet behaves as follows:

■ If the redirect URL refers to a location in the JSF portlet application and does not contain a queryString parameter named x_DirectLink with a value of true, the portlet in the containing page navigates to the URL specified in the URL view activity.

■ Otherwise, the client redirects to the URL specified in the URL view activity.

For more information about using a task flow’s URL view activity, see Section 21.3, “Using URL View Activities.”

For information about the methods that you can use to get a URL, see the following reference document:

■ *Java API Reference for Oracle ADF Controller*
21.4 Using Router Activities

Use a router activity to route control to activities based on the runtime evaluation of EL expressions. Figure 21–6 shows a router activity (isCustomerLogin) in the customer-task-flow-definition.xml task flow from the Summit ADF task flow sample application that can branch to different control flows leading from it to different activities.

![Figure 21–6 Router for Alternate Control Flow Cases](image)

Each control flow corresponds to a different router case. Each router case uses the following elements to choose the activity to which control is next routed:

- **expression**: an EL expression that evaluates to true or false at runtime.
  - The router activity returns the outcome that corresponds to the EL expression that returns true.

- **outcome**: a value returned by the router activity if the EL expression evaluates to true, for example, customerLogin.
  - If the router case outcome matches a from-outcome on a control flow case, control passes to the activity that the control flow case points to. If none of the cases for the router activity evaluate to true, or if no router activity cases are specified, the outcome specified in the router Default Outcome field (if any) is used.

Figure 21–6, for example, shows a router activity that passes control flow based on the evaluation of an EL expression that determines if the user is logged in and has a specific application role. If true, control passes to the setCurrentRowWithKeyValue method call activity. Otherwise, control passes to the Customers view activity.
**Best Practice:**

Use a router activity if your routing condition can be expressed in an EL expression.

Using a router activity allows you to do more when you design the task flow that contains it. The router activity allows you to show more information about the condition on the task flow. This makes it more readable and useful to someone who looks at the diagram for your task flow.

Using a router activity also makes it easier to modify your application later. For example, you may want to modify or add a routing condition later.

### 21.4.1 How to Configure Control Flow Using a Router Activity

You define a control flow by dragging a router activity from the Components window to the diagram for the task flow. You configure the Activity ID and Default Outcome properties of the router activity and add router cases to the router activity.

**Before you begin:**

It may be helpful to have an understanding of the properties of a router activity that can affect functionality. For more information, see Section 21.4, "Using Router Activities.”

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities.”

**To configure control flow using the router activity:**

1. In the Applications window, expand the WEB-INF node and double-click the task flow where you want to configure a control flow using a router activity.

2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a Router activity onto the diagram.

3. In the Properties window, expand the General section and enter values for the following:
   - **Activity ID**: write a value that identifies the router activity in the task flow’s source file.
   - **Default Outcome**: specify an activity that the router activity passes control to if no control flow cases evaluate to true or if no control flow case is specified.

4. Click the Add icon for the Cases section and specify values for each router case that you add:
   - **Expression**: An EL expression that evaluates to true or false at runtime.
     For example, to reference the value in an input text field of a view activity, write an EL expression similar to the following:
     
     ```
     #{pageFlowScope.value==‘view2’}
     ```
     If this EL expression returns true, the router activity invokes the outcome that you specify in the Outcome field.
21.4.2 What Happens When You Configure Control Flow Using a Router Activity

JDeveloper writes values to the source file of the task flow based on the values that you specify for the properties of the router activity. Example 21–8 shows the values that appear in the customer-task-flow-definition.xml task flow from the Summit ADF task flow sample application that branch to different control flows leading from the router activity to different activities.

At runtime, the router activity passes control to the control flow case specified by outcome if the EL expression returns true.

Example 21–8 Router Activity in the Summit ADF Task Flow Sample Application

```xml
<router id="isCustomerLogin">
    <case id="__4">
        <expression>#{securityContext.userInRole['Application Customer Role']}</expression>
        <outcome>customerLogin</outcome>
    </case>
    <default-outcome>notCustomerLogin</default-outcome>
</router>
```

21.5 Using Method Call Activities

Use a method call activity to call a custom or built-in method that invokes application logic from anywhere within an application's control flow. You can specify methods to perform tasks such as initialization before displaying a page, cleanup after exiting a page, exception handling, and so on.

Figure 21–7 shows the customers-task-flow-definition.xml task flow from the Summit ADF task flow sample application where the SetCurrentRowWithKeyValues method call activity invokes a setCurrentRowWithKeyValues operation from the BackOfficeAppModuleDataControl data control.
You can set an outcome for the method that specifies a control flow case to pass control to after the method finishes. You can specify the outcome as either:

- **fixed-outcome**: On successful completion, the method always returns this single outcome, for example, **success**. If the method does not complete successfully, an outcome is not returned. If the method type is void, you must specify a fixed-outcome, not a to-string.

- **to-string**: If specified as true, the outcome is based on calling the `toString()` method on the Java object returned by the method. For example, if `toString()` returns `editBasicInfo`, navigation goes to a control flow case named `editBasicInfo`.

**Example 21–9** shows the metadata for the method call activity in Figure 21–7 where the fixed-outcome element specifies `setCurrentRowWithKey` as the outcome to return.

**Example 21–9  Method Call Activity Metadata with Return and Outcome Elements**

```xml
<method-call id="setCurrentRowWithKeyValue">
  <method>${bindings.setCurrentRowWithKeyValue.execute}</method>
  <outcome>
    <fixed-outcome>setCurrentRowWithKey</fixed-outcome>
  </outcome>
</method-call>
```

For more information about control flows, see Section 20.1.3, "About Control Flows."

### 21.5.1 How to Add a Method Call Activity

Drag a method call activity from the Components window to the task flow diagram. You can associate the method call activity with an existing method by dropping a data control operation from the Data Controls panel directly onto the method call activity in the task flow diagram.

In the Summit ADF task flow sample application, for example, you could drag a `setCurrentRowWithKey` or `setCurrentRowWithKeyValues` operation to the diagram from the `BackOfficeAppModuleDataControl` data control in the Data
Controls panel to create a method call activity that displays or selects the current row in a table.

---

**Note:** Parameters for data control method parameters are defined in the page definition for the corresponding page rather than within ADF Controller metadata.

---

You can also drag methods and operations directly to the task flow diagram. A new method call activity is created automatically after you drop it on the diagram. You can specify an EL expression and other options for the method.

**Tip:** To identify the method that a method call activity invokes, right-click the method call activity in the diagram of the task flow and choose Go to Method. JDeveloper navigates to the method that the method call activity invokes.

**Before you begin:**

It may be helpful to have an understanding of how the properties of a method call activity affect the functionality of a task flow. For more information, see Section 21.5, "Using Method Call Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

You will need to complete this task:

- Create a bounded or unbounded task flow. For more information, see Section 20.2, "Creating a Task Flow."

**To add a method call activity to a task flow:**

1. In the Applications window, expand the WEB-INF node and double-click the task flow where you want to add a method call activity.

2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a method call activity onto the diagram.

   The method call activity optionally displays a default activity ID, methodCall1n, and a warning icon that indicates that a method EL expression has not yet been specified.

   For more information about turning on the warning icons, see Section 20.3.1, "How to Add an Activity to a Task Flow."

3. In the Properties window, expand the General section, and enter an activity ID in the Activity ID field if you want to change the default value.

   If you enter a new value, the new value appears under the method call activity in the diagram.

4. In the Method field, enter an EL expression that identifies the method to call.

   For example, enter an EL binding expression similar to the following:

   ```
   #{bindings.setCurrentRowWithKeyValue.execute}
   ```
You can also use the Expression Builder shown in Figure 21–8 to build the EL expression for the method:

a. Choose **Method Expression Builder** from the context menu that appears when you click the icon that appears when you over the **Method** property field.

b. In the Expression Builder dialog, navigate to the method that you want to invoke and select it.

The Expression Builder dialog should look similar to Figure 21–8. In Figure 21–8, for example, the EL expression shown at the top of the Expression Builder references the `CreateInsert` action binding from the method call activity in the `emp-reg-task-flow-definition.xml` task flow of the Summit ADF task flow sample application.

**Figure 21–8  EL Expression for Method in Expression Builder Dialog**

You can also use the Expression Builder shown in Figure 21–8 to build the EL expression for the method:

a. Choose **Method Expression Builder** from the context menu that appears when you click the icon that appears when you over the **Method** property field.

b. In the Expression Builder dialog, navigate to the method that you want to invoke and select it.

The Expression Builder dialog should look similar to Figure 21–8. In Figure 21–8, for example, the EL expression shown at the top of the Expression Builder references the `CreateInsert` action binding from the method call activity in the `emp-reg-task-flow-definition.xml` task flow of the Summit ADF task flow sample application.

**Figure 21–8  EL Expression for Method in Expression Builder Dialog**

Tip: If the method call activity is going to invoke a managed bean method, double-click the method call activity in the diagram. This invokes a dialog where you can specify the managed bean method you want to invoke.

5. In the Properties window, expand the **General** section, and specify one of the following in the **Outcome** group:

   - **Fixed Outcome**: On successful completion, the method always returns this single outcome, for example, `success`. If the method does not complete...
Using Method Call Activities

... an outcome is not returned. If the method type is void, you must specify a value for Fixed Outcome rather than for toString.

- toString(): If you select true, the outcome is based on calling the toString() method on the Java object returned by the method.

21.5.2 How to Specify Method Parameters and Return Values

You can specify parameters and return values for a method. Figure 21–9 shows a single parameter defined for a method called calculateSalesTax. The Value field contains an EL expression that evaluates to the parameter value at runtime.

Figure 21–9  Method Parameters in a Method Call

If parameters have not already been created by associating the method call activity to an existing method, add the parameters yourself.

Before you begin:
It may be helpful to have an understanding of how the properties of a method call activity affect the functionality of a task flow. For more information, see Section 21.5, "Using Method Call Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

You will need to complete this task:
Add a method call activity to the task flow diagram, as described in Section 21.5.1, "How to Add a Method Call Activity."

To add method parameters:
1. In the Applications window, expand the WEB-INF node and double-click the task flow that contains the method call activity to which you want to add method parameters.
2. In the task flow diagram, select the method call activity.
3. In the Properties window, expand the Parameters section, and click Add to set the following values for the parameter that you want to add:
   - Class: Enter the parameter class, for example, java.lang.Double.
   - Value: Enter an EL expression that retrieves the value of the parameter. For example:

```java
#{pageFlowScope.shoppingCart.totalPurchasePrice}
```
4. In the **Return Value** field, enter an EL expression that identifies where to store the method return value, for example, #{pageFlowScope.Return}.

5. Repeat the above steps to add additional parameters.

### 21.5.3 What Happens When You Add a Method Call Activity

After you specify parameters and return values for a method, the XML source file is updated. **Example 21–10** shows the `setCurrentRowWithKeyValue` method call activity in the `customers-task-flow-definition.xml` task flow from the Summit ADF task flow sample application.

**Example 21–10  Method Call Activity in the Summit ADF Sample Application**

```xml
<method-call id="setCurrentRowWithKeyValue">
  <method>#{bindings.setCurrentRowWithKeyValue.execute}</method>
  <outcome>
    <fixed-outcome>setCurrentRowWithKey</fixed-outcome>
  </outcome>
</method-call>
```

### 21.6 Using Task Flow Call Activities

You can use a task flow call activity to call a bounded task flow from either the unbounded task flow or a bounded task flow. A task flow call activity allows you to call a bounded task flow located within the same or a different application.

The called bounded task flow executes its default activity first. There is no limit to the number of bounded task flows that can be called. For example, a called bounded task flow can call another bounded task flow, which can call another, and so on.

To pass parameters into a bounded task flow, you must specify input parameter values on the task flow call activity. These values must correspond to the input parameter definitions on the called bounded task flow. For more information, see Section 21.6.3, "How to Specify Input Parameters on a Task Flow Call Activity."

Also note the following:

- The value on the task flow call activity **Input Parameter** specifies where the value will be taken from within the calling task flow.

- The value on the **Input Parameter Definition** for the called task flow specifies where the value will be stored within the called bounded task flow once it is passed.

**Tip:** When a bounded task flow is associated with a task flow call activity, input parameters are automatically inserted on the task flow call activity based on the input parameter definitions defined on the bounded task flow. Therefore, the application developer needs only to assign values to the task flow call activity input parameters.

By default, all objects are passed by reference. Primitive types (for example, `int`, `long`, or `boolean`) are always passed by value.

The technique for passing return values out of the bounded task flow to the caller is similar to the way that input parameters are passed. For more information, see Section 22.4, "Configuring a Return Value from a Bounded Task Flow."

To use a task flow call activity:
1. Call a bounded task flow using a task flow call activity.
2. Specify input parameters on a task flow call activity if you want to pass parameters into the bounded task flow.
3. Call a bounded task flow in another web application using a URL.
4. Specify before and after listeners on a task flow call activity.

21.6.1 How to Call a Bounded Task Flow Using a Task Flow Call Activity

Add a task flow call activity to the calling bounded or unbounded task flow to call a bounded task flow.

Before you begin:
It may be helpful to have an understanding of how a task flow call activity interacts with a task flow. For more information, see Section 21.6, "Using Task Flow Call Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

To call a bounded task flow using a task flow call activity:
1. In the Applications window, expand the WEB-INF node and double-click the task flow (calling task flow) to which you are going to add a task flow call activity to call a bounded task flow.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a Task Flow Call activity onto the diagram.
3. Choose one of these options to identify the called task flow:
   - In the task flow diagram, double-click the task flow call activity. The Create Bounded Task Flow dialog appears, where you specify options for creating a new bounded task flow.
   - Drag an existing bounded task flow from the Applications window and drop it on the task flow call activity.
**Tips:** You can drop a bounded task flow on a page or page fragment. If the bounded task flow consists of pages (not page fragments), you can choose the Task Flow Call as Button or Task Flow Call as Link menu options that appear to add a button or link component on the page where you drop the task flow. An end user can click the button or link to call the task flow. This may in turn automatically generate the task flow call activity if the page is already associated with an existing view activity in a task flow.

You cannot drop a bounded task flow from one application to a task flow diagram contained in another application using the Applications window, even though both applications appear in the Applications window. In addition, you cannot drop a bounded task flow contained in one project onto a task flow diagram contained in another project.

Instead, you can package the bounded task flow in an ADF library, then reuse it in your current application or project. You can then drag the bounded task flow from the Resources window or from the Components window page that is created when you import the library. For more information, see Section 44.1.4.2, "Using the Resources Window."

- If you know the name of the bounded task flow that you want to invoke, perform the following steps:
  a. In the task flow diagram, select the task flow call activity.
  b. In the Properties window, expand the General section, and select Static from the Task Flow Reference dropdown list.
  c. In the Document field, enter the name of the source file for the bounded task flow to call. For example, called-task-flow-definition.xml.
  d. In the ID field, enter the bounded task flow ID contained in the XML source file for the called bounded task flow, for example, targetTaskFlow.

- If you do not know the name of the bounded task flow to invoke and it is dependent on an end user selection at runtime, perform the following steps:
  a. In the task flow diagram, select the task flow call activity.
  b. In the Properties window, expand the General section, and select Dynamic from the Task Flow Reference dropdown list.
  c. Select Expression Builder from the context menu that appears when you click the icon that appears when you hover over the Dynamic Task Flow Reference property field.
  d. Write an EL expression that identifies the ID of the bounded task flow to invoke at runtime.

Figure 21–10 shows the customers-task-flow task flow in the Summit ADF task flow sample application. This task flow contains a task flow call activity (create-edit-orders-task-flow-definition) that invokes the task flow of the same name.
21.6.2 What Happens When You Call a Bounded Task Flow Using a Task Flow Call Activity

JDeveloper generates metadata entries in the source file for the task flow that calls the bounded task flow. Example 21–11 shows the metadata that corresponds to Figure 21–10 from the Summit ADF task flow sample application. At runtime, the task flow call activity invokes the orders-select-many-items task flow.

Example 21–11 Task Flow Call Activity in the Summit ADF Sample Application

```xml
<task-flow-call id="orders-select-many-items">
  <task-flow-reference>
    <document>/WEB-INF/flows/orders/orders-select-many-items.xml</document>
    <id>orders-select-many-items</id>
  </task-flow-reference>
  <run-as-dialog>
    <display-type>
      <inline-popup/>
    </display-type>
  </run-as-dialog>
</task-flow-call>
```

21.6.3 How to Specify Input Parameters on a Task Flow Call Activity

The suggested method for mapping parameters between a task flow call activity and its called bounded task flow is to first specify input parameter definitions for the called bounded task flow. Then you can drag the bounded task flow from the Applications window and drop it on the task flow call activity. The task flow call activity input parameters will be created automatically based on the bounded task flow’s input parameter definition. For more information, see Section 22.3, "Passing Parameters to a Bounded Task Flow."

You can, of course, first specify input parameters on the task flow call activity. Even if you have defined them first, they will automatically be replaced based on the input parameter definitions of the called bounded task flow, once it is associated with the task flow call activity.
If you have not yet created the called bounded task flow, you may still find it useful to specify input parameters on the task flow call activity. Doing so at this point allows you to identify any input parameters you expect the task flow call activity to eventually map when calling a bounded task flow.

**Before you begin:**
It may be helpful to have an understanding of how a task flow call activity interacts with a task flow. For more information, see Section 21.6, "Using Task Flow Call Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

### To specify input parameters on a task flow call activity:

1. In the Applications window, expand the `WEB-INF` node and double-click the task flow that contains the task flow call activity.

2. In the diagram, select the task flow call activity.

3. In the Properties window, expand the `Parameters` section, and click the `Add` icon to specify a new input parameter in the `Input Parameters` list as follows:

   - **Name**: Enter a name to identify the input parameter.
   - **Value**: Enter an EL expression that identifies the parameter value. The EL expression identifies where the parameter value will be retrieved from within the calling task flow. For example, enter an EL expression similar to the following:
     
     $$\#{\text{pageFlowScope.callingTaskflowParm}}$$

     By default, all objects are passed by reference. Primitive types (for example, `int`, `long`, or `boolean`) are always passed by value.

     Click in the Value field and use the dropdown list to use the Expression Builder if needed.

4. After you have specified an input parameter, you can specify a corresponding input parameter definition for the called bounded task flow. For more information, see Section 22.3, "Passing Parameters to a Bounded Task Flow."

### 21.6.4 How to Call a Bounded Task Flow Using a URL

You can call a bounded task flow that does not use page fragments (.jsff) in another web application using a URL. Use a task flow call activity to call the bounded task flow that you want to invoke. You write an EL expression for the task flow call activity’s `remote-app-url` property that, when evaluated, returns a URL.

In addition to writing a value for the `remote-app-url` property, you specify values for task flow reference properties that identify the bounded task flow to call. The task flow reference and the `remote-app-url` property are combined at runtime to generate a URL to the called bounded task flow in the remote web application.

You also need to set visibility properties for the bounded task flow in the remote web application that you want to call so that it invokes when it receives the URL generated from the task flow call activity in the calling task flow.

Be aware that JSF portlets provide all content from the same web application. As a result, do not configure your web application to invoke a task flow using a URL if you plan to use your web application in a JSF portlet.
**Note:** If, in JDeveloper’s Applications window, you right-click the bounded task flow that you want to call using a URL and select Run, the bounded task flow executes as if it were called using a URL at runtime. For this reason, make sure to set the visibility properties for the bounded task flow even if you want to execute it as part of testing in JDeveloper.

**Before you begin:**
It may be helpful to have an understanding of how a task flow call activity interacts with a task flow. For more information, see Section 21.6, "Using Task Flow Call Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

**To call a bounded task flow using a URL:**
1. In the Applications window, expand the WEB-INF node and double-click the task flow that you want to configure to invoke a bounded task flow in a remote web application.
2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag a Task Flow Call activity and drop it on the diagram for the task flow.
3. In the Properties window, expand the General section and specify values to invoke a bounded task flow.
   For more information, see Section 21.6.1, "How to Call a Bounded Task Flow Using a Task Flow Call Activity."
4. For the Remote Application URL property, use the Expression Builder to write an EL expression that, when evaluated, returns a string with the parts required to construct a URL of the remote web application. Invoke the Expression Builder by selecting Expression Builder from the context menu that appears when you click the icon that appears when you hover over the property field.
   For example, the following EL expression invokes a managed bean method that returns a string with the parts required to construct a URL:

   ```
   #{myOrdersBean.createOrder}
   ```

5. Open the bounded task flow in the remote web application that you want to invoke.
   
   **Note:** The bounded task flow you specify cannot use page fragments (.jsff).

6. In the Structure window, right-click the node for the bounded task flow (task-flow-definition Task Flow ID) and choose Go to Properties.
7. In the Properties window, expand the General section and select values for the following:
   - **URL Invoke:** select url-invoke-allowed from the dropdown list if you want to allow a URL to invoke the bounded task flow. Select url-invoke-disallowed if
you do not want to allow a URL to invoke the bounded task flow. Selecting this value returns a HTTP 403 status code if a URL attempts to invoke the bounded task flow. The default value (calculated) allows a URL to invoke the bounded task flow if the bounded task flow does not specify an initializer and it has a view activity as its default activity. If the bounded task flow does not meet these conditions, a HTTP 403 status code is returned. Selecting `url-invoker-allowed` or `url-invoker-disallowed` overrides the default behavior.

- Library Internal: select `true` if you want the bounded task flow to be internal when you package it in an ADF Library JAR. The default value is `false`.

For more information about packaging a bounded task flow in an ADF Library JAR, see Section 44.2, "Packaging a Reusable ADF Component into an ADF Library."

8. Save and close the bounded task flow.

### 21.6.5 What Happens When You Configure a Bounded Task Flow to be Invoked by a URL

JDeveloper generates metadata entries in the source file of the task flow that invokes the task flow call activity to the bounded task flow in a remote web application. Example 21–12 shows an example entry for a task flow call activity.

**Example 21–12 Metadata Entries for a Task Flow Call Activity to a Bounded Task Flow**

```xml
<task-flow-call id="createOrder">
  <task-flow-reference>
    <document id="__6">myorders-task-flow.xml</document>
    <id id="__5">myorders-task-flow</id>
  </task-flow-reference>
  <remote-app-url id="__7">#{myOrdersBean.createOrder}</remote-app-url>
</task-flow-call>
```

The `createOrder` method in Example 21–12 returns a string with the URL syntax required to invoke a bounded task flow. For more information about the URL syntax, including descriptions of the required parts in the returned string and an example URL, see Section 21.6.6, "What You May Need to Know About Calling a Bounded Task Flow Using a URL."

JDeveloper also generates entries in the source file for the bounded task flow to invoke when you configure it so it can be called by a URL. Example 21–13 shows sample metadata entries that allow a bounded task flow to be invoked by a URL.

**Example 21–13 Metadata Entries to Allow a URL Invoke a Bounded Task Flow**

```xml
<task-flow-definition id="task-flow-definition3">
  <visibility id="__2">
    <url-invoker-allowed/>
    <library-internal/>
  </visibility>
</task-flow-definition>
```

### 21.6.6 What You May Need to Know About Calling a Bounded Task Flow Using a URL

Adding a context parameter in your local application's deployment descriptor may ease the administration of interaction with a remote web application.
Context Parameter for Remote Web Application

Consider adding a context parameter to the deployment descriptor (web.xml) for your Fusion web application (local application) if you use a URL to invoke a bounded task flow in another Fusion web application (remote application). Set the value of the context parameter to the URL of the remote application. Use the context parameter name when writing EL expressions in the local application, as shown in the following example where `remoteAppUrl` is the name of the context parameter:

```
#{initParam.remoteAppUrl}
```

If the URL of the remote application changes, you can update the context parameter to reference the changed URL.

URL Syntax to Invoke a Bounded Task Flow

Typically, you write an EL expression that references a managed bean method which, in turn, retrieves the required parts of the URL or you could write an EL expression that returns the URL directly, as shown in Example 21–14.

Example 21–14 Example URL to Invoke a Bounded Task Flow

Example 21–15 describes the parts of the URL syntax to invoke a bounded task flow.

Example 21–15 URL Syntax for a Call to a Bounded Task Flow Using Named Parameters

```
<server root>/<app_context>/faces/adf.task-flow?adf.tfId=<task flow definition ID>&adf.tfDoc=<document name>&<named parameter>=<named parameter value>
```

The following list describes each part of the URL syntax in Example 21–15:

- `<server root>`: Provided by customization at site or admin level. For example:
  
  `http://mycompany.com/internalApp`
  
  The `<server root>` value depends on the application server where you deploy the bounded task flow. The bounded task flow URL is a resource within the JSF servlet’s URL path.

- `<app context>`: The web application context root, for example, MyApp. The context root is the base path of a web application.

- `<faces>`: Faces servlet mapping.

- `<adf.task-flow>`: A reserved keyword that identifies ADF Controller for the remote web application.

- `<adf.tfId>`: A URL parameter that supplies the task flow ID to call.

- `<task flow ID>`: The identifier of the bounded task flow to call, for example, displayHelp. This is the same task flow ID that is used when calling locally. Note that this identifier is not the same as the task flow call activity instance ID. The parameter value must be represented as a string.

- `<adf.tfDoc>`: A URL parameter that supplies the document name containing the bounded task flow ID to be called.

- `<document name>`: A document name containing the bounded task flow ID to be called, for example, %2FWEB-INF%2FtoUppercase%2FdisplayHelp.xml. If you are handcrafting the bounded task flow URL, you are responsible for the appropriate encoding.
Using Task Flow Call Activities

- `<named parameter>`: (optional) The name of an input parameter definition for the called bounded task flow, for example, `topic`. You must supply all required input parameter definitions.
- `<named parameter value>`: (optional) The value of the input parameter.

---

**Note:** URL parameter names that begin with an underscore ('_') are intended for internal use only and should not be used. Although you may see these names on URLs generated by ADF Controller, you should not attempt to use or depend on them.

### Object Type for Parameter Converters

Parameter converters, if specified, can be used to convert task flow parameter values to and from the string representations used in a URL. A parameter converter is an EL expression that evaluates to an object of the following type:

```
oracle.adf.controller.UrlParameterConverter
```

If you do not specify a parameter converter, a default converter checks the parameters for cross-site-scripting (XSS) attacks. If you know that the parameter values used in your application contain special characters, you should create your own implementation of `UrlParameterConverter` and use it to perform conversion of the task flow parameter values.

### 21.6.7 How to Specify Before and After Listeners on a Task Flow Call Activity

Use task flow call activity before and after listeners to identify the start and end of a bounded task flow. Specifying a listener in the task flow call activity means that the listener executes on that specific usage of the called bounded task flow.

You specify the listener as an EL expression for a method that will be called upon entry or exit of a bounded task flow, for example:

```
<before-listener>#{global.showState}</before-listener>
```

The method cannot have parameters.

- **Before listener:** An EL expression for a Java method called before a bounded task flow is entered. It is used when the caller needs to know when a bounded task flow is being initiated.

- **After listener:** An EL expression for a Java method called after a bounded task flow returns. It is used when the caller needs to know when a bounded task flow exits and control flow returns to the caller.

If multiple before listeners or multiple after listeners are specified, they are called in the order in which they appear in the source document for the unbounded or bounded task flow. A task flow call activity can have only have before listener and one after listener.

In order for the task flow call after listeners to be called, control flow must return from the bounded task flow using a control flow rule. If an end user leaves a bounded task flow using the browser back button or other URL, task flow call after listeners will not be called. You must use a bounded task flow finalizer to release all acquired resources and perform cleanup of a bounded task flow that the end user left by clicking a browser back button.
Before you begin:

It may be helpful to have an understanding of how a task flow call activity interacts with a task flow. For more information, see Section 21.6, "Using Task Flow Call Activities."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

To specify a before or after listener on a task flow call activity:

1. In the Applications window, expand the WEB-INF node and double-click the calling task flow.

2. In the diagram for the calling bounded task flow, select the task flow call activity.

3. In the Properties window, expand the Listeners section and open the Expression Builder for either the Before Listener property or the After Listener property. To open the Expression Builder, choose Method Expression Builder from the context menu that invokes when you click the icon that appears when you hover over the property field.

   Use the Expression Builder to navigate to the Java class that contains the method for the listener. For example, you might create an EL expression similar to the following:

   #{pageFlowscope.managedBean.methodListener}

4. Click OK.

21.6.8 What Happens When You Add a Task Flow Call Activity

After you add a task flow call activity to a task flow diagram, you must specify a reference to the called bounded task flow using one of the methods described in Section 21.6.1, "How to Call a Bounded Task Flow Using a Task Flow Call Activity."

For example, if you drop an existing bounded task flow on the task flow call activity, JDeveloper generates the task flow reference automatically. The task flow reference is used to invoke the called bounded task flow.

If the task flow reference is static, each task flow reference consists of:

- **Document**: The name of the XML source file containing the ID of the called bounded task flow. If Document is not specified, adfc-config.xml is assumed. The document is a physical XML file and must be accessible via MDS.

- **ID**: The bounded task flow ID contained in the XML source file for the called bounded task flow. For example, a called task flow might have an ID called targetFlow. The same XML source file can contain multiple bounded task flows, each bounded task flow identified by a unique ID.

**Note**: If you use JDeveloper to create the bounded task flow, there is only one bounded task flow per document.

Example 21–16 contains an example static task flow reference within a task flow call activity. In order to invoke a bounded task flow, you need to know its ID and the name of the file (<document>) containing the ID.
Example 21–16  Static Task Flow Reference

```xml
<adfc-config xmlns='http://xmlns.oracle.com/adf/controller' version='1.2' id='__1'>
  ...
  <task-flow-definition id='task-flow-definition'>
    <default-activity>view1</default-activity>
    <task-flow-call id='taskFlowCall'>
      <task-flow-reference>
        <document>/WEB-INF/called-task-flow-definition.xml</document>
        <id>called-task-flow-definition</id>
      </task-flow-reference>
    </task-flow-call>
  </task-flow-definition>
  ...
</adfc-config>
```

Example 21–17 shows the metadata that JDeveloper generates for a dynamic task flow reference within a task flow call activity.

Example 21–17  Dynamic Task Flow Reference

```xml
<adfc-config xmlns='http://xmlns.oracle.com/adf/controller' version='1.2' id='__1'>
  <task-flow-definition id='bounded_tf'>
    <default-activity id='__2'>taskFlowCall1</default-activity>
    <task-flow-call id='taskFlowCall1'>
      <dynamic-task-flow-reference id='__3'>#{EL_Expression_Retrieve_TaskflowID}</dynamic-task-flow-reference>
    </task-flow-call>
  </task-flow-definition>
</adfc-config>
```

21.6.9 What Happens at Runtime: How a Task Flow Call Activity Invokes a Task Flow

The ADF Controller performs the following steps when a bounded task flow is called using a task flow call activity:

1. Verifies that the user is authorized to call the bounded task flow.
2. Invokes task flow call activity before listener or listeners, if specified (see Section 21.6.7, "How to Specify Before and After Listeners on a Task Flow Call Activity").
3. Evaluates the input parameter values on the bounded task flow.
4. Pushes the called bounded task flow onto the stack and initializes its page flow scope.
5. Sets input parameter values in the called bounded task flow’s context.
6. Invokes a bounded task flow initializer method, if one is specified.
7. Executes the bounded task flow’s default activity.

21.7 Using Task Flow Return Activities

A task flow return activity identifies the point in an application’s control flow where a bounded task flow completes and sends control flow back to the caller. You can use a task flow return activity only within a bounded task flow.
A gray circle around a task flow return activity icon indicates that the activity is an exit point for a bounded task flow. A bounded task flow can have zero to many task flow return activities. Figure 21–11 shows the orders-select-many-items.xml bounded task flow in the Summit ADF task flow sample application that contains task flow return activities named **commit** and **rollback**.

Each task flow return activity specifies an **outcome** that it returns to the calling task flow. For example, Figure 21–11 shows a task flow return activity in the Summit ADF task flow sample application. The value for the this task flow return activity’s Outcome Name property is **commit**.

**Figure 21–11  Multiple Task Flow Return Activities**

The **outcome** returned to an invoking task flow depends on the end user action. You can configure control flow cases in the invoking task flow to determine the next action by the invoking task flow. Set the **From Outcome** property of a control flow case to the value returned by the task flow return activity’s **outcome** to invoke an action based on that outcome. This determines control flow upon return from the called task flow.

Set a value for the **Restore Save Point** property to specify if model changes made in a bounded task flow are saved or discarded when the bounded task flow exits by using a task flow return activity. Set to **true** to roll back transactions to the ADF Model save point that was created when the Fusion web application first entered the bounded task flow. The default value is **false**. You can specify a value for this property only if the bounded task flow on which the task flow return activity is located was entered without starting a new transaction. For more information, see Section 24.3.1, "How to Enable Transactions in a Bounded Task Flow."

### 21.7.1 How to Add a Task Flow Return Activity to a Bounded Task Flow

You drag a task flow return activity from the Components window and drop it on the diagram for the bounded task flow.

**Before you begin:**

It may be helpful to have an understanding of how a task flow return activity interacts with a task flow. For more information, see Section 21.7, "Using Task Flow Return Activities."
You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

**To add a task flow return activity to a bounded task flow:**

1. In the Applications window, expand the **WEB-INF** node and double-click the bounded task flow to which you want to add a task flow return activity.

2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a **Task Flow Return** onto the diagram.

3. In the Properties window, expand the **General** section, and enter an outcome in the **Name** field.

   The task flow return activity returns this outcome to the calling task flow when the current bounded task flow exits. You can specify only one outcome per task flow return activity. The calling task flow should define control flow rules to handle control flow upon return. For more information, see Section 20.4.1, "How to Add a Control Flow Rule to a Task Flow."

4. Expand the **Behavior** section and in the **Reentry** dropdown list, choose one of the following options:

   - **<default>** (not outcome dependent): Reentry is not dependent on an outcome.
   - **reentry-allowed**: Reentry is allowed on any view activity within the bounded task flow.
   - **reentry-not-allowed**: Reentry of the bounded task flow is not allowed.

   If you specify **reentry-not-allowed** on a bounded task flow, an end user can still click the browser back button and return to a page within the bounded task flow. However, if the user does anything on the page such as clicking a button, an exception (for example, **InvalidTaskFlowReentry**) is thrown indicating the bounded task flow was reentered improperly. The actual reentry condition is identified upon the submit of the reentered page.

   For more information about reentering a bounded task flow, see Section 24.4, "Reentering Bounded Task Flows."

   Your selection defines the default behavior when the bounded task flow is reentered by an end user clicking a browser’s Back button. This selection applies only if **reentry-outcome-dependent** has been set on the bounded task flow where the task flow return activity is located. For more information, see Section 24.4, "Reentering Bounded Task Flows."

5. In the **End Transaction** dropdown list, choose one of the following options:

   - **commit**: Select to commit the existing transaction to the database.
   - **rollback**: Select to roll back the transaction to what it was on entry of the called task flow. This has the same effect as canceling the transaction, since it rolls back a new transaction to its initial state when it was started on entry of the bounded task flow.

6. In the **Restore Save Point** dropdown list, select **true** when either of the following conditions apply:
21.7.2 What Happens When You Add a Task Flow Return Activity to a Bounded Task Flow

JDeveloper generates metadata entries in the source file of the bounded task flow for the changes that you configure for the task flow return activity in the Properties window. Example 21–18 shows entries that appear in the orders-select-many-items.xml task flow of the Summit ADF task flow sample application.

Example 21–18 Metadata Entries for a Task Flow Return Activity

```xml
<task-flow-return id="commit">
  <outcome>
    <name>commit</name>
    <commit/>
  </outcome>
</task-flow-return>

<task-flow-return id="rollback">
  <outcome>
    <name>rollback</name>
    <rollback/>
  </outcome>
</task-flow-return>
```

21.8 Using Task Flow Activities with Page Definition Files

Page definition files define the binding objects that populate data at runtime. They are typically used in a Fusion web application to bind page UI components to data controls. A number of task flow activities can also use page definition files to bind to data controls. These are:

- **Method call**

  You can drag and drop a data control operation from the Data Controls panel onto a task flow to create a method call activity or onto an existing method call activity. In both cases, the method call activity binds to the data control operation.

- **Router**

  Associating a page definition file with a router activity creates a binding container. At runtime, this binding container makes sure that the router activity references the correct binding values when it evaluates the router activity cases’ EL expressions. Each router activity case specifies an outcome to return if its EL expression evaluates to true. For this reason, only add data control operations to the page definition file that evaluate to true or false.

- **Task flow call**
Associating a page definition file with a task flow call activity creates a binding container. At runtime, the binding container is in context when the task flow call activity passes input parameters. The binding container makes sure that the task flow call activity references the correct values if it references binding values when passing input parameters from a calling task flow to a called task flow.

- **View**
  
  You cannot directly associate a view activity with a page definition file. Instead, you associate the page that the view activity references.

If you right-click any of the above task flow activities (except view activity) in the diagrammer for a task flow, JDeveloper displays an option on the context menu that enables you to create a page definition file (Create Page Definition) if one does not yet exist. If a page definition file does exist, JDeveloper displays a context menu option for all task flow activities to go to the page definition file (Go to Page Definition). JDeveloper also displays a context menu option (Edit Binding) when you right-click a method call activity that is associated with a page definition file.

A task flow activity that is associated with a page definition file displays an icon in the lower-right section of the task flow activity icon. Figure 21–12 shows an example for each of the task flow activities.

![Figure 21–12  Task Flow Activities Associated with Page Definition Files](image)

### 21.8.1 How to Associate a Page Definition File with a Task Flow Activity

JDeveloper provides a context menu option that you can access from the task flow activity. You use this context menu option to associate the task flow activity with a page definition file.

**Before you begin:**

It may be helpful to have an understanding of how task flow activities use page definition files. For more information, see Section 21.8, "Using Task Flow Activities with Page Definition Files."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 21.1.2, "Additional Functionality for Task Flow Activities."

**To associate a page definition file with a task flow activity:**

1. In the Applications window, expand the WEB-INF node and double-click the task flow that contains the task flow activity with which you want to associate a page definition file.

2. In the diagram, right-click the task flow activity for which you want to create a page definition file and choose Create Page Definition.

3. In the resulting page definition file, add the bindings that you want your task flow activity to reference at runtime.
For more information about page definition files, see Section 17.7, "Working with Page Definition Files."

21.8.2 What Happens When You Associate a Page Definition File with a Task Flow Activity

At design time, JDeveloper generates a page definition file for the task flow activity. The filename of the page definition file comprises the originating task flow and either the name of the task flow activity or the data control operation to invoke. For example, `taskflowName_taskflowName_methodCall1PageDef.xml` or `taskflowName_taskflowName_CreateInsertPageDef.xml`.

JDeveloper also generates an EL expression from the task flow activity to the binding in the created page definition file. Example 21–19 shows a method call activity that references a `CreateInsert` action binding.

**Example 21–19  Task Flow Activity Referencing an Action Binding**

```xml
<method-call id="CreateInsert">
    <method>${bindings.CreateInsert.execute}</method>
    <outcome>
        <fixed-outcome>CreateInsert</fixed-outcome>
    </outcome>
</method-call>
```

At runtime, a binding container makes sure that a task flow activities’ EL expressions reference the correct value.
This chapter describes how to configure parameters in view activities and in ADF bounded task flows that you create in the Fusion web application. Using these capabilities allows you to manipulate data in task flows, share data between task flows across one or more transactions, and configure return values to return from one task flow to another task flow.

This chapter includes the following sections:

- Section 22.1, "About Using Parameters in Task Flows"
- Section 22.2, "Passing Parameters to a View Activity"
- Section 22.3, "Passing Parameters to a Bounded Task Flow"
- Section 22.4, "Configuring a Return Value from a Bounded Task Flow"

### 22.1 About Using Parameters in Task Flows

A task flow’s ability to accept input parameters and return parameter values allow you to manipulate data in task flows and share data between task flows. Using these abilities, you can optimize the reuse of task flows in your Fusion web application.

You can use view activity input page parameters as aliases. The alias allows you to map bounded task flow input parameters to page parameters. The view activity input page parameters map managed beans and any information available to the calling task flow to a managed bean on the page itself. To pass values out of view activities, store values in pageFlow scope or managed beans. For information about using view activities in a task flow, see Section 21.2, "Using View Activities."

For example, a page might specify `#{pageFlowScope.empNo}` as a page parameter and a bounded task flow might specify `#{pageFlowScope.employeeID}` as the value of an input parameter definition.

The from-value on the view activity input page parameter would be `#{pageFlowScope.employeeID}` and the to-value would be `#{pageFlowScope.empNo}`. This enables reuse of both the page definition and bounded task flow because you do not have to redefine parameters for every context in which each is used.

Other values contained within the task flow can be mapped to input page parameters, not just bounded task flow input parameter definition values.

#### 22.1.1 Task Flow Parameters Use Cases and Examples

Figure 22–1 shows a task flow that defines an input parameter definition to hold information about a user in a pageFlow scope.
22.2 Passing Parameters to a View Activity

Figure 22–2 illustrates how to configure an input page parameter mapping. You can pass a parameter to the Employee activity as a `pageFlowScope` value or a value on a managed bean. You can pass a parameter to the Employee activity using an EL expression or a literal expression. The Employee activity, in turn, can pass a value to the Target activity by specifying the value it wants to pass to the Target activity in the `to-value` element.

22.2.1 How to Pass Parameters to a View Activity

You add one or more input page parameters to the view activity that you want to pass parameters to.
Before you begin:

It may be helpful to have an understanding of the configuration options available to you before you define an input page parameter for a view activity. For more information, see Section 22.2, "Passing Parameters to a View Activity."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 22.1.2, "Additional Functionality for Task Flows Using Parameters."

To define an input page parameter for a view activity:

1. In the Applications window, double-click the task flow that contains the view activity to which you want to pass a parameter.
2. Select the view activity in the diagram for the task flow and, in the Properties window, expand the Page Parameters category.
3. In the Input Page Parameters list, click the Add icon and enter values as follows:
   - **From Value**: write an EL expression that, when evaluated, specifies where the view activity retrieves the value for the input page parameter. For example, write an EL expression similar to the following:
     ```el
     #{pageFlowScope.EmployeeID}
     ```
     You can configure the view activity to retrieve a value that is input to the task flow if you write an EL expression for **From Value** that corresponds to the value for the input parameter that you defined for the task flow, as described in Section 22.3.1, "How to Pass an Input Parameter to a Bounded Task Flow."
   - **To Value**: write an EL expression, that when evaluated, specifies where the page associated with the view activity can retrieve the value of the input page parameter. For example, write an EL expression similar to the following:
     ```el
     #{pageFlowScope.EmployeeNo}
     ```

22.2.2 What Happens When You Pass Parameters to a View Activity

JDeveloper writes entries to the source file of the task flow at design time, as illustrated in Example 22–1.

**Example 22–1  Metadata to Define an Input Page Parameter on a View Activity**

```xml
<view id="reducedAccess">
  <page>/secured/Information.jsf</page>
  <input-page-parameter>
    <from-value>${res['infoUsage.reducedAccess.messageHeader']}</from-value>
    <to-value>${pageFlowScope.infoPageHeaderText}</to-value>
  </input-page-parameter>
  <input-page-parameter>
    <from-value>${res['infoUsage.reducedAccess.messageHeader']}</from-value>
    <to-value>${pageFlowScope.infoPageMsg}</to-value>
  </input-page-parameter>
  <input-page-parameter>
    <from-value>info</from-value>
    <to-value>${pageFlowScope.infoPageType}</to-value>
  </input-page-parameter>
</view>
```

At runtime, the view activity retrieves the value of the input parameter from the location you specified in the <from-value> element. The view activity makes the
value of the parameter available to its associated page in the location you specified in the <to-value> element.

### 22.2.3 What You May Need to Know About Specifying Parameter Values

You can specify parameter values using standard EL expressions if you call a bounded task flow using a task flow call activity or you render the bounded task flow in an ADF region or an ADF dynamic region. For example, you can specify parameters using the following syntax for EL expressions:

- #{bindings.bindingId.inputValue}
- #{CustomerBean.zipCode}

**Example 22–2** shows the metadata for a task flow binding that renders in an ADF region.

**Example 22–2 ADF Region taskFlow Binding**

```xml
<taskFlow id="Department1" taskFlowId="/WEB-INF/Department.xml#Department"
    xmlns="http://xmlns.oracle.com/adf/Controller/binding">
  <parameters>
    <parameter id="DepartmentId" value="#{bindings.DepartmentId.inputValue}" xmlns="http://xmlns.oracle.com/adfm/uimodel"/>
  </parameters>
</taskFlow>
```

Appending `inputValue` to the EL expression makes sure that you assign the parameter the value of the binding rather than the actual binding object.

### 22.3 Passing Parameters to a Bounded Task Flow

A called bounded task flow can accept input parameters from the task flow that calls it or from a task flow binding. To pass an input parameter to a bounded task flow, you specify one or more:

- Input parameters on the task flow call activity in the calling task flow
  - Input parameters specify where the calling task flow stores parameter values.
- Input parameter definitions on the called bounded task flow
  - Input parameter definitions specify where the called bounded task flow can retrieve parameter values at runtime.

Specify the same name for the input parameter that you define on the task flow call activity in the calling task flow and the input parameter definition on the called bounded task flow. Do this so you can map input parameter values to the called bounded task flow.

If you do not specify an EL expression to reference the value of the input parameter, the EL expression for `value` defaults to the following at runtime:

```
#{pageFlowScope.parmName}
```

where `parmName` is the value you entered for the input parameter name.

In an input parameter definition for a called bounded task flow, you can specify an input parameter as required. If the input parameter does not receive a value at runtime or design time, the task flow raises a warning in a log file of the Fusion web application that contains the task flow. An input parameter that you do not specify as required can be ignored during task flow call activity creation.
Task flow call activity input parameters can be passed by reference or passed by value when calling a task flow using a task flow call activity unless you are calling a task flow in an ADF region. If the task flow renders in an ADF region, the task flow call activity passes the input parameters by reference. By default, primitive types (for example, int, long, or boolean) are passed by value (pass-by-value).

The Pass By Value checkbox applies only to objects, not primitives and is used to override the default setting of passing by reference. Mixing the two, however, can lead to unexpected behavior in cases where parameters reference each other. If input parameter A on the task flow call activity is passed by value and if input parameter B on the task flow call activity is passed by reference, and B has a reference to A, the result can be two different instances of A and B.

Section 22.3.1, "How to Pass an Input Parameter to a Bounded Task Flow," describes how to pass an input parameter from a calling task flow to a called bounded task flow using a task flow call activity. Although you can pass parameter values from any activity on the calling task flow, the passed parameter in Section 22.3.1, "How to Pass an Input Parameter to a Bounded Task Flow" contains the value of an input text field on a page in the calling task flow.

If you call a bounded task flow using a URL rather than a task flow call activity, you pass parameters and values on the URL itself. For more information, see Section 21.6.4, "How to Call a Bounded Task Flow Using a URL."

Instead of explicitly passing data controls as parameters between task flows, you can simply share them by specifying the data-control-scope option on the called bounded task flow. For more information, see Section 24.2, "Sharing Data Controls Between Task Flows."

A called task flow can also return values to the task flow that called it when it exits. For more information about returning values from a bounded task flow, see Section 22.4, "Configuring a Return Value from a Bounded Task Flow."

### 22.3.1 How to Pass an Input Parameter to a Bounded Task Flow

You define values on the calling task flow and the called task flow.

**Before you begin:**

- It may be helpful to have an understanding of the configuration options available to you before you configure a bounded task flow to receive an input parameter. For more information, see Section 22.3, "Passing Parameters to a Bounded Task Flow."
- You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 22.1.2, "Additional Functionality for Task Flows Using Parameters."

You will need to complete these tasks:

- Create a calling and called task flow
  
  The calling task flow can be bounded or unbounded. The called task flow must be bounded. For more information about creating task flows, see Section 20.2, "Creating a Task Flow."
- Add a task flow call activity to the calling task flow
  
  Figure 22–3 shows an example where the view activity passes control to the task flow call activity.
To pass an input parameter to a bounded task flow:

1. In the Applications window, double-click the JSF page that contains an input component where an end user enters a value that gets passed to a bounded task flow as a parameter at runtime.

   The JSF page that you open should be referenced by a view activity in the calling task flow.

2. Select an input text component on the JSF page where an end user enters a value at runtime.

3. In the Properties window, expand the **Common** section and enter a value for the input text component in the **Value** field.

   You can specify the value as an EL expression, for example: 
   `#{pageFlowScope.inputValue}`.

4. In the Applications window, double-click the task flow that is going to be called.

5. In the editor window, click the **Overview** tab.

6. In the overview editor, click the **Parameters** navigation tab and then click the **Add** icon to define a new entry in the **Input Parameter Definition** section.

7. In the **Name** field, enter a name for the parameter, for example, `inputParm1`.

8. In the **Value** field, enter an EL expression where the parameter value is stored and referenced, for example, `#{pageFlowScope.inputValue}`.

9. In the Applications window, double-click the calling task flow that contains the task flow call activity to invoke the called bounded task flow.

10. In the Applications window, drag the called bounded task flow and drop it on top of the task flow call activity that is located in the diagram of the calling task flow.

   Dropping a bounded task flow on top of a task flow call activity in a diagram automatically creates a task flow reference to the bounded task flow. As shown in **Figure 22–4**, the task flow reference contains the bounded task flow ID and a document name. The bounded task flow ID (id) is an attribute of the bounded task flow's `<task-flow-definition>` element. The document name points to the source file for the task flow that contains the ID.
11. In the Properties window for the task flow call activity, expand the Parameters section to view the Input Parameters section.

12. Enter a name that identifies the input parameter.
   Because you dropped the bounded task flow on a task flow call activity having defined input parameters, the name should already be specified. You must keep the same input parameter name.

13. Enter a parameter value, for example, #{pageFlowScope.parm1}.
   The value on the task flow call activity input parameter specifies where the calling task flow stores parameter values.
   The value on the input parameter definition for the called task flow specifies where the value will be retrieved from for use within the called bounded task flow once it is passed.

14. At runtime, the called task flow is able to use the input parameter. Since you specified pageFlowScope as the value in the input parameter definition for the called task flow, you can use the parameter value anywhere in the called bounded task flow. For example, you can pass it to a view activity on the called bounded task flow. For more information, see Section 21.2.1.2, "What Happens When You Pass Control Between View Activities."

22.3.2 What Happens When You Pass an Input Parameter to a Bounded Task Flow
JDeveloper writes entries to the source files for the calling task flow and called task flow based on the values that you select. Example 22–3 shows an input parameter definition specified on a bounded task flow.

Example 22–3  Input Parameter Definition
<task-flow-definition id="sourceTaskflow">
   ...
   <input-parameter-definition>
      <name>inputParameter1</name>
      <value>#{pageFlowScope.parmValue1}</value>
      <class>java.lang.String</class>
   </input-parameter-definition>
   ...
</task-flow-definition>

Example 22–4 shows the input parameter metadata for the task flow call activity that calls the bounded task flow shown in Example 22–3. At runtime, the task flow call activity calls the bounded task flow and passes it the value specified by its value element.
22.4 Configuring a Return Value from a Bounded Task Flow

You can configure a bounded task flow to return a parameter value to the task flow that calls it. The value that the bounded task flow returns is in addition to the outcome that it returns to the caller when the bounded task flow invokes a task flow return activity, as described in Section 21.7, "Using Task Flow Return Activities." To return a value, you must configure:

- **Return value definitions on the called bounded task flow**
  The return value definition specifies where you store the value that you want to return from the called bounded task flow.

- **Return values on the task flow call activity in the calling task flow to identify where the calling task flow can find the returned value**
  You can configure the calling task flow to ignore return value definition from the called task flow by not identifying any return values on the task flow call activity in the calling task flow.

The task flow call activity returns values by reference. For this reason, you do not need to make a copy of the values that you want to return to the calling task flow.

22.4.1 How to Configure a Return Value from a Bounded Task Flow

You configure a return value definition on the called task flow and add a parameter to the task flow call activity in the calling task flow that retrieves the return value at runtime.

**Before you begin:**
It may be helpful to have an understanding of the interaction between the calling task flow and the called task flow. For more information, see Section 22.4, "Configuring a Return Value from a Bounded Task Flow."

You may also find it helpful to understand functionality that can be added using other task flow features and parameters. For more information, see Section 22.1.2, "Additional Functionality for Task Flows Using Parameters."

You will need to complete this task:

Create a bounded or unbounded task flow (calling task flow) and a bounded task flow (called task flow). For more information, see Section 20.2, "Creating a Task Flow."

**To configure a return value from a called bounded task flow:**

1. In the Applications window, double-click the called task flow.
2. In the editor window, click the **Overview** tab.

3. In the overview editor, click the **Parameters** navigation tab.

4. In the Parameters page, click the **Add** icon for the **Return Value Definitions** section and add values as follows to define a return value:
   - **Name**: Enter a name to identify the return value. For example, `returnValue1`.
   - **Class**: Enter a Java class that defines the data type of the return value. The default value is `java.lang.String`.
   - **Value**: Enter an EL expression that specifies where to read the return value from. For example, enter an EL expression similar to the following:
     ```java
     #{pageFlowScope.ReturnValueDefinition}
     ```

5. In the Applications window, double-click the calling task flow.

6. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a task call activity onto the diagram.

7. In the Properties window for the task flow activity, expand the **Parameters** section, click the **Add** icon next to the **Return Values** entry and add values as follows to define a return value:
   - **Name**: Enter a name to identify the return value. For example, `returnValue1`.
     The value you enter must match the value you entered for the **Name** field when you defined the return value definition in Step 4.
   - **Value**: Enter an EL expression that specifies where to store the return value. For example, enter an EL expression similar to the following:
     ```java
     #{pageFlowScope.ReturnValueDefinition}
     ```
     The value you enter must match the value you entered for the **Value** field when you defined the return value definition in Step 4.

### 22.4.2 What Happens When You Configure a Return Value from a Bounded Task Flow

At design time, JDeveloper writes entries to the source files for the task flows that you configured. Example 22–5 shows an example entry that JDeveloper writes to the source file for the calling task flow.

**Example 22–5 Metadata in the Calling Task Flow to Configure a Return Value**

```xml
<task-flow-call id="taskFlowCall1">
  <return-value id="__3">
    <name id="__4">returnValue1</name>
    <value id="__2">#{pageFlowScope.ReturnValueDefinition}</value>
  </return-value>
</task-flow-call>
```

Example 22–6 shows an example entry that JDeveloper writes to the source file for the called task flow.

**Example 22–6 Metadata in the Called Task Flow to Configure a Return Value**

```xml
<return-value-definition id="__2">
  <name id="__3">returnValue1</name>
  <value>#{pageFlowScope.ReturnValueDefinition}/</value>
</return-value-definition>
```
At runtime, the called task flow returns a value. If configured to do so, the task flow call activity in the calling task flow retrieves this value.
This chapter describes how to render ADF task flows in pages or page fragments using ADF regions in your Fusion web application. Key features such as the ability to specify parameters, how to refresh or activate an ADF region, navigate to a parent page, and create dynamic ADF regions are also described.

This chapter includes the following sections:

- Section 23.1, "About Using Task Flows in ADF Regions"
- Section 23.2, "Creating an ADF Region"
- Section 23.3, "Specifying Parameters for an ADF Region"
- Section 23.4, "Specifying Parameters for ADF Regions Using Parameter Maps"
- Section 23.5, "Configuring an ADF Region to Refresh"
- Section 23.6, "Configuring Activation of an ADF Region"
- Section 23.7, "Navigating Outside an ADF Region’s Task Flow"
- Section 23.8, "Configuring Transaction Management in an ADF Region"
- Section 23.9, "Creating ADF Dynamic Regions"
- Section 23.10, "Adding Additional Task Flows to an ADF Dynamic Region"
- Section 23.11, "Configuring a Page To Render an Unknown Number of Regions"
- Section 23.12, "Handling Access to Secured Task Flows by Unauthorized Users"

### 23.1 About Using Task Flows in ADF Regions

You can execute a bounded task flow in a JSF page or page fragment (.jsff) by using an ADF region. A primary reason for executing a bounded task flow as an ADF region is reuse. You can isolate specific pieces of application functionality in a bounded task flow and an ADF region in order to reuse it throughout the application. You can extract, configure, and package application functionality within a bounded task flow so that it can be added to other pages using an ADF region. ADF regions can be reused wherever needed, which means they are not dependent on a parent page. This also means that you can isolate the presentation of the parent pages from the ADF region; menus, buttons, and navigation areas are not affected by what is displayed in the ADF region. If you modify a bounded task flow, the changes apply to any ADF region that uses the task flow.

An ADF region comprises the following:

- An `af:region` tag that appears in the page or page fragment where you render the region
An instance object that implements RegionModel from the following package:
 oracle.adf.view.rich.model

For more information about RegionModel, see the Java API Reference for Oracle ADF Faces

One or other of the following:
- A task flow binding (taskFlow) in the page definition that identifies the bounded task flow to use in the ADF region
- A multi task flow binding (multiTaskFlow) in the page definition that identifies a list of bounded task flows to use in the ADF region

When first rendered, the ADF region’s content is that of the first view activity in the bounded task flow. The view activities used in the bounded task flow must be associated with page fragments, not pages.

You can pass values to the ADF region using task flow binding input parameters or contextual events. In addition, you can configure the task flow binding’s parametersMap property to determine what input parameters the task flow binding passes from the bounded task flow to the ADF region.

ADF regions can be configured so that you determine when the region activates or refreshes. You can also configure an ADF region and a bounded task flow so that navigation control stops in the bounded task flow and passes to the page that contains the ADF region. Finally, you can create dynamic regions (ADF dynamic regions) where the task flow binding determines at runtime what bounded task flow renders in the region and configure a dynamic region link so that end users can change the bounded task flow that renders in the ADF dynamic region at runtime.

Figure 23–1 shows how an ADF region references a bounded task flow using a task flow binding in the page definition file of the page that hosts the ADF region.

Figure 23–1  ADF Region Referencing a Bounded Task Flow

23.1.1 About Page Fragments and ADF Regions

A page fragment is a JSF document (file extension is .jsff) that renders as content in another JSF page. A page fragment should not have more than one root component. Wrapping multiple root components in a single root component helps you to optimize the display performance of the page fragment. In addition, if a page fragment has only
one visual root component and a popup component (which is invisible to end users until invoked), consider wrapping these components in a single root component. For example, place the popup component in a panelStretchLayout component’s bottom facet with the bottomHeight attribute set to 0 pixels.

If a page fragment has more than one root component, the Fusion web application logs a message at runtime, as shown in Example 23–1, where r1 identifies the ADF region that renders the page fragment.

Example 23–1  Log Message for a Page Fragment with Multiple Root Components
<RegionRenderer> <encodeAll> The region component with id: r1 has detected a page fragment with multiple root components. Fragments with more than one root component may not display correctly in a region and may have a negative impact on performance. It is recommended that you restructure the page fragment to have a single root component.

Apart from having only one root component element, a page fragment must not contain any of the following tags:

■  <af:document>
■  <f:view>
■  <f:form>
■  <html>
■  <head>
■  <body>

These tags can only appear once in a document and do not support nesting in a JSF page. For example, a page fragment embedded in a page cannot have an <html> tag because the JSF page already has one.

Example 23–2 contains an example of a simple page fragment. Unlike a JSF page, it contains no <f:view> or <f:form> tags.

Example 23–2  Page Fragment Source Code
<?xml version='1.0' encoding='UTF-8'?>
xmlns:af="http://xmlns.oracle.com/adf/faces/rich">
  <af:button text="button 1" id="b1"/>
</ui:composition>

You must nest a page fragment that you include in another JSF page within a region (af:region tag). A bounded task flow that you add to a JSF page as a region cannot call pages; it must call page fragments.

23.1.2 About View Ports and ADF Regions
A view port is a display area capable of navigating independently of other view ports. A browser window and an ADF region are both examples of view ports. The root view port displays the main page in a browser window. The root view port may have child view ports, for example, regions on the page, but does not have a parent view port.

Java classes that implement the ViewPortContext interface in the oracle.adf.controller package get you more information about view ports. For more information, see the Java API Reference for Oracle ADF Controller.
23.1.3 Task Flows and ADF Region Use Cases and Examples

Figure 23–2 shows the General Information page fragment (GeneralInfo.jsff) from the edit-customer-task-flow-definition.xml task flow in the Summit sample application for ADF task flows. This task flow renders in an ADF region and displays information about customers in a series of page fragments that authenticated users can navigate through and edit using the provided controls. For more information about creating this type of region, see Section 23.2, "Creating an ADF Region."

Figure 23–2 ADF Region in the Summit ADF Task Flow Sample Application

Figure 23–2 also shows links (labeled Register as Employee and Register as Customer) that invoke different task flows in the ADF dynamic region that the showDetailItem component labeled Welcome renders. For more information about creating this type of region, see Section 23.9, "Creating ADF Dynamic Regions."

Figure 23–3 shows the edit-customer-task-flow-definition.xml task flow in JDeveloper. It contains three view activities to display information about customers to end users.

Figure 23–3 Edit Customer Task Flow in ADF Summit Application for ADF Task Flows

23.1.4 Additional Functionality for Task Flows that Render in ADF Regions

You may find it helpful to understand how a task flow that renders in an ADF region interacts with other task flow and ADF functionality. Following are links to other functionality that may be of interest.
Creating an ADF Region

You can set security on a bounded task flow that displays in an ADF region and associated page definitions. If an end user displays a page that contains an ADF region that the user is not authorized to view, the contents of the ADF region do not display. No authentication mechanism is triggered. For more information, see Chapter 41, "Enabling ADF Security in a Fusion Web Application."

Task flows can invoke managed beans. For more information about managed beans, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

You can use contextual events to exchange information with a bounded task flow. For more information, see Section 40, "Using Contextual Events."

23.2 Creating an ADF Region

You create an ADF region by dragging and dropping a bounded task flow that contains at least one view activity or one task flow call activity to the page where you want to render the ADF region. This makes sure that the ADF region you create has content to display at runtime.

The bounded task flow’s view activities must be associated with page fragments (.jsff). If you attempt to drag and drop a bounded task flow that is associated with pages rather than page fragments, JDeveloper does not display the context menu that allows you to create an ADF region. You can convert a bound task flow that uses pages to use page fragments. For more information, see Section 20.6.4, "How to Convert Bounded Task Flows."

The context menu that appears to create an ADF region presents options to create a nondynamic and a dynamic region. A dynamic region (ADF dynamic region) determines the bounded task flow that it renders at runtime. For more information about creating an ADF dynamic region, see Section 23.9, "Creating ADF Dynamic Regions." You determine at design time the bounded task flow that a nondynamic region (ADF region) displays.

23.2.1 How to Create an ADF Region

Drag a bounded task flow from the Applications window to the page where you want to render an ADF region.

Before you begin:
It may be helpful to have an understanding of the requirements for a bounded task flow that you use in an ADF region. For more information, see Section 23.2, "Creating an ADF Region."

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Section 23.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."

You will need to complete these tasks:

- Create a bounded task flow with one or more view activities associated with page fragments or one task flow call activity to a task flow with view activities.
  For more information, see Section 20.2, "Creating a Task Flow."

- Create a JSF page to host the ADF region.
  For more information, see the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.
Creating an ADF Region

To create an ADF region:

1. In the Applications window, double-click the JSF page where you want to locate the ADF region.

2. From the Applications window, drag and drop the bounded task flow onto the JSF page, and from the context menu, choose Create > Region.

3. If the Edit Task Flow Binding dialog appears, click OK.

   The Edit Task Flow Binding dialog appears if the bounded task flow that you drop on the JSF page has an input parameter defined, as described in Section 22.3.1, "How to Pass an Input Parameter to a Bounded Task Flow."

   For more information about specifying parameters for an ADF region, see Section 23.3, "Specifying Parameters for an ADF Region."

4. In the Structure window, right-click the node for the ADF region that you added (af:region) and choose Go to Properties.

5. Review or modify (as appropriate) the following fields which JDeveloper automatically populates with default values in the Properties window for the ADF region:
   - **Id**: An ID that the JSF page uses to reference the ADF region, for example, r1.
   - **Value**: An EL reference to the ADF region model, for example, #{bindings.region1.regionModel}. This is the region model that describes the behavior of the region.
   - **Rendered**: If true (the default value), the ADF region renders when the JSF page renders.

6. For information about how to map parameters between the view activity associated with the JSF page and the ADF region, see Section 23.3, “Specifying Parameters for an ADF Region.”

23.2.2 What Happens When You Create an ADF Region

When you drop a bounded task flow onto a JSF page to create an ADF region, JDeveloper adds an af:region tag to the page. The af:region tag references an object that implements RegionModel. Example 23–3 shows the af:region tag that appears in the Customers.jsff page fragment of the Summit ADF task flow sample application.
Example 23–3  Metadata Added to a JSF Page to Create an ADF Region

<af:region value="#{bindings.editcustomertaskflowdefinition1.regionModel}" id="r2"/>

JDeveloper also adds a task flow binding to the page definition file of the page that hosts the ADF region. Example 23–4 shows a sample of the metadata that JDeveloper adds. The task flow binding provides a bridge between the ADF region and the bounded task flow. It binds a specific instance of an ADF region to its associated bounded task flow and maintains all information specific to the bounded task flow. The taskFlowId attribute specifies the directory path and the name of the source file for the bounded task flow.

Example 23–4  Metadata Added to Page Definition to Create a Task Flow Binding

The bounded task flow preserves all of the data bindings when you drop it on the JSF page. At runtime, a request for a JSF page containing an ADF region initially handles like any other request for a JSF page. As the JSF page definition executes, data loads in to the JSF page. When the component tree for the parent JSF page encounters the <af:region> tag, it executes it in order to determine the first page fragment of content to display. Once it determine the first page fragment of content, it adds the appropriate UI components from the page fragment to the component tree for the parent JSF page.

The task flow binding creates an object for its task flow that implements the following interface in order to get the current view activity:

oracle.adf.controller.ViewPortContext

The task flow binding’s taskFlowId attribute can also reference an EL expression that evaluates to one of the following:

- java.lang.String
- oracle.adf.controller.TaskFlowId

You use this capability if you create an ADF dynamic region. For more information, see Section 23.9, "Creating ADF Dynamic Regions."

23.3 Specifying Parameters for an ADF Region

You can make input parameters that you defined for a bounded task flow available to an ADF region by adding them to the task flow binding that the ADF region references. Use EL expressions to reference input parameters available in memory scopes, managed beans, or the ADF binding layer.

Specifying input parameters is one method of providing information to an ADF region. An alternative method is to use contextual events. The nature of the information that you want to provide to the ADF region determines the method you choose to provide the information. For example, choose:

- Input parameters if the required information is at the beginning of the task flow and a change in the value of this information requires a restart of the task flow.
For example, you have a page that contains a table of employees. An ADF region on that page contains a task flow to enroll a selected employee in a benefits program. A change in the selected employee requires that you restart the benefits enrollment task flow from the beginning for the newly selected employee. Using input parameters to the task flow is the right decision for this use case.

You can pass input parameters by reference or by value. If you pass by reference, an update on the main page for the selected employee's information, such as last name, is automatically reflected in the task flow running in the ADF region without restarting the task flow.

Contextual events if you can only determine the information to exchange after the start of a task flow and a change in the information does not require a restart of the task flow. For example, the Inventory Control tab in the Summit ADF task flow sample application uses contextual events to display the appropriate chart for product inventory in one region in response to the product that a user selects in another region. For more information, see Chapter 40, "Using Contextual Events."

For information about creating an ADF region and adding task flow bindings, see Section 23.2, "Creating an ADF Region." For information about how to define an input parameter for a bounded task flow, see Section 22.3, "Passing Parameters to a Bounded Task Flow."

### 23.3.1 How to Specify Parameters for an ADF Region

Use EL expressions to specify parameters available in memory scopes, managed beans, or the ADF binding layer as input for the ADF region.

**Before you begin:**

It may be helpful to have an understanding of the requirements for specifying parameters for an ADF region. For more information, see Section 23.3, "Specifying Parameters for an ADF Region."

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Section 23.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."

**To specify input parameters for an ADF region:**

1. In the Applications window, right-click the JSF page that holds the ADF region and choose **Go to Page Definition**.

2. In the overview editor, click the **Bindings and Executables** navigation tab, select the task flow binding for which you want to specify parameters and click the **Edit** icon.

3. In the **Edit Task Flow Binding** dialog, write EL expressions that retrieve the values of each input parameter you want to specify for the ADF region. Note that you must write an EL expression for parameters that you defined as required. For example, write an EL expression similar to the following:

   ```el
   #{pageFlowScope.inputParameter1}
   ```

   Figure 23–5 shows the **Edit Task Flow Binding** dialog where the Input Parameters section lists a number of input parameters that were defined for the bounded task, as described in Section 22.3, "Passing Parameters to a Bounded Task Flow."
23.3.2 What Happens When You Specify Parameters for an ADF Region

JDeveloper writes entries that are child elements of the `taskFlow` element in the page definition of the JSF page, as illustrated in example Example 23–5.

Example 23–5 Metadata Entries to Specify Input Parameters for an ADF Region

```xml
<taskFlow id="tflow_tf1" taskFlowId="/WEB-INF/tflow_tf1.xml#tflow_tf1" activation="deferred" xmlns="http://xmlns.oracle.com/adf/controller/binding">
  <parameters>
    <parameter id="inputParameter1" value="#{pageFlowScope.inputParameter1}"/>
    <parameter id="inputParameter2" value="#{pageFlowScope.inputParameter2}"/>
  </parameters>
</taskFlow>
```

At runtime, the values specified by the EL expression in the value attribute are passed to the ADF region.

23.4 Specifying Parameters for ADF Regions Using Parameter Maps

In addition (or as an alternative) to listing all the input parameters on the task flow binding, as described in Section 23.3, "Specifying Parameters for an ADF Region," you can use the `parametersMap` property of the task flow binding to specify a parameter map object on a managed bean. The parameter map object that you reference must be of a type that implements the following interface:

---

**Note:** You can write an EL expression that references a list of input parameters specified in a managed bean using the Input Parameters Map field of the Edit Task Flow Binding dialog. For more information about implementing this functionality, see Section 23.4, "Specifying Parameters for ADF Regions Using Parameter Maps."
java.util.Map

The parameter map object that you reference specifies keys that map to the values you want to input to the ADF region. Using this approach reduces the number of parameter child elements that appear under the task flow binding (taskFlow) element or the multi task flow binding (multiTaskFlow) in the page definition for the page. This approach also allows you more flexibility in determining what input parameters pass to the ADF region. In particular, it provides a way to pass parameters to ADF dynamic regions as the number of input parameters can differ between the different task flow bindings in an ADF dynamic region. For more information, see Section 23.9, "Creating ADF Dynamic Regions."

You can configure an ADF region or an ADF dynamic region’s task flow binding to reference a parameter map. You can also configure a multi task flow binding to reference a parameter map. Make sure that the name of an input parameter you define for a bounded task flow matches the name of a key that you define in the parameter map object.

If you specify a parameter with the same id attribute in a <parameter> element and in a <parametersMap> element, the <parametersMap> element always takes precedence. This is because the <parametersMap> element may need to override the static value of the parameter if you create an ADF dynamic region, as described in Section 23.9, "Creating ADF Dynamic Regions."

23.4.1 How to Create a Parameter Map to Specify Input Parameters for an ADF Region

You configure the task flow binding’s parametersMap property to reference the parameter map object that defines the key-value pairs you want to pass to the ADF region.

Before you begin:
It may be helpful to have an understanding of the configuration options available to you when passing input parameters to an ADF region. For more information, see Section 23.4, "Specifying Parameters for ADF Regions Using Parameter Maps."

You may also find it helpful to understand functionality that can be added using other task flow and ADF region features. For more information, see Section 23.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."

You will need to complete this task:

Create a managed bean or edit an existing managed bean so that it returns an object that implements the java.util.Map interface. Configure the managed bean so the object returns key-value pairs with the values that you want to pass to the ADF region. For more information about managed beans, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

To create a parameter map to specify input parameters for an ADF region:
1. In the Applications window, right-click the JSF page that holds the ADF region and choose Go to Page Definition.
2. In the overview editor, click the Bindings and Executables navigation tab, select the task flow binding or multi task flow binding for which you want to specify a parameter map, and then click the Edit icon.
   The type of task flow binding that you select determines the dialog that appears.
3. In the Edit Task Flow Binding dialog or the Edit Multi Task Flow Binding dialog, select Expression Builder from the Input Parameters Map dropdown menu.
4. Write or build an EL expression that references a parameter map. For example, write an EL expression similar to the following:

`#{pageFlowScope.userInfoBean.parameterMap}`

5. Click OK.

### 23.4.2 What Happens When You Create a Parameter Map to Specify Input Parameters

At runtime, the task flow binding or multi task flow binding evaluates the EL expression specified for its `parametersMap` property. It returns values to the ADF region from the managed bean for keys that match the name of the input parameters defined for the bounded task flow that render in the ADF region.

Example 23–6 shows code snippets from a managed bean that puts two values (`isLoggedIn` and `principalName`) into a parameter map named `parameterMap`.

**Example 23–6 Managed Bean Defining a Parameter Map**

```java
import java.util.HashMap;
import java.util.Map;

public class UserInfoBean {
    private Map<String, Object> parameterMap = new HashMap<String, Object>();

    public Map getParameterMap() {
        parameterMap.put("isLoggedIn", getSecurity().isAuthenticated());
        parameterMap.put("principalName", getSecurity().getPrincipalName());
        return parameterMap;
    }
}
```

Figure 23–6 shows the Edit Task Flow Binding dialog after you close the Expression Builder dialog, having specified the parameter map object (`parameterMap`) shown in Example 23–6. The **Input Parameters** field in the Edit Task Flow Binding dialog lists the input parameters defined for the bounded task flow associated with this ADF region (checkout-flow). The task flow binding retrieves the values for these parameters from the managed bean shown in Example 23–6.
Configuring an ADF Region to Refresh

Example 23–7 shows the metadata that appears for the task flow binding in the page definition file of the page that renders the ADF region. The metadata for the task flow binding references both the bounded task flow (taskFlowId attribute) and the managed bean (parametersMap).

**Example 23–7  Task Flow Binding Specifying a Parameter Map**

```xml
<taskFlow id="checkoutflow1"
    taskFlowId="/WEB-INF/checkout-flow.xml#checkout-flow"
    activation="deferred"
    xmlns="http://xmlns.oracle.com/adf/controller/binding"
    parametersMap="#{pageFlowScope.userInfoBean.parameterMap}"/>
```

You specify the `<parameterMap>` element in the page definition.

**Note:** If you specify `Refresh="ifNeeded"`, parameters are not supported in the `<parameterMap>` element. The only condition that determines whether the region need to be refreshed is the boolean value returned by the evaluation of `RefreshCondition`. For more information, see Section 23.5.2, "What You May Need to Know About Configuring an ADF Region to Refresh."

23.5 Configuring an ADF Region to Refresh

You can configure when an ADF region refreshes and whether it invokes a task flow. An ADF region can only invoke a task flow when the ADF region is in an active state. An ADF region in an inactive state cannot invoke a task flow and returns a null value for the ID of the referenced task flow to the parent page.
23.5.1 How to Configure the Refresh of an ADF Region

You set values for the task flow binding of the task flow associated with the ADF
region to determine when an ADF region switches from an inactive to an active state
and to determine when an ADF region refreshes.

Before you begin:

It may be helpful to have an understanding of the requirements for a bounded task
flow that you use in an ADF region. For more information, see Section 23.5,
"Configuring an ADF Region to Refresh."

You may also find it helpful to understand functionality that can be added using other
task flow features and ADF region features. For more information, see Section 23.1.4,
"Additional Functionality for Task Flows that Render in ADF Regions."

To configure the refreshing of an ADF Region:

1. In the Applications window, select the page that contains the ADF region,
right-click and choose Go to Page Definition.

2. In the page definition file, select the task flow binding or multi task flowing
binding in the Executables section, as illustrated in Figure 23–7.

3. Choose the appropriate option to refresh the ADF region.
   - Refresh if the value of a task flow binding parameter changes.
     In the Properties window, select ifNeeded from the Refresh dropdown list.
     Do not select ifNeeded if you want to set a value for the RefreshCondition
property. The RefreshCondition property will not be evaluated if you
select ifNeeded for the Refresh property.
   - Refresh if a condition that you specify returns true.
     In the Properties window, write an EL expression in the RefreshCondition
field that returns a boolean value. If the EL expression returns true, the ADF
region refreshes.

4. In the Properties window, select a value from the activation dropdown list, as
described in the following list:
   - conditional: activates the ADF region if the EL expression set as a value for
the task flow binding active property returns true.
   - deferred: select this option if your application uses Facelets XHTML pages in
the view layer and you want to activate the ADF region when a Facelets
XHTML page first requests a viewID. If your application uses JSP technology
in the view layer, selecting this option has the same effect as selecting **immediate** (the ADF region activates immediately) provided that the parent component for the ADF region is not a popup or panelTabbed component that has its childCreation attribute set to deferred. If this latter scenario occurs, the parent component (popup or panelTabbed) determines behavior.

Use this option if your application uses Facelets XHTML pages. For more information about Facelets with ADF Faces, see the "Getting Started with ADF Faces and JDeveloper" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- **immediate**: activates the ADF region immediately. This is the default value.

The value that you select in the dropdown list determines when an ADF region switches from an inactive to an active state. An ADF region must have an active state before it can invoke a task flow.

5. If you selected **conditional** as the value for the activation property, write an EL expression that returns a boolean value at runtime for the active property. If the EL expression returns **true**, the ADF region invokes the task flow.

### 23.5.2 What You May Need to Know About Configuring an ADF Region to Refresh

An ADF region initially refreshes when the parent JSF page on which the region is located first displays. During the initial refresh, any ADF region task flow binding parameter values are passed in from the parent page. The parameter values are used to display the initial page fragment within the ADF region. If the bounded task flow relies on input parameter values that are not available when the page is first created, make sure that your task flow behaves correctly if the input parameter values are null by, for example, using a **NullPointerException** object. Alternatively (or additionally), make sure that the task flow does not activate until the input parameters become available by configuring the task flow binding’s active property.

An ADF region task flow binding can be refreshed again based on one of the following task flow binding attributes:

- **taskFlowId**
  This attribute specifies the directory path and the name of the source file for the bounded task flow. The ADF region refreshes if this attribute value changes.

- Neither **Refresh** or **RefreshCondition** attributes are specified (default)
  If neither the **Refresh** or **RefreshCondition** task flow binding attribute is specified, the ADF region is refreshed only once at the time the parent page is first displayed unless you configure a value for the task flow binding’s active property.

- **RefreshCondition="#{EL.expression}"**
  The ADF region is refreshed a single time when its **RefreshCondition** property evaluates true. The **RefreshCondition** must evaluate to a boolean value. At the time the **RefreshCondition** is evaluated, if the variable bindings is used within the EL Expression, the context refers to the binding container of the parent page, not the page fragment displayed within the ADF region.

  **RefreshCondition** is independent of the change of value of binding parameters. If the task flow binding parameters do not change, nothing within the ADF region will change.

- **Refresh="ifNeeded"**
Any change to a task flow binding parameter value causes the ADF region to refresh. If the ADF region task flow binding does not have parameters, Refresh="ifNeeded" is equivalent to not specifying the Refresh attribute.

Refresh="ifNeeded" is not supported if you pass parameters to the task flow binding using a dynamic parameter map. You must instead use the RefreshCondition="#{EL.Expression}".

For more information about specifying parameter values using a parameter map, see Section 23.4, "Specifying Parameters for ADF Regions Using Parameter Maps."

The Refresh="ifNeeded" property takes precedence over RefreshCondition and RefreshCondition will not be evaluated if you set Refresh="ifNeeded".

If the bindings variable is used within the EL expression at the time RefreshCondition is evaluated, the context refers to the binding container of the parent page, not the page fragment displayed within the ADF region. The expression is evaluated during the PrepareRender phase of the ADF page lifecycle. For more information, see Chapter 27, "Understanding the Fusion Page Lifecycle".

Example 23–8 contains a sample task flow binding located within the page definition of a page on which an ADF region has been added.

Example 23–8 Refresh Option Specified in ADF Region Binding

```xml
<taskFlow id="Department1" taskFlowId="/WEB-INF/Department#Department"
xmlns="http://xmlns.oracle.com/adf/controller/binding">
<parameters>
  <parameter id="DepartmentId" value="#{bindings.DepartmentId.inputValue}"
xmlns="http://xmlns.oracle.com/adfm/uimodel"/>
</parameters>
</taskFlow>
```

You do not need to refresh an ADF region to refresh the data controls inside the ADF region. During the ADF lifecycle, the refresh events telling the iterators to update will be propagated to the binding container of the current page of the ADF region.

### 23.6 Configuring Activation of an ADF Region

You can configure when an ADF region activates. This has the effect of determining when the task flows contained in ADF regions activate. Configuring the activation of ADF regions can optimize the performance of a Fusion web application's page. For example, a page that contains 5 ADF regions may reference 5 task flows. You may not want these 5 task flows to execute simultaneously when the Fusion web application page loads so you configure an activation property to determine when a task flow executes.

#### 23.6.1 How to Configure Activation of an ADF Region

You configure the activation property for the task flow binding associated with the ADF region to determine when to activate the ADF region.

**Before you begin:**

It may be helpful to have an understanding of the configuration options for activating an ADF region. For more information, see Section 23.6, "Configuring Activation of an ADF Region."
You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Section 23.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."

**To configure the activation of an ADF region:**

1. In the Applications window, select the page that contains the ADF region(s), right-click and choose **Go to Page Definition**.

2. In the page definition file, select the task flow binding or multi task flow binding in the **Executables** section, as illustrated in Figure 23–8.

**Figure 23–8 Task Flow Bindings for ADF Region Configured for Activation**

3. In the Properties window, select a value from the **activation** dropdown list, as described in the following list:
   - **conditional**: activates the ADF region if the EL expression set as a value for the task flow binding **active** property returns **true**.
   - **deferred**: select this option if your application uses Facelets XHTML pages in the view layer and you want to activate the ADF region when a Facelets XHTML page first requests a **viewID**. If your application uses JSP technology in the view layer, selecting this option has the same effect as selecting **immediate** (the ADF region activates immediately).
     
     Use this option if your application uses Facelets XHTML pages. For more information about Facelets with ADF Faces, see the "Getting Started with ADF Faces and JDeveloper" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
   - **immediate**: activates the ADF region immediately. This is the default value.

   The value that you select in the dropdown list determines when an ADF region switches from an inactive to an active state. An ADF region must have an active state before it can invoke a task flow.

4. If you selected **conditional** as the value in the **activation** dropdown list, write an EL expression that returns a boolean value at runtime for the active property. If the EL expression returns **true**, the ADF region invokes the task flow. If the EL expression returns **false**, the ADF region deactivates a task flow that was active in the ADF region.
23.6.2 What Happens When You Configure Activation of an ADF Region

The behavior of the ADF region at runtime depends on the options that you set for the `activation` property.

Figure 23–9 shows the default behavior where all task flows in ADF regions execute when the page loads the ADF regions (Tab # 1, Tab # 2, Tab # 3).

![Default Activation of ADF Regions](image)

Figure 23–9 Default Activation of ADF Regions

- Tab #1: Task Flow
- Tab #2: Task Flow
- Tab #3: Task Flow

Figure 23–10 shows an example where the activation property was set to `deferred` and the application uses Facelets. The regions in Tab # 1 and Tab # 2 have an active state because the end user navigated to these regions. The region in Tab # 3 is inactive.

![Deferred Activation of ADF Regions](image)

Figure 23–10 Deferred Activation of ADF Regions

- Tab #1: Task Flow
- Tab #2: Task Flow
- Tab #3: Task Flow

Figure 23–11 shows an example where the activation property was set to `conditional` and the active property to an EL expression that returns a boolean value at runtime. The region in Tab # 1 is in an active state because the EL expression specified for the active property returns `true`. The regions in Tab # 2 and Tab # 3 are inactive because the EL expression specified for the active property returns `false`.

Note that the following events occur if a region deactivates a task flow (the value returned by the `active` property changes from `true` to `false`):

- A task flow with an active transaction rolls back the transaction.
  
  For more information about transaction options in task flows, see Section 24.3, "Managing Transactions in Task Flows."

- If a task flow has a data control frame with a `data-control-scope` value of `isolated`, the task flow releases the data control frame and any data controls in the data control frame.

  For more information about data controls, see Section 24.2, "Sharing Data Controls Between Task Flows" and Section 24.3.3, "What You May Need to Know About Sharing Data Controls and Managing Transactions."
ADF Controller releases the view port data structures for the region (including pageFlow and view scopes).

For more information about view ports, see Section 23.1.2, "About View Ports and ADF Regions." For more information about memory scopes, see Section 20.2.4, "What You May Need to Know About Memory Scope for Task Flows."

Figure 23–11  Conditional Activation of ADF Regions

Conditional Region Activation

Tab #1  Tab #2  Tab #3
Region1: TaskFlow
Region2: visible=true active=true
Region3: visible=false active=false
Region4: visible=false active=true

23.7 Navigating Outside an ADF Region’s Task Flow

A bounded task flow running in an ADF region may need to trigger navigation of its parent view activity or to navigate to the root page of its application. The parent action activity exposes properties (parent-outcome and root-outcome) that you configure if you want to implement either of these use cases.

For example, you might specify a value for parent-outcome if you have a page that displays employee information and an ADF region that contains an enroll button for an employee. After the enroll page completes and the ADF region returns, the employee information page refreshes with the next employee.

Note: An ADF region does not maintain state when you navigate away from the region.

23.7.1 How to Trigger Navigation Outside of an ADF Region’s Task Flow

You add a parent action activity to the bounded task that runs in the ADF region and configure it so that it navigates to the parent’s view activity.

Before you begin:
It may be helpful to have an understanding of the configuration options for activating an ADF region. For more information, see Section 23.6, "Configuring Activation of an ADF Region."

You may also find it helpful to understand functionality that can be added using other task flow features and ADF region features. For more information, see Section 23.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."

To trigger navigation outside of an ADF region’s task flow:
1. In the Applications window, double-click the bounded task flow that runs in the ADF region.
2. In the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop a Parent Action onto the diagram for the bounded task flow.
3. Select the parent action activity in the diagram for the bounded task flow.
4. In the Properties window, choose the appropriate option:

- **Parent Outcome**: enter a literal value or write an EL expression that returns an outcome so that the parent action activity navigates to the parent view activity. The outcome is then used to navigate the parent view activity’s task flow rather than navigating the ADF region’s bounded task flow.

  The parent view activity’s task flow should contain a control flow case or wildcard control flow rule that accepts the value you specify for `parent-outcome`.

- **Root Outcome**: enter a literal value or write an EL expression that returns an outcome so that the parent action activity navigates to the root page of the application.

  For example, to navigate from an ADF region to the home page in your application, you specify a value for **Root Outcome**, as illustrated in Figure 23–12.

*Figure 23–12 Navigating to Home Page*

5. (Optional) In the **Outcome** field, enter a literal value that specifies an outcome for control flow within the ADF region after the parent action activity adds `parent-outcome` or `root-outcome` to the appropriate queue.

  Specifying an `outcome` element is useful in cases where the parent view activity or root page does not navigate as a result of the `parent-outcome` or `root-outcome` sent by the parent action activity. In addition, the ADF region should not continue to display the same view. If you do not specify a value for `outcome`, the ADF region’s `viewId` remains unchanged.

### 23.7.2 What Happens When You Configure Navigation Outside a Task Flow

At design time, JDeveloper writes entries to the source file for the bounded task flow based on the property values you set for the parent action activity. **Example 23–9** shows sample entries that JDeveloper generates when you write a literal value for the Parent Outcome and Outcome properties of the parent action activity.

**Example 23–9 Metadata for a Parent Action Activity with a Parent Outcome**

```xml
<parent-action id="parentAction1">
  <parent-outcome>parent_outcome</parent-outcome>
  <outcome id="__2">outcome</outcome>
</parent-action>
```

**Note**: **Parent Outcome** and **Root Outcome** are mutually exclusive.
Example 23–10 shows sample entries that JDeveloper generates when you write a literal value for the Root Outcome and Outcome properties of the parent action activity.

**Example 23–10  Metadata for a Parent Action Activity with a Root Outcome**

```
<parent-action id="parentAction1">
  <root-outcome>root_outcome</root-outcome>
  <outcome id="__2">outcome</outcome>
</parent-action>
```

At runtime, the bounded task flow navigates to its parent view activity or the root page of the Fusion web application depending on the property that you configured for the parent action activity.

### 23.7.3 What You May Need to Know About How a Page Determines the Capabilities of an ADF Region

In some cases, a page may need to determine the capabilities currently available within one of the ADF regions that it contains. For example, the page may need to initiate control flow within the ADF region based on its current state using the `queueActionEventInRegion()` method. *Region capabilities* are used by a parent page to identify the current outcomes of one of its regions based on the region's current state. They identify to the parent page whether or not an outcome is possible within the region.

The following scenario describes how region capabilities might typically be used in an application:

1. An ADF region within a page displays its associated page fragment.
2. A user selects a button or performs some other action in the ADF region.
3. The parent page identifies the outcomes (region capabilities) for the ADF region.
4. The parent page updates its buttons based on the ADF region capabilities.

The syntax of an EL expression to determine an ADF region’s capabilities is as follows:

```
#{bindings.[regionId].regionModel.capabilities['outcome']}
```

where `regionId` is the ID of the ADF region component on the page and `outcome` is the possible outcome being verified within the ADF region.

Region capabilities require the availability of the specified ADF region’s `regionModel` through an EL expression. The EL expression should never access bindings in any other binding container other than the current binding container. Region capabilities cannot be used in some cases. For example, a nested ADF region where a `regionModel` cannot be reached within the current binding container. This is because a nested region’s nested binding container might not yet exist or might have already been released.

### 23.8 Configuring Transaction Management in an ADF Region

ADF task flows provide options to implement transactions, as described in Section 24.3, "Managing Transactions in Task Flows." You can choose whether a task flow shares or isolates its data controls with a calling task flow by setting a value for its `data-control-scope` property, as described in Section 24.2, "Sharing Data Controls Between Task Flows." Whether a task flow creates a new transaction depends on the
values you choose for the transaction and data-control-scope properties, as described in Section 24.3.3, "What You May Need to Know About Sharing Data Controls and Managing Transactions."

If, for example, you share a task flow's data control with a calling task flow, a new transaction is created if you configure the task flow's transaction option to Always Begin New Transaction (new-transaction) or to Use Existing Transaction If Possible (requires-transaction). The requires-transaction option creates a new transaction only if a transaction does not already exist. The created transaction has the same lifespan as the ADF region that renders the task flow. This may cause behavior that you do not intend when the task flow renders in an ADF region. For example, if an ADF region refreshes, it restarts the task flow that it renders and causes the following events to occur:

- Discards the current view port that the ADF region uses

---

**Note:** Save points require a root view port to work. For more information about view ports, see Section 23.1.2, "About View Ports and ADF Regions." For more information about save points, see Section 24.7, "Using Save Points in Task Flows."

---

- Releases the data control that the task flow uses

  This may cause the loss of changes made in the parent page of the calling task flow because it shares the data control of the task flow that renders in the ADF region.

- Executes a commit or rollback if the End Transaction property of the task flow's task flow return activity specifies one of these actions. For more information, see Section 21.7, "Using Task Flow Return Activities."

There are a number of ways to prevent the inadvertent termination of a task flow's transaction by the refresh of an ADF region. All these options disassociate the lifespan of the transaction in the task flow that renders in an ADF region from the lifespan of the ADF region. These options make sure that the region's parent page owns the transaction and/or that the transaction starts before the region renders. Choose the most appropriate option for your application:

- Set the transaction option on the taskflow that renders in the ADF region to Always Use Existing Transaction (requires-existing-transaction). This throws an exception if a transaction does not exist and prevents the ADF region from owning the transaction.

- Set the calling task flow's transaction option to Always Begin New Transaction (new-transaction) so that the lifespan of the transaction is associated with the lifespan of the parent page.

- Invoke the DataControlFrame interface's beginTransaction() method in the action that navigates to the parent page that contains the region.

- Configure a method call activity that invokes the DataControlFrame interface's beginTransaction() method from a managed bean with a request scope before navigating to the parent page of the ADF region.

The following code begins a transaction:

```java
public void beginTransaction()
{
    BindingContext context = BindingContext.getCurrent();

    String dcFrameName = context.getCurrentDataControlFrame();
```
DataControlFrame dcFrame = context.findDataControlFrame(dcFrameName);
dcFrame.beginTransaction(new TransactionProperties());
}

If you share the data controls of a task flow with a calling task flow, use the rollback or commit options exposed by the task flow’s task flow return activity to commit or rollback changes rather than programmatically use the methods exposed by the ADF Model layer’s DataControlFrame interface. Using the methods exposed by the DataControlFrame interface closes the transaction and may cause the task flow that renders in the ADF region to create a new transaction.

23.9 Creating ADF Dynamic Regions

An ADF dynamic region is an ADF region where the task flow binding dynamically determines the value of its taskFlowId attribute at runtime. This allows the Fusion web application to determine which bounded task flow to execute within the ADF dynamic region based on the result of evaluation of the task flow binding’s taskFlowId attribute.

Figure 23–13 shows a runtime example from the Summit ADF task flow sample application where the index.jsf page renders a different registration task flow in the showDetailItem component labeled Welcome in response to the link component that the end user clicks. For example, if the end user clicks Register as Employee, the application renders the emp-reg-task-flow-definition.xml task flow in the ADF dynamic region. If the end user clicks Register as Customer, the application renders the edit-customer-task-flow-definition.xml task flow in the ADF dynamic region.

At runtime, the ADF dynamic region swaps the task flows that it renders during the Prepare Render lifecycle phase. To give components from a previous task flow the opportunity to participate smoothly in the lifecycle phases, do not navigate off the regionModel until the JSF Invoke Application lifecycle phase. It is good practice, therefore, not to navigate a task flow in a dynamic region in response to contextual events. For more information about lifecycle phases, see Chapter 27, "Understanding the Fusion Page Lifecycle," and for more information about contextual events, see Chapter 40, "Using Contextual Events."

Figure 23–13 ADF Dynamic Region in the Summit ADF Task Flow Sample Application

You create an ADF dynamic region by dragging and dropping a bounded task flow to the page where you want to render the ADF dynamic region. The view activities in the bounded task flow must be associated with page fragments (.jsff).
If you attempt to drag and drop a bounded task flow that is associated with pages rather than page fragments, JDeveloper does not display the context menu that allows you to create an ADF dynamic region. You can convert a bound task flow that uses pages to use page fragments. For more information, see Section 20.6.4, "How to Convert Bounded Task Flows."

After you create an ADF dynamic region, you can add additional bounded task flows to the dynamic region by creating ADF dynamic region links, as described in Section 23.10, "Adding Additional Task Flows to an ADF Dynamic Region."

### 23.9.1 How to Create an ADF Dynamic Region

Drag and drop bounded task flows to the page where you want to render the ADF dynamic region.

**Before you begin:**

It may be helpful to have an understanding of the configuration options available to you when creating an ADF dynamic region. For more information, see Section 23.9, "Creating ADF Dynamic Regions."

You may also find it helpful to understand other functionality that can be added using other task flow and ADF region features. For more information, see Section 23.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."

**To create an ADF dynamic region:**

1. In the Applications window, double-click the JSF page where you want to create the ADF dynamic region.
2. From the Applications window, drag and drop the first bounded task flow onto the JSF page, and from the context menu, choose **Create > Dynamic Region.**
3. Choose the appropriate option in the Choose Managed Bean for Dynamic Region dialog:
   - If you want an existing managed bean to store the bounded task flow’s ID, select an existing managed bean from the **Managed Bean** dropdown list.
     - The managed bean passes the value of the bounded task flow’s ID into the task flow binding of the ADF dynamic region. Make sure that the managed bean you select is not used by another ADF dynamic region.
   - If no managed bean exists for the page, click the **Add** icon next to the **Managed Bean** dropdown list to create a new one. Enter values in the dialog that appears as follows:
     a. **Bean Name:** Enter a name for the new managed bean. For example, enter `DynamicRegionBean`.
     b. **Class Name:** Enter the name of the new managed bean class.
     c. **Package:** Enter the name of the package that is to contain the managed bean or browse to locate it.
     d. **Extends:** Enter the name of the Java class that the managed bean extends. The default value is `java.lang.Object`.
     e. **Scope:** This field is read-only and its value is set to `backingBean`. For more information about the memory scope for managed beans, see Section 20.2.4, "What You May Need to Know About Memory Scope for Task Flows."
1. Click **OK** to close the dialogs where you configure the managed bean.

4. Choose the appropriate option in the Edit Task Flow Binding dialog:
   - Click **OK** if you do not want specify input parameters or an input parameter map for the ADF dynamic region.
   - Specify input parameters for the ADF dynamic region.
     
     For more information, see Section 23.3, "Specifying Parameters for an ADF Region."

     **Figure 23–14** shows the Edit Task Flow Binding dialog that appears after you configure a managed bean.

     **Note:** You can write an EL expression that references a list of input parameters specified in a managed bean using the Input Parameters Map field of the Edit Task Flow Binding dialog. For more information about implementing this functionality, see Section 23.4, "Specifying Parameters for ADF Regions Using Parameter Maps."

     **Figure 23–14  Edit Task Flow Binding Dialog for an ADF Dynamic Region**

     ![Edit Task Flow Binding Dialog](image)

     5. Click **OK**.

### 23.9.2 What Happens When You Create an ADF Dynamic Region

When you drop a bounded task flow onto a JSF page to create an ADF dynamic region, JDeveloper adds an `af:region` tag to the page. The `af:region` tag contains a reference to a task flow binding. **Example 23–11** shows the `af:region` tag that renders the ADF dynamic region in the `index.jsf` page of the Summit ADF task flow sample application.

**Example 23–11  Metadata Added to a JSF Page to Create an ADF Dynamic Region**

```xml
<af:region value="#{bindings.dynamicRegion1.regionModel}" id="r4" rendered="#{WelcomePageBean.isRegistration}"/>
```

JDeveloper also adds a task flow binding to the page definition file of the page that hosts the ADF dynamic region. **Example 23–12** shows a sample of the metadata that JDeveloper adds. The task flow binding provides a bridge between the ADF dynamic region and the bounded task flow. It binds the ADF dynamic region to the bounded task flow and maintains all information specific to the bounded task flow.
Example 23–12 Metadata Added to Page Definition to Create a Task Flow Binding

```xml
<taskFlow id="dynamicRegion1"
    taskFlowId="${WelcomePageBean.dynamicTaskFlowId}"
    activation="deferred"
    xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

The `taskFlowId` attribute in the task flow binding metadata specifies the managed bean that determines at runtime what bounded task flow to associate with the ADF dynamic region. JDeveloper creates this managed bean or modifies an existing managed bean to store this data. Example 23–13 shows extracts of the code that JDeveloper writes to the managed bean.

Example 23–13 Managed Bean Entries to Retrieve Bounded Task Flow for an ADF Dynamic Region

```java
import oracle.adf.controller.TaskFlowId;
...
    private String taskFlowId = "/directoryPath/toTaskFlow";
    ...
    public TaskFlowId getDynamicTaskFlowId() {
      return TaskFlowId.parse(taskFlowId);
    }
...
```

At runtime, the managed bean stores the value of the bounded task flow’s ID (`taskFlowId`) that displays inside the ADF dynamic region. The managed bean swaps the different bounded task flows into the task flow binding of the ADF dynamic region.

When an ADF dynamic region reinitializes, the Fusion web application must reinitialize the task flow binding associated with the ADF dynamic region. This includes evaluating if there are new input parameters and input parameter values to pass to the ADF dynamic region.

23.10 Adding Additional Task Flows to an ADF Dynamic Region

An ADF dynamic region link swaps another bounded task flow within an ADF dynamic region. An end user clicks a command component (a button or a link) to update the ADF dynamic region with the new bounded task flow.

For example, a bounded task flow in the ADF dynamic region displays general information about an employee such as an ID and photo. When the end user clicks a link command component labeled Details, the ADF dynamic region updates with a table containing more information about the employee from another bounded task flow. The end user’s action (clicking the link) invokes a method on the ADF dynamic region’s managed bean. The value of the new bounded task flow is passed to the method, and the ADF dynamic region refreshes with the new bounded task flow. The new bounded task flow now displays within the ADF dynamic region.

By default, a ADF dynamic region link swaps another bounded task flow in for the original, but cannot swap back to the original. To toggle back to the original bounded task flow, you could add a second ADF dynamic region link on the page that, when clicked, swaps the current task flow back to the original one.

You can add an ADF dynamic region link if you already have at least one ADF dynamic region on a page and are adding a new bounded task flow as an ADF dynamic region to the same page. After you drop the bounded task flow on the page...
and choose to create an ADF dynamic region link, a menu displays all of the dynamic regions currently on the page, as shown in Figure 23–15.

A list of the current dynamic regions in a document appears when you choose Dynamic Region Link from the menu that appears after you drag and drop a bounded task that you want to add as an option to an existing dynamic region in the document, as shown in Figure 23–15.

**Figure 23–15  ADF Dynamic Region Link Menu**

Use this menu to select the ADF dynamic region within which you want to display the contents of the bounded task flow.

**Tip:** You can use the values in the dynamic region link in other UI components. For example, you could create a selection list in which each of the items in the list links to a different bounded task flow. All of the linked bounded task flows would display in the same dynamic region. The links perform a method in the class behind the managed bean created to swap the bounded task flow it displays.

#### 23.10.1 How to Create an ADF Dynamic Region Link

You drag and drop a bounded task flow to a page that already contains an ADF dynamic region and you select Dynamic Region Link on the context menu that appears to view a list of ADF dynamic regions to which you can create a link.

**Before you begin:**

It may be helpful to have an understanding of the configuration required before you attempt to create an ADF dynamic region link. For more information, see Section 23.10, "Adding Additional Task Flows to an ADF Dynamic Region."

You may also find it helpful to understand functionality that can be added using other task flow and ADF region features. For more information, see Section 23.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."

You will need to complete this task:

Add at least one ADF dynamic region to the JSF page where you are going to create an ADF dynamic region link. For information about adding an ADF dynamic region to a JSF page, see Section 23.9, "Creating ADF Dynamic Regions."

**To create an ADF dynamic region link:**

1. In the Applications window, double-click the JSF page where you want to create the ADF dynamic region link.

2. From the Applications window, drag and drop a bounded task flow onto the JSF page and, from the context menu, choose Dynamic Region Link.
3. In the context menu that displays a list of the ADF dynamic regions that have already been added to the page, select the name of the ADF dynamic region in which you want to display the contents of the bounded task flow.

4. Click OK.

23.10.2 What Happens When You Create an ADF Dynamic Region

JDeveloper adds a link to the page, as shown in Example 23–14. JDeveloper also updates the managed bean for the ADF dynamic region and updates the corresponding task flow binding with any new parameters.

Example 23–14 Dynamic Region Link

```xml
<af:link text="region2" action="#{RegionBean.region2}" id="dynamicRegionLink1"/>
```

23.11 Configuring a Page To Render an Unknown Number of Regions

You can configure a page at design time when you do not know the number of regions that render in the page at runtime. For example, you want to add or remove regions to tabs using the panelTabbed component. Each tab that you add or remove renders a region that references a bounded task flow.

To implement this functionality, you configure the JSF page definition file’s multiTaskFlow element to reference a list of task flow bindings contained in a managed bean of the following type:

```java
oracle.adf.controller.binding.TaskFlowBindingAttributes
```

Example 23–15 shows the code for the class of a managed bean named MultiBean that returns a list containing two task flows.

Example 23–15 Managed Bean Returning a List of Task Flow Bindings

```java
package view;
import java.util.ArrayList;
import java.util.List;
import oracle.adf.controller.TaskFlowId;
import oracle.adf.controller.binding.TaskFlowBindingAttributes;

public class MultiBean {
    private List<TaskFlowBindingAttributes> mTaskFlowBindingAttrs = new ArrayList<TaskFlowBindingAttributes>(5);

    public MultiBean() {
        TaskFlowBindingAttributes tfAttr = new TaskFlowBindingAttributes();
        tfAttr.setId("region1");
        tfAttr.setTaskFlowId(new TaskFlowId("/WEB-INF/r1.xml", "r1"));
        mTaskFlowBindingAttrs.add(tfAttr);
    }
}
```

**Note:** The view activities of the bounded task flow must be associated with page fragments. You can convert a bounded task flow that uses pages to use page fragments. For more information, see Section 20.6.4, "How to Convert Bounded Task Flows."
Configuring a Page To Render an Unknown Number of Regions

```
  tfAttr = new TaskFlowBindingAttributes();
  tfAttr.setId("region2");
  tfAttr.setTaskFlowId(new TaskFlowId("/WEB-INF/r2.xml", "r2"));
  mTaskFlowBindingAttrs.add(tfAttr);
}

public List<TaskFlowBindingAttributes> getTaskFlowList() {
    return mTaskFlowBindingAttrs;
}
```

For more information about the `TaskFlowBindingAttributes` class, see the Java API Reference for Oracle ADF Controller.

At runtime, the `multiTaskFlow` binding references a list of one or more task flows that an end user can add or remove to the page using command components that you also expose. Figure 23–16 shows the relationships between the different parts that make up this use case.

**Note:** The page fragments that the bounded task flows render must use the Facelets document type.

**Figure 23–16 ADF Regions Derived from a Multi Task Flow Binding**

23.11.1 How to Configure a Page to Render an Unknown Number of Regions

Configure the JSF page definition file's `multiTaskFlow` element to reference a list of bounded task flows. This list can be modified at runtime by adding or removing elements of type `TaskFlowBindingAttributes`.

**Before you begin:**

It may be helpful to have an understanding of the configuration options available to you when configuring a page to render an unknown number of ADF regions. For more information, see Section 23.11, "Configuring a Page To Render an Unknown Number of Regions."

You may also find it helpful to understand other functionality that can be added using other task flow and ADF region features. For more information, see Section 23.1.3, "Task Flows and ADF Region Use Cases and Examples."
You will need to complete this task:

Create a managed bean with a pageFlow scope that returns a list of type TaskFlowBindingAttributes. Example 23–15 shows the code for the class of a managed bean that returns such a list. For more information about how to create a managed bean, see Section 26.4.1, "How to Use a Managed Bean to Store Information."

To configure a page to render an unknown number of regions:

1. In the Applications window, right-click the JSF page where you want to add or remove ADF regions at runtime and choose Go to Page Definition.
2. If a confirmation dialog appears, click Yes.
3. In the overview editor, click the Binding and Executables tab, and then click the Add icon in the Executables section.
4. In the Insert Item dialog, select ADF Task Flow Bindings from the dropdown menu, then select multiTaskFlow as the item to create and click OK.
5. In the Insert multiTaskFlow dialog, enter the following values:
   - id*: Enter a unique ID for the multi task flow binding.
   - taskFlowList *: Enter an EL expression that returns the list of TaskFlowBindingAttributes to return at runtime. For example, to return the list in Example 23–15, enter the following EL expression:
     \#{pageFlowScope.multiBean.taskFlowList}
6. In the Applications window, double-click the JSF page where you want end users to add or remove ADF regions at runtime.
7. In the ADF Faces page of the Components window, from the Operations panel, drag and drop a For Each onto the component in the Structure window that you want to enclose the For Each component.
8. In the Properties window for the For Each component, enter values in the following fields:
   - Items: Enter an EL expression that references the method that return the list of task flow bindings from the multi task flow binding runtime object. For example, enter an EL expression similar to the following:
     \#{bindings.multiRegion1.taskFlowBindingList}
   - Var: Enter a value to identify the list of task flow bindings.
9. In the JSF page that contains the For Each component, insert a Region component inside the For Each component that references the Region component’s region model using an EL expression, as shown in Example 23–16.

Example 23–16  ADF Region Referencing a Region Model

```xml
<af:forEach var="tf" items="#{bindings.multiRegion1.taskFlowBindingList}"
    <af:panelBox text="#{tf.name}" id="pb1">
    <f:facet name="toolbar"/>
    <af:region value="#{tf.regionModel}" id="r1"/>
  </af:panelBox>
</af:forEach>
```
23.11.2 What Happens When You Configure a Page to Render an Unknown Number of Regions

Metadata similar to that shown in Example 23–17 appears in the JSF page definition file for the multi task flow binding.

Example 23–17  Metadata Added to Page Definition to Create a Multi Task Flow Binding

```xml
<multiTaskFlow id="multiRegion1"
    taskFlowList="${pageFlowScope.multiBean.taskFlowList}" activation="deferred"
    xmlns="http://xmlns.oracle.com/adf/controller/binding"/>
```

The taskFlowList attribute in the multi task flow binding metadata specifies the managed bean. The managed bean stores the list of objects describing the task flows that can be added to the page at runtime.

23.11.3 What You May Need to Know About Configuring a Page to Render an Unknown Number of Regions

- Attempt to limit the number of ADF regions that you create in a page to 10.
- Each task flow binding inherits attributes defined for the multi task flow binding unless you override this behavior using the methods exposed by `TaskFlowBindingAttributes`.
- Each task flow binding inherits parameters defined in the multi task flow binding in addition to those defined using the `parametersMap` property, as described in Section 23.4, "Specifying Parameters for ADF Regions Using Parameter Maps."

23.12 Handling Access to Secured Task Flows by Unauthorized Users

A bounded task flow does not render in an ADF region if it is invoked by a user who does not have the security permissions to access it. The region renders a blank area in place of the requested task flow when this occurs. This may confuse your users as it does not provide feedback as to why the task flow that they attempted to invoke does not appear. To improve the user experience, you can specify an alternative bounded task flow to render when a user attempts to access a bounded task for which they do not have the required security permissions. You can, for example, configure the alternative bounded task flow to display a page to inform users that they do not have the necessary security permissions. A more complex approach may be to render a bounded task flow that takes the users step-by-step through the process to request the necessary permissions from their system administrator.

Configure the level of security for the alternative bounded task flow to make sure that users can view it should they fail to access a bounded task flow for which they do not have security permissions. This may involve making the alternative bounded task flow public, as described in Section 41.5.1, "How to Make an ADF Resource Public.” For more information about securing your Fusion web application, including bounded task flows, see Section 41, "Enabling ADF Security in a Fusion Web Application.”

23.12.1 How to Handle Access to Secured Task Flows by Unauthorized Users

You configure an alternative bounded task flow with the content that you want to display to users when they cannot access a bounded task flow because of a lack of security permissions. You specify the alternative bounded task flow as the value for the Unauthorized Region Taskflow property in your Fusion web application’s `adf-config.xml` file.
Before you begin:

It may be helpful to have an understanding of why you may need to display a message to users without security permissions for a task flow. For more information, see Section 23.12, "Handling Access to Secured Task Flows by Unauthorized Users."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 23.1.4, "Additional Functionality for Task Flows that Render in ADF Regions."

You will need to complete these tasks:

1. Create an alternative bounded task flow to display to users when they cannot access a bounded task flow for which they do not have security permissions.
   For more information about creating a bounded task flow, see Section 20.2, "Creating a Task Flow."

2. Configure this task flow so that users can access it.
   For more information, see Section 41.5.1, "How to Make an ADF Resource Public."

To display messages to users without security permissions for task flows:

1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click the adf-config.xml file.

2. In the overview editor, click the Controller navigation tab.

3. In the Controller page, in the Unauthorized Region Taskflow field, enter the name of the bounded task flow to invoke or click Browse to select it.

23.12.2 What Happens When You Handle Access to Secured Task Flows by Unauthorized Users

JDeveloper writes the name of the bounded task flow that you selected as a value for the <unauthorized-region-taskflow> element in the adf-config.xml file, as illustrated in Example 23–18.

Example 23–18  Metadata Entry to Specify Task Flow Accessible Without Authentication

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
    xmlns:config="http://xmlns.oracle.com/bc4j/configuration"
    xmlns:adf="http://xmlns.oracle.com/adf/config/properties">
    ...
<adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
    <unauthorized-region-taskflow>/WEB-INF/task-flow-definition.xml
</unauthorized-region-taskflow>
</adf-controller-config>
    ...
</adf-config>
```

At runtime, the Fusion web application renders this alternative bounded task flow when users attempt to invoke a bounded task flow for which they do not have security permissions.
This chapter describes how to use advanced features of ADF task flows that you create in Fusion web applications. These include the ability to define transaction options for a task flow, configure reentry options to a task flow for a user that previously exited, handle exceptions, configure save points for your task flow, use ADF Faces components such as train, and create task flows from task flow templates.

This chapter includes the following sections:

- Section 24.1, "About Creating Complex Task Flows"
- Section 24.2, "Sharing Data Controls Between Task Flows"
- Section 24.3, "Managing Transactions in Task Flows"
- Section 24.4, "Reentering Bounded Task Flows"
- Section 24.5, "Handling Exceptions in Task Flows"
- Section 24.6, "Configuring Your Application to Use Save Points"
- Section 24.7, "Using Save Points in Task Flows"
- Section 24.8, "Using Train Components in Bounded Task Flows"
- Section 24.9, "Creating Task Flow Templates"
- Section 24.10, "Creating a Page Hierarchy Using Task Flows"

24.1 About Creating Complex Task Flows

After creating a task flow, adding activities to it, and configuring control flow between the activities, you can extend the task flow’s functionality by adding some of the features described in the following list:

- Bounded task flows can be configured to include additional transactional management facilities beyond those provided by the underlying data controls so that a Fusion web application can commit or roll back the data controls associated with the task flow’s activities as a group.

- Reentry options can be configured for bounded task flows to determine the response if a user clicks the browser’s back button.

- Task flows contain a number of features that allow you to proactively handle exceptions. In addition, you can write custom code to handle exceptions thrown by a task flow.

- Task flows can also be configured to capture the state of a Fusion web application at a particular instance using save points. These allow you to save the application’s state if, for example, a user leaves a page without finalizing a task.
Train components are ADF Faces components that render navigation items to guide a user through a multistep process. You can configure a bounded task flow to render these navigation items by default for the view activities in a task flow.

Task flow templates can serve as a starting point for the creation of task flows that share common elements.

Create a page hierarchy from the view activities that the default unbounded task flow in your application (and additional task flows in the application) reference.

Invoke initializers and finalizers when a bounded task flow is entered and exited. An initializer is custom code that is invoked when a bounded task flow is entered. A finalizer is custom code that is invoked when a bounded task flow is exited via a task flow return activity or because an exception occurred. The finalizer is a method on a managed bean. Common finalizer tasks include releasing all resources acquired by the bounded task flow and performing cleanup before exiting the task flow.

You specify both the initializer and the finalizer as an EL expression for a method on a managed bean, for example:

```el
#{pageFlowScope.modelBean.releaseResources}
```

There are two techniques for running initializer code at the beginning of the bounded task flow, depending on whether or not the task flow may be reentered via a browser back button:

- No reentry via back button expected: Designate a method call activity as the default activity (first to execute) in the bounded task flow. The method call activity calls a custom method containing the initializer code. For more information, see Section 21.5, "Using Method Call Activities" and Section 28.5.4, "What You May Need to Know About the Browser Back Button and Navigating Through Records."

- Back button reentry possible: Specify an initializer method using an option on the bounded task flow metadata. For more information, see Section 20.2, "Creating a Task Flow." Use this technique if you expect that a user may reenter the task flow using a browser back button. In such a case, the designated default activity for the bounded task flow may never be called, but a method designated using the Initializer method will.

### 24.1.1 Complex Task Flows Use Cases and Examples

Figure 24–1 shows the Structure window for a task flow that implements many of the use cases discussed in Section 24.1, "About Creating Complex Task Flows." For example, it specifies an error page to handle errors, makes use of the ADF Faces train component to render navigation items, and specifies two task flow return activities that either commit or roll back changes that the task flow makes as part of transaction management.
You may find it helpful to understand other Oracle ADF features before you configure or use task flows. Additionally, you may want to read about what you can do with your task flows. Following are links to other functionality that may be of interest.

- You can specify exception handlers to manage errors that occur during execution of task flows. For more information about error handling, see Section 18.3, "Customizing Error Handling."
- Task flow save points can save application state. For more information about application state management, see Section 49, "Using State Management in a Fusion Web Application."
- Bounded task flows can be secured by defining the privileges that are required for someone to use them. For more information, see Section 41, "Enabling ADF Security in a Fusion Web Application."
- You can use Business Process Execution Language (BPEL) with task flows to:
  - Invoke a BPEL process from an unbounded or bounded task flow to perform a function or use services
  - Call a bounded task flow from a BPEL process in order to model user interactions with a web interface
You can use a task flow method call activity to invoke a managed bean method or a web service that interacts with a BPEL process. For more information about the task flow method call activity, see Section 21.5, "Using Method Call Activities."
- You can write custom code that extends your task flows. For example, you can write custom code to invoke when a task flow throws an exception, as described in Section 24.5.3, "How to Designate Custom Code as an Exception Handler." For information about the APIs that you can use to write custom code, see the following reference documents:
  - Java API Reference for Oracle ADF Controller
  - Java API Reference for Oracle ADF Faces
### 24.2 Sharing Data Controls Between Task Flows

When one task flow calls another, the task flows can either share an instance of a data control, or create two separate isolated instances of the same data control so the task flows can maintain independent state. The internal object that task flows use to share their data controls or to store their own isolated data control is known as a data control frame.

Task flows making use of the task flow transaction management options when committing or rolling back use the data control frame to know which data controls to perform the transaction operations on. A data control frame is created at runtime for your application’s unbounded task flow and any bounded task flow with a data-control-scope value of isolated. When a task flow specifies a data-control-scope value of shared, the called task flow uses the data control frame of the calling task flow rather than creating its own. This allows the called task flow to share data control instances attached to the data control frame. Alternatively, if a called task flow specifies a data-control-scope value of isolated, a new data control frame is created and a new instance of any data controls used by the bounded task flow will be attached to the newly-created data control frame.

To specify whether data controls are shared between the calling and called task flows, you must set a data-control-scope value of either shared or isolated on the called bounded task flow. The default value is shared.

If data-control-scope is set to shared on both the calling and called bounded task flow, the data control frame used will be the one for the calling task flow.

In Figure 24–2, the bounded task flows BTF1, BTF2, and BTF3 use the data control frame created for the application’s unbounded task flow (UTF1) because these bounded task flows all have a data-control-scope value of shared. In contrast, the bounded task flow BTF4 uses a different data control frame because it has a data-control-scope value of isolated. It shares this data control frame with the bounded task flow that it calls (BTF5) because this latter bounded task flow has a data-control-scope value of shared.

**Figure 24–2  Sharing and Isolating Data Control Frames**

![Data Control Frames](image)

The value that you set for the data-control-scope element of a called task flow determines if a calling task flow and a called task flow share flow data controls. Other factors, such as whether a task flow renders in a page or page fragment, do not change this behavior.

#### 24.2.1 How to Share a Data Control Between Task Flows

You share data controls between task flows by specifying a value for the data-control-scope element of the called task flow.

---

24-4  Developing Fusion Web Applications with Oracle Application Development Framework
Before you begin:

It may be helpful to have an understanding of the properties that determine how you share data controls between task flows. For more information, see Section 24.2, "Sharing Data Controls Between Task Flows."

You may also find it helpful to understand functionality that can be added using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To share a data control between task flows:

1. In the Applications window, double-click the called task flow.
2. In the Properties window expand the Behavior section and select Shared from the Share data controls with calling task flow list.

---

Note: After you select Shared from the Share data controls with calling task flow list (data-control-scope), you may need to configure transaction options for the task flow. For more information, see Section 24.3.3, "What You May Need to Know About Sharing Data Controls and Managing Transactions."

---

24.2.2 What Happens When You Share a Data Control Between Task Flows

JDeveloper writes an entry in the source file for the called task flow when you select Shared from the Share data controls with calling task flow list, as illustrated in Example 24–1.

Example 24–1 Metadata to Share Data Controls Between Task Flows

```xml
<task-flow-definition id="task-flow-definition">
  ...
  <data-control-scope id="__1">
    <shared/>
  </data-control-scope>
  ...
</task-flow-definition>
```

24.2.3 What Happens at Runtime: How Task Flows Share Data Controls

An end user can open the same application more than once in different browser windows or browser tabs. If an end user does this, each window or tab has its own view port, and each window or tab is isolated from all other windows or tabs within the same HTTP session. As a result, the windows or tabs do not share data controls and, therefore, state. The windows or tabs start with a new data control frame as if they were running with an isolated data control scope. The exception to this rule is if an end user opens a modal dialog in a secondary browser window, then the primary and secondary browser windows have the same server-side state and share data controls. For more information about using modal dialogs, see Section 25.2, "Running a Bounded Task Flow in a Modal Dialog." For more information about view ports, see Section 23.1.2, "About View Ports and ADF Regions."

Data controls are not instantiated until needed. One of two things can occur when a parent task flow calls a child task flow that specifies data-control-scope as shared (the default) and references a data control named D:
1. If a data control named D already exists in the parent task flow’s data control frame, then the child task flow’s reference to D resolves to the existing data control named D that is in scope.

2. If a data control named D does not exist in the parent task flow’s data control frame, then Oracle ADF instantiates the first data control named D that it finds when performing a top-down search through the DataBindings.cpx files for the task flow call stack.

The above rules are unlikely to be applied because most applications define data controls with unique names. However, if a task flow from an application calls a task flow in an ADF Library JAR, the application and the ADF Library JAR task flows may reference data controls that use the same names. It is important to consider the above rules if this happens.

If, when the parent task flow calls the child task flow, the data control D from the parent task flow’s ADF Library JAR is already instantiated, then the child task flow uses it. If it is not already instantiated, then the data control D from the parent task flow will be instantiated and used by the child task flow. In particular, in this task flow calling scenario, the child task flow’s data control D will not be instantiated.

Another scenario to consider is where a parent task flow in a JSF page calls a child task flow that renders in a region in the same JSF page. The region’s location in the JSF page can determine which data control frame the task flows use. If the JSF page’s calling task flow references a data control before the region with the called task flow renders, the calling task flow’s data control frame is used. If the region with the called task flow is the first databound component in the JSF page, then the called task flow’s data control is used.

For more information about data controls, see Section 17.3, "Exposing Application Modules with ADF Data Controls."

24.3 Managing Transactions in Task Flows

In the context of systems relating to databases, a transaction is a persisted collection of work items that can be committed or rolled back together as a group. ADF, through technologies such as ADF Business Components, offers all the advantages that transactions provide. However, support for transactions does not stop at the ADF Model layer. In the ADF Controller layer, bounded task flows optionally provide their own abstract implementation of transactions over the underlying ADF Model layer. This implementation allows you to control transactions from the task flow and also declaratively manage the transaction boundaries.

The transaction options that you can configure on a called bounded task flow can be grouped into two categories:

- You delegate transaction management to the ADF Model layer by choosing the <No Controller Transaction> option for the called bounded task flow. The called bounded task flow does not use the ADF Controller’s task flow transaction management facilities to commit or rollback all data controls attached to the task flow and associated data control frame. Instead, you must individually commit and rollback data controls attached to the task flow.

- You use one of the following ADF task flow transaction management options:
  - Always Begin New Transaction: A new transaction starts when the bounded task flow is entered, regardless of whether or not a transaction is in progress. The new transaction completes when the bounded task flow exits.
Managing Transactions in Task Flows

- **Always Use Existing Transaction**: When called, the bounded task flow participates in an existing transaction already in progress.

- **Use Existing Transaction If Possible**: When called, the bounded task flow either participates in an existing transaction if one exists, or starts a new transaction upon entry of the bounded task flow if one does not exist.

**Best Practice**: Oracle recommends that you choose one of the above categories for transaction management when you chain task flows together. That is, do not configure a set of task flows that call each other where one or more task flows in the set use the `<No Controller Transaction>` option and one or more of the remaining task flows in the set use one of the ADF task flow transaction management options (**Always Begin New Transaction** and so on). This type of configuration can lead to complex runtime behavior.

If a called bounded task flow starts a new ADF task flow transaction (based on the transaction option that you selected), you can specify whether the transaction commits or rolls back when the task flow returns to its caller. The commit and rollback options are set on the task flow return activity that returns control back to the calling task flow. The same task flow that starts a transaction must also resolve the transaction.

In a called bounded task flow, you can specify two different return task flow activities that result in either committing or rolling back a transaction in the called bounded task flow. Each of the task flow return activities pass control back to the same calling task flow. The difference is that one task flow return activity specifies the commit option, while the other specifies the rollback option. **Figure 24–3** shows the orders-select-many-items.xml task flow from the Summit ADF task flow sample application. If transaction processing successfully completes, control flow passes to the commit task flow return activity, which specifies options to commit the transaction. If the transaction is cancelled before completion, the rollback task flow activity specifies options to roll back the transaction.

**Figure 24–3  Task Flow Return Activities in Called Bounded Task Flow**

Use the `restore-save-point` option on the task flow return activity if you want to discard the changes an end user makes within a called bounded task flow when the called bounded task flow exits. ADF Controller rolls back to the previous ADF Model save point that was created when the bounded task flow was entered. The `restore-save-point` option applies only to cases when a bounded task flow is...
entered by joining an existing transaction (either the `requires-existing-transaction` or `requires-transaction` option is also specified) and a save point is created upon entry.

If you use the ADF task flow transaction management features that commit and rollback the data controls associated with the data control frame of the current task flow, you must use task flow return activities with their End Transaction property set to `commit` or `rollback`, or programmatically commit or rollback the associated data control frame. Alternatively if you use the `<No Controller Transaction>` setting or you only want to commit or rollback one data control, use the associated commit or rollback operations from the Data Controls panel or programmatically execute the associated commit and rollback bindings.

In the Summit sample application for ADF task flows, a number of task flows create transactions. For example, the `orders-select-many-items.xml` task flow uses the ADF task flow transaction management’s Use Existing Transaction if Possible option. This task flow allows an end user to add multiple items to an order and commit or rollback this change when the end user interacts with the `showshuttle.jsf` page shown in Figure 24–4.

Figure 24–4 Task Flow Transaction

24.3.1 How to Enable Transactions in a Bounded Task Flow

You define the transaction options on a bounded task flow that is called by another task flow. Add a task flow return activity on the called bounded task flow that returns control to the task flow that calls the bounded task flow.

Before you begin:

It may be helpful to have an understanding of what a transaction is and how you can configure it. For more information, see Section 24.3, “Managing Transactions in Task Flows.”
You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To enable a bounded task flow to run as a transaction:

1. In the Applications window, double-click the called bounded task flow.
2. In the editor window, click the Overview tab.
3. In the overview editor, click the Behavior navigation tab.
4. In the Behavior page, expand the Transaction section and choose one of the following from the dropdown list:
   - **<No Controller Transaction>:** The called bounded task flow does not use the task flow transaction management facilities to commit or rollback all data controls attached to the task flow and associated data control frame. Instead, you must individually commit and rollback data controls attached to the task flow. The Data Controls panel exposes operations that you can invoke using command components to commit and rollback data controls. For more information, see Section 28.4, "Creating Command Components Using Data Control Operations."
   - **Always Use Existing Transaction:** When called, the bounded task flow participates in an existing transaction already in progress.
   - **Use Existing Transaction If Possible:** When called, the bounded task flow either participates in an existing transaction if one exists, or starts a new transaction upon entry of the bounded task flow if one does not exist.
   - **Always Begin New Transaction:** A new transaction starts when the bounded task flow is entered, regardless of whether or not a transaction is in progress. The new transaction completes when the bounded task flow exits.

   **Note:** After choosing a transaction option, you may also need to configure the Share data controls with calling task flow option (data-control-scope) for the bounded task flow to determine whether there are any interactions between the options. For more information, see Section 24.3.3, "What You May Need to Know About Sharing Data Controls and Managing Transactions."

5. Optionally, select **Isolated** from the Share data controls with calling task flow checkbox (data-control-scope) so that data controls are not shared with the calling task flow if you chose one of the following options in Step 4:
   - **Use Existing Transaction If Possible**
   - **Always Begin New Transaction**

   The default behavior is to share data controls. For more information, see Section 24.3.3, "What You May Need to Know About Sharing Data Controls and Managing Transactions."

6. Optionally, select the **No save point on task flow entry** checkbox to prevent the creation of an ADF Model save point on task flow entry if you chose one of the following options in Step 4:
   - **Always Use Existing Transaction**
   - **Use Existing Transaction If Possible**
Managing Transactions in Task Flows

An ADF Model save point is a saved snapshot of ADF Model state. Selecting the **No save point on task flow entry** checkbox means that overhead associated with a save point is not created for the transaction.

7. Select the task flow return activity in the called bounded task flow.

8. In the Properties window, expand the **Behavior** section.

9. If the called bounded task flow supports creation of a new transaction (bounded task flow specifies **Use Existing Transaction If Possible** or **Always Begin New Transaction** options), select one of the following in the **End Transaction** dropdown list:
   - **commit**: Select to commit the existing transaction to the database.
   - **rollback**: Select to roll back a new transaction to its initial state on task flow entry. This has the same effect as cancelling the transaction.

10. In the **Restore Save Point** dropdown list, select **true** if you want changes the user makes within the called bounded task flow to be discarded when the task flow exits. The save point that was created upon task flow entry will be restored.

### 24.3.2 What Happens When You Specify Transaction Options

Example 24–2 shows the metadata for transaction options on a called bounded task flow. The `<new-transaction>` element indicates that a new transaction always starts when the called bounded task flow is invoked. The `<new-transaction>` element is generated when you select **Always Begin New Transaction** value in the Transaction section's dropdown list.

**Example 24–2 Called Bounded Task Flow Metadata**

```xml
<task-flow-definition id='trans-taskflow-definition'>
  <default-activity>taskFlowReturn1</default-activity>
  <transaction>
    <new-transaction/>
  </transaction>
  <task-flow-return id='taskFlowReturn1'>
    <outcome>
      <name>success</name>
      <commit/>
    </outcome>
  </task-flow-return>
</task-flow-definition>
```

Example 24–2 also shows the metadata for transaction options on the task flow return activity on the called task flow. The `<commit/>` element commits the existing transaction to the database. The `<outcome>` element specifies a literal outcome, for example, **success**, that is returned to the caller when the bounded task flow exits. The calling ADF task flow can define control flow rules based on this outcome. For more information about defining control flow upon return, see Section 21.7, "Using Task Flow Return Activities."

### 24.3.3 What You May Need to Know About Sharing Data Controls and Managing Transactions

Data controls cannot be shared across more than one transaction at the same time. If your task flow is involved in managing transactions, the value you select for the
Managing Transactions in Task Flows

Creating Complex Task Flows

The data-control-scope option may affect the transaction option settings for a bounded task flow. Table 24–1 describes how these options interact.

The ADF Model layer exposes the DataControlFrame interface to manage a transaction in which the data controls within the frame participate. The DataControlFrame interface exposes methods such as:

- `beginTransaction()`
- `commit()`
- `rollback()`

Similarly, ADF Controller allows a task flow to demarcate a transaction boundary, to begin a transaction at task flow entry, and to either commit or roll back the transaction on task flow exit. It does this by invoking methods exposed by ADF Model layer’s DataControlFrame interface.

ADF Controller supports the transaction options listed in Table 24–1. The behavior of these transaction options depends on whether you select Shared or Isolated from the Share data controls with calling task flow list (XML element: `<data-control-scope>`) in the overview editor for a task flow.

**Table 24–1  Transaction Settings Behavior**

<table>
<thead>
<tr>
<th>Transaction Setting</th>
<th>Share Data Control Scope</th>
<th>Isolate Data Control Scope</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>&lt;No Controller Transaction&gt;</code></td>
<td>The DataControlFrame is shared without the need for an open transaction on the frame.</td>
<td>A new DataControlFrame is created without an open transaction.</td>
</tr>
<tr>
<td><strong>Always Begin New Transaction</strong></td>
<td>Begins a new transaction if one is not already open and throws an exception if one is already open.</td>
<td>Always begins a new transaction.</td>
</tr>
<tr>
<td>XML element: <code>&lt;new-transaction/&gt;</code></td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Always Use Existing Transaction</strong></td>
<td>Throws an exception if the transaction is not already open.</td>
<td>Invalid. The checkbox cannot be deselected.</td>
</tr>
<tr>
<td>XML element: <code>&lt;requires-existing-transaction/&gt;</code></td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Use Existing Transaction if Possible</strong></td>
<td>Begins a new transaction if one is not already open.</td>
<td>Always begins a new transaction.</td>
</tr>
<tr>
<td>XML element: <code>&lt;requires-transaction/&gt;</code></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

A number of examples illustrate how bounded task flows interact when you configure different combinations of values for the data control scope and transaction properties described in Table 24–1:

- Isolate two bounded task flow transactions completely so that they can be committed or rolled back separately. For more information, see Section 24.3.3.1, “Creating Completely Separate Transactions.”

- Guarantee that two bounded task flows share a transaction to save connection resources and stop the transaction if the called bounded task flow cannot join the transaction of the calling bounded task flow. For more information, see Section 24.3.3.2, “Guaranteeing a Called Bounded Task Joins an Existing Transaction.”

- Call a bounded task flow that joins the transaction of the calling bounded task flow if one exists and, if not, creates its own transaction. For more information, see Section 24.3.3.3, “Using an Existing Transaction if Possible.”

The above list describes common use cases rather than all possible configuration options.
24.3.3.1 Creating Completely Separate Transactions

Figure 24–5 shows a number of task flows that are configured to create separate transactions. Two bounded task flows are chained together in Figure 24–5 yet maintain completely separate transactions. This implementation may be appropriate where you have a call center agent taking an order from a customer and entering the order details in your application. At some point near the end of the order process, the customer realizes that the delivery address that they have provided is incorrect. To assist the call center agent, you designed your application so that it updates and commits the delivery address in a separate transaction to the transaction for the order details (order number, quantity, and so on). In the scenario where the customer wishes to modify the delivery address, the call center agent does not need to roll back changes to the order details in order to modify the delivery address because a separate transaction manages the order details.

In Figure 24–5, the unbounded task flow calls Bounded Task Flow #1. This results in the creation of Data Control Frame #1 because Bounded Task Flow #1 is configured as follows:

- A data-control-scope value of isolated
- Always Begin New Transaction

Bounded Task Flow #1 exposes attributes from two different view objects as data control fields (viewObject1.X and viewObject2.Y). X and Y are initially set to 10 and 20 respectively. The end user, while accessing Bounded Task Flow #1, updates X from 10 to 30 and leaves Y unchanged. This marks the transaction as changed or "dirty". That is, there are changes in the transaction that must be committed or rolled back.

Bounded Task Flow #1 calls Bounded Task Flow #2. The application creates Data Control Frame #2 because Bounded Task Flow #2 is configured as follows:

- A data-control-scope value of isolated
- Always Begin New Transaction

Note that the transaction of Data Control Frame #1 has yet to be committed and that Data Control Frame #2 has a separate database connection and a separate task flow transaction. As a result, the initial values of the data control fields X and Y in Bounded Task Flow #2 are 10 and 20. The end user, while accessing Bounded Task Flow #2, updates Y to 40 and leaves X unchanged. This marks the transaction for Bounded Task Flow #2 as dirty. Bounded Task Flow #2 next calls a task flow return activity that commits the change to Y to the database and returns control to Bounded Task Flow #1. As Bounded Task Flow #2 did not modify the value of X, no change for this data control field occurs.

Because Bounded Task Flow #1 has a separate data control frame (Data Control Frame #1) and transaction, the values of the data control fields X and Y in Bounded Task Flow #1 remain at 30 and 20, their values when Bounded Task Flow #1 called Bounded Task Flow #2. Bounded Task Flow #1 now calls a task flow return activity (set to commit), saving the value of X to the database. The value of Y remains unchanged because Bounded Task #1’s transaction did not modify the value of Y.

On returning to the unbounded task flow and refreshing the values of X and Y from the database, the updated values of 30 and 40 are returned.
24.3.3.2 Guaranteeing a Called Bounded Task Joins an Existing Transaction

Figure 24–6 shows two bounded task flows in a configuration that guarantees that the second bounded task flow joins the transaction of the first bounded task flow that calls it. An example scenario where such an implementation may be appropriate is if your application creates invoices and, separately, the individual lines of the invoice. When creating an invoice line, it does not make sense that an invoice line is created without the parent invoice that is to contain the invoice line. If you were to build two separate task flows to create the invoice and invoice lines, the invoice line task flow needs to enforce that it wants to join a transaction of the calling task flow, in this case the invoice task flow, rather than creating a separate transaction.

Figure 24–6 illustrates how the above use case can be addressed by configuring an unbounded task flow that calls a bounded task flow (Bounded Task Flow #1). The unbounded task flow has its own data control frame (Data Control Frame #0). Bounded Task Flow #1 starts a transaction and also has a data control frame (Data Control Frame #0) because it is configured as follows:

- A data-control-scope value of isolated
Always Begin New Transaction

Bounded Task Flow #1 exposes attributes from two different view objects as data control fields (viewObject1.X and viewObject2.Y). X and Y are initially set to 10 and 20 respectively. The end user, while accessing Bounded Task Flow #1, updates X from 10 to 30 and leaves Y unchanged. This marks Task Flow Transaction A associated with Data Control Frame #1 as changed or "dirty". That is, there are changes in the transaction that must be committed or rolled back.

Bounded Task Flow #1 calls Bounded Task Flow #2. Bounded Task Flow #2 is configured as follows:

- A data-control-scope value of shared

Always Use Existing Transaction

Because of this configuration, no new data control frames are created. Bounded Task Flow #2 uses the same data control frame (Data Control Frame #1) as Bounded Task Flow #1. The changes applied to X in Bounded Task Flow #1 are visible to Bounded Task Flow #2. Updates made to Y in Bounded Task Flow #2 are visible to Bounded Task Flow #1 when it receives control back from Bounded Task Flow #2 after it executes a task flow return activity that specifies a commit. This update to Y is visible in Bounded Task Flow #1 because of the shared data control scope, not because of the commit option that the task flow return activity of Bounded Task Flow #2 specifies.

Remember that the commit and rollback options of a task flow return activity are only valid for the bounded task flow that starts a transaction. That is why the commit of Bounded Task Flow #1’s task flow return activity finalizes changes in the database and not Bounded Task Flow #2.
24.3.3.3 Using an Existing Transaction if Possible

Section 24.3.3.2, "Guaranteeing a Called Bounded Task Joins an Existing Transaction," described how to configure a bounded task flow to call a second bounded task flow and guarantee that the called bounded task flow joins the transaction of the calling bounded task flow. The effect of changing the configuration of the calling bounded task flow to have:

- A data-control-scope value of isolated
- <No Controller Transaction>

while leaving the called bounded task flow unchanged is to stop execution of the bounded task flows and throw the following error message at runtime:

ADFC-00006: Existing transaction is required when calling task flow '{0}'

The above scenario illustrates the benefit of configuring the called bounded task flow as follows:

- A data-control-scope value of shared
Managing Transactions in Task Flows

- **Use Existing Transaction if Possible**

  This latter configuration means that the called bounded task flow creates a transaction if the calling bounded task flow has not created a transaction.

  Another configuration option for a called bounded task that guarantees it creates its own transaction is to configure it as follows:

  - A `data-control-scope` value of `isolated`

- **Use Existing Transaction if Possible**

  This causes the called bounded task flow to create its own transaction regardless of the transaction options that you configure for the calling bounded task flow. The effect is the same as if you set the called bounded task flow to use **Always Begin New Transaction**.

### 24.3.4 What You May Need to Know About ADF Business Component Database Connections and Task Flow Transaction Options

ADF Controller shares the ADF Business Component application modules' database connections in an application that has more than one root application module (and each application module has a database connection) where task flow transaction options combine to share connections. That is, you configured a set of chained task flows in your application that have a `data-control-scope` value of `shared` in combination with the following transaction options:

- **Always Begin New Transaction**
- **Always Use Existing Transaction**
- **Use Existing Transaction if Possible**

This implementation helps to reduce the number of database connections that each user creates and, as a result, makes the application more scalable. This is particularly useful when you add task flows and root application modules to your application through ADF Library JARs.

A set of chained task flows is where task flows call other task flows so that your application contains a chain with two or more task flows. For example, in Figure 24–2 the unbounded task flow UTF1 calls the bounded task flow BTF1 that in turn calls the bounded task flow BTF2, and so on.

- **Note:** Remember to configure your application's chained task flows to use a `data-control-scope` value of `isolated` if you do not want root application modules to share database connections.

However, you may want to configure different behavior where you want to have separate root application modules connect to different data sources within the same ADF Model project. For example, you may want to show data from two different database systems or you need to connect to two different schemas in the same database.

To implement this last scenario (have the root application modules maintain their own database connections), you set the `transaction` property's value to No Controller Transaction (the default value) for the task flows in your application. This makes sure that each root application module manages its own database connection in isolation and that the ADF Controller does not manage the transaction behavior of the ADF Business Components.
24.4 Reentering Bounded Task Flows

To deal with cases in which the end user clicks the back button to navigate back into a bounded task flow that was already exited, you can specify task-flow-reentry options for the bounded task flow. These options specify whether a page in the bounded task flow can be reentered.

Upon reentry, bounded task flow input parameters are evaluated using the current state of the application, not the application state existing at the time of the original bounded task flow entry.

24.4.1 How to Set Reentry Behavior

You can set reentry behavior on a bounded task flow by specifying task-flow-reentry options.

Before you begin:
It may be helpful to have an understanding of what reentry options you can configure for a bounded task flow. For more information, see Section 24.4, "Reentering Bounded Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To set reentry behavior:
1. In the Applications window, double-click the bounded task flow.
2. In the editor window, click the Overview tab.
3. In the overview editor, click the Behavior navigation tab.
4. In the Behavior page, choose one of the following from the Task Flow Reentry dropdown list:
   - reentry-allowed: Reentry is allowed on any view activity within the bounded task flow.
   - reentry-not-allowed: Reentry of the bounded task flow is not allowed. If you specify reentry-not-allowed on a bounded task flow, an end user can still click the browser back button and return to a page within the bounded task flow. However, if the user does anything on the page such as clicking a button, an exception (for example, InvalidTaskFlowReentry) is thrown indicating the bounded task flow was reentered improperly. The actual reentry condition is identified upon the submit of the reentered page.
   You can set up an exception handler to display the exception and route control flow in order to navigate to the default activity of the called bounded task flow. If the bounded task flow was not called from another bounded task flow, a normal web error is posted and handled as specified in the web.xml file.
   - reentry-outcome-dependent: Reentry of a bounded task flow using the browser back button is dependent on the outcome that was received when the same bounded task flow was previously exited via task flow return activities. If specified, any task flow return activities on the called bounded task flow must also specify either reentry-allowed or reentry-not-allowed to define outcome-dependent reentry behavior.
      If you choose this option, the user can navigate to a task flow using a back button based solely on how the user originally exited the task flow. For
example, a task flow representing a shopping cart can be reentered if the user exited by canceling an order, but not if the user exited by completing the order.

### 24.4.2 How to Set Outcome-Dependent Options

You can set outcome-dependent options on bounded task flows that have specified the `reentry-outcome-dependent` option, as described in Section 24.4.1, "How to Set Reentry Behavior."

**Before you begin:**

It may be helpful to have an understanding of what reentry options you can configure for a bounded task flow. For more information, see Section 24.4, "Reentering Bounded Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

**To set outcome-dependent options:**

1. In the Applications window, double-click the bounded task flow.
2. In the task flow diagram for the bounded task flow, select the task flow return activity.
   
   For information about adding a task flow return activity, see Section 21.7, "Using Task Flow Return Activities."
3. In the Properties window, expand the General section and enter the name of a literal outcome, for example, success or failure in the Name field.
4. Expand the Behavior section and choose one of the following options in the Reentry dropdown list:
   - **reentry-allowed**: Reentry is allowed on any view activity within the bounded task flow.
   - **reentry-not-allowed**: Reentry of the bounded task flow is not allowed. If you specify `reentry-not-allowed` on a bounded task flow, an end user can still click the browser back button and return to a page within the bounded task flow. However, if the user does anything on the page such as clicking a button, an exception (for example, `InvalidTaskFlowReentry`) is thrown indicating the bounded task flow was reentered improperly. The actual reentry condition is identified upon the submit of the reentered page.

   You can set up an exception handler to display the exception and route control flow in order to navigate to the default activity of the called bounded task flow. If the bounded task flow was not called from another bounded task flow, a normal web error is posted and handled as specified in the web.xml file.

### 24.4.3 What Happens When You Configure a Bounded Task Flow for Reentry

JDeveloper updates the task flow’s metadata with the configuration options that you specify for reentry. Example 24–3 shows a task flow that has been configured to allow reentry based on a specific outcome.

**Example 24–3  Task Flow Configured for Outcome Dependent Reentry**

```xml
<task-flow-definition id="task-flow-definition1">
  <default-activity>view1</default-activity>
</task-flow-definition>
```
At runtime, the following events occur to a task flow that is configured to allow reentry:

- The task flow is reentered if the user invokes a component that, in turn, invokes a HTTP POST or GET method.
- The task flow’s managed bean values in pageFlow scope are not restored to the values they had when the task flow exited.
- If the reentered task flow defines input parameters, as described in Chapter 22, "Using Parameters in Task Flows," their values are recreated using the current state of the parent task flow at the time that the task flow is reentered.

24.5 Handling Exceptions in Task Flows

During execution of a task flow, exceptions can occur that may require some kind of exception handling, for example:

- A method call activity throws an exception.
- A custom method you have written as a task flow initializer or finalizer throws an exception.
- A user is not authorized to execute the activity.

To handle exceptions thrown from an activity or caused by some other type of ADF Controller error, you can designate one activity in a bounded or unbounded task flow as an exception handler.

When a task flow throws an exception, control flow passes to the designated exception handling activity. For example, the exception handling activity might be a view activity that displays an error message. Alternatively, the activity might be a router activity that passes control flow to a method based on an EL expression that evaluates the type of exception. For example:

```
#{controllerContext.currentViewPort.exceptionData.class.name == 'oracle.adf.controller.ControllerException'}
```

After control flow passes to the exception handling activity, flow from the exception handling activity uses standard control flow rules. For example, you designate a router activity as the exception handling activity. At runtime, the task flow passes control to the exception handling activity (in this example, a router activity) in response to an exception. In addition to designating the router activity as an exception handler, you can define task flow control cases that the router invokes based on the type of exception that it has to handle. This allows you to manage your end user’s application...
session gracefully when an exception occurs. For more information, see Section 20.1.3, "About Control Flows."

You can optionally specify an exception handler for both bounded and unbounded task flows. Each task flow can have only a single exception handler. However, a task flow called from another task flow can have a different exception handler from that of the caller. In addition, a region on a page can have a different exception handler from that of the task flow containing the page. The exception handler activity can be any supported activity type, for example, a view or router activity.

If a bounded task flow does not have a designated exception handler activity, control passes to an exception handler activity in a calling bounded task flow, if there is a calling task flow and if it contains an exception handler activity. The exception is propagated up the task flow stack until either an exception handler activity or the top-level unbounded task flow is reached. If no exception handler is found, the exception is propagated to the web container.

If a bounded task flow does have a designated exception handler activity, make sure the exception handler activity leaves the application in a valid state after it handles an exception. One way to do this is to redirect to a view activity in the same task flow after the exception handler activity.

Other modules, such as ADF Model, also provide exception handling capabilities. In certain scenarios this can determine the way that your application handles exceptions. For example, a databound method activity is a method activity that has a page definition and an EL expression with the following format:

```
#{bindings.somebindingname.execute}
```

where `somebindingname` is a method binding defined in the page definition.

An exception thrown by any type of binding is caught by ADF Model which calls the `reportException()` method and stores the exception in the binding container.

Later, when the page renders, the error displays in the page.

When a method activity invokes a method binding, there is no page to display an error that the exception raises because the exception occurs during navigation between two pages. To make the application aware of an error, Oracle ADF rethrows the exception so that it is caught by ADF Controller’s exception handler mechanism that navigates to an exception handler activity if one exists.

Keep this in mind, particularly if you decide to override methods, such as the `reportException()` method, described in Section 18.3, "Customizing Error Handling," because in that scenario both ADF Controller and ADF Model exception handlers will be called.

### 24.5.1 How to Designate an Activity as an Exception Handler

You can designate an exception handler activity for a bounded task flow running as an ADF region. If an exception occurs in the bounded task flow and it is not handled by the task flow’s exception handler, the exception is not propagated up the task flow stack of the parent page. Instead, it becomes an unhandled exception.

**Before you begin:**

It may be helpful to have an understanding of what exception handling options you can configure for a task flow. For more information, see Section 24.5, "Handling Exceptions in Task Flows."
You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

**To designate an activity as an exception handler for a task flow:**

1. In the Applications window, double-click the task flow where you want to designate an activity as an exception handler.

2. In the task flow diagram, right-click the activity and choose **Mark Activity > Exception Handler.**

   A red exclamation point is superimposed on the activity in the task flow to indicate that it is an exception handler. Figure 24–7 shows an example.

3. To unmark the activity, right-click the activity in the task flow diagram, and choose **Unmark Activity > Exception Handler.**

   If you mark an activity as an exception handler in a task flow that already has a designated exception handler, the old handler is unmarked.

**24.5.2 What Happens When You Designate an Activity as an Exception Handler**

After you designate an activity to be the exception handling activity for a task flow, JDeveloper updates the task flow metadata with an `<exception-handler>` element that specifies the ID of the activity, as shown in Example 24–4.

Example 24–4  `<exception-handler>` element

```xml
<exception-handler>activityID</exception-handler>
```

**24.5.3 How to Designate Custom Code as an Exception Handler**

Rather than designate a task flow activity as the activity to invoke, you can write custom code to invoke when a task flow throws an exception. This requires you to:

- Write a Java class that extends the class `ExceptionHandler` from the following package:
  
  `oracle.adf.view.rich.context.ExceptionHandler`

- Register the Java class that you write as a service in the `.adf\META-INF` directory of your Fusion web application

Example 24–5 shows custom code that checks if an exception thrown by a task flow corresponds to a particular type of error message (ADF_FACES-30108). If it does, the custom code redirects the task flow to the `faces/SessionExpired.jsf` page.

Example 24–5  **Custom Code for an Exception Handler**

```java
package oracle.summit.frmwkext;
```
import javax.faces.context.ExternalContext;
import javax.faces.context.FacesContext;
import javax.faces.event.PhaseId;
import oracle.adf.view.rich.context.ExceptionHandler;

public class CustomExceptionHandler extends ExceptionHandler {
    public CustomExceptionHandler() {
        super();
    }

    public void handleException(FacesContext facesContext, Throwable throwable, PhaseId phaseId) throws Throwable {
        String error_message;
        error_message = throwable.getMessage();

        if (error_message != null &&
            error_message.indexOf("ADF_FACES-30108") > -1) {
            ExternalContext ectx = facesContext.getExternalContext();
            ectx.redirect("faces/SessionExpired.jsf");
        }

        else {
            //Code to execute if the if condition is not met
            throw Throwable
        }
    }
}

For information about the APIs that you can use to write custom code, see the following reference documents:

- Java API Reference for Oracle ADF Controller
- Java API Reference for Oracle ADF Faces

Before you begin:
It may be helpful to have an understanding of what exception handling options you can configure for a task flow. For more information, see Section 24.5, "Handling Exceptions in Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To designate custom code as an exception handler:
1. In the .adf\META-INF directory of your application, create a directory named services so that you have the following directory path:
   application_root\adf\META-INF\services
   where application_root refers to the root directory of application.
2. Create a text file named oracle.adf.view.rich.context.ExceptionHandler in the services folder.
3. Write the package name and class name of the custom code that you wrote to handle exceptions in the text file named oracle.adf.view.rich.context.ExceptionHandler.
Configuring Your Application to Use Save Points

For example, if you want to register the custom code in Example 24–5, write the following:

```
oracle.summit.frmwkext.CustomExceptionHandler
```

4. Save and close the text file.

### 24.5.4 What Happens When You Designate Custom Code as an Exception Handler

At runtime, the task flow passes control to the custom code that you specified if the task flow throws an exception.

### 24.5.5 What You May Need to Know About Handling Exceptions During Transactions

Designate an exception handling activity for a bounded task flow that is enabled to run as a transaction. A Fusion web application attempts to commit a transaction if you set `commit` as the value for a task flow return activity's End Transaction property on a bounded task flow that runs as a transaction. If an exception occurs when the Fusion web application attempts to commit a transaction, the exception handling activity receives control and provides the end user with an opportunity to correct the exception. You can use the exception handling activity (for example, a view activity) to display a warning message to an end user with information about how to correct the exception and how to recommit the transaction. For information about enabling a bounded task flow as a transaction and setting `commit` as a value for the End Transaction property, see Section 24.3.1, "How to Enable Transactions in a Bounded Task Flow."

### 24.5.6 What You May Need to Know About Handling Validation Errors

For validation errors on a JSF page, you can rely on standard JSF to attach validator error messages to specific components on a page or to the whole page. A component-level validator typically attaches an error message inline with the specific UI component. There is no need to pass control to an exception handler activity.

In addition, your application should define validation logic on data controls that are executed during the Validate Model Updates phase of the JSF lifecycle. In this way, data errors are found as they are submitted to the server without waiting until attempting the final commit.

Validations done during the Validate Model Updates phase typically do not have direct access to the UI components because the intention is to validate the model after the model has been updated. These validations are often things like checking to see whether dependent fields are synchronized. In these cases, the error message is usually attached to the whole page, which this logic can access.

You should attach errors detected during the Validate Model Updates phase to the JSF page, and call `FacesContext.renderResponse()`. This signals that following this phase, the current (submitting) page should be rendered showing the attached error messages. There is no need to pass control to an exception handler activity.

For more information, see Chapter 12, "Implementing Validation and Business Rules Programmatically."

### 24.6 Configuring Your Application to Use Save Points

Before you can add save points to a task flow, as described in Section 24.7, "Using Save Points in Task Flows," and configure related functionality, you need to make sure that the Fusion web application allows save points. To do this, you define a value for the
Configuring Your Application to Use Save Points

You define a value for the `<savepoint-datasource>` element in your application’s `adf-config.xml` file to specify the JNDI name for the data source that contains the save points’ database table. Optionally, you can also specify an expiration time for save points.

Before you begin:
It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Section 24.6, "Configuring Your Application to Use Save Points."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To configure your Fusion web application to allow save points:
1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click `adf-config.xml`.
2. In the overview editor, click the Controller navigation tab and then expand the Savepoints section to write a value for the Data Source property that specifies the JNDI name for the data source that contains the database table for save points.

   For example, write the following:
   ```
   java:comp/env/jdbc/Connection1DS
   where Connection1 is the JDeveloper connection name.
   ```
3. Optionally, write a value in seconds for the Expiration property to specify the time between when a task flow creates a save point and when the save point manager removes it. The default value is 86400 seconds.
   
   For more information, see Section 24.7.9, "What You May Need to Know About the Time-to-Live Period for a Save Point."
4. Save the `adf-config.xml` file.

24.6.2 What Happens When You Configure a Fusion Web Application to Use Save Points

JDeveloper generates an entry, similar to Example 24–6, in the `adf-config.xml` file to specify the JNDI name for the data source that contains the save points’ database table.

Example 24–6  Save Point Data Source Definition in adf-config.xml

```xml
<adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
 ... 
 <savepoint-datasource>
```
24.6.3 What You May Need to Know About the Database Table for Save Points

A database table named ORADFCSAVPT stores save points. If this database table does not exist, it is created the first time that a save point is created if your Fusion web application has the necessary permissions to create a database table. If your Fusion web application does not have the necessary permissions, you or an administrator with the necessary permissions can use SQL scripts to create and maintain the ORADFCSAVPT database table. These SQL scripts are:

- adfc_cleanup_save_point_table.sql
  Each save point in the ORADFCSAVPT database table has an expiration date. Use this script to delete save points that have passed their expiration date.

- adfc_create_save_point_table.sql
  Use this script to create the ORADFCSAVPT database table that stores save points.

You can find these SQL scripts in the following directory of your JDeveloper installation:

jdev_install\oracle_common\common\sql

24.7 Using Save Points in Task Flows

You can configure a task flow to capture the state of a Fusion web application at a particular instance creating what is called a save point. This allows you to save application state if, for example, a user leaves a page without finalizing it. The application state can be restored at a later point.

Table 24–2 describes what information a save point captures.
You add a method call activity to a bounded task flow that invokes a `createSavePoint` method to create save points. Later, you use a save point restore activity to restore application state and data associated with the created save points.

The same save point can be used if a user repeatedly performs a save for later on a task flow instance that executes in one session within the same browser window. The new save point overwrites the existing save point when a user performs a save for later following navigation from page to page in a task flow. For more information about restoring a save point, see Section 24.7.3, "How to Restore a Save Point."

You can specify the `createSavePoint` method exposed by the `currentViewPort` node of ADF Controller Objects in the Expression Builder. Alternatively, you can write a custom method that updates the save point with the values of attributes you specify in your custom method, as illustrated in Example 24–7.

**Example 24–7  Example Custom Method for Creating a Save Point**

```java
package viewController;

import java.io.Serializable;
import oracle.adf.controller.ControllerContext;
import oracle.adf.controller.savepoint.SavePointManager;

public class SaveForLater implements Serializable {
    public SaveForLater() {
        super();
    }

    public String saveTaskFlow() {
        ControllerContext cc = ControllerContext.getInstance();
        if (cc != null) {
            SavePointManager mgr = cc.getSavePointManager();
            // Code to create save point
        }
    }
}
```

<table>
<thead>
<tr>
<th>Saved State Information</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>User Interface State</td>
<td>UI state of the current page, including selected tabs, selected checkboxes, selected table rows, and table column sort order. This state assumes the end user cannot select the browser back button on save point restore.</td>
</tr>
<tr>
<td>Managed Beans</td>
<td>State information saved in several possible memory scopes, including session and page flow scope. The managed beans must be serializable in order to be saved. If you have page flow scope beans that are not serializable and you attempt to create a save point, a runtime exception occurs. Request scope is not supported since its lifespan is a single HTTP request and its lifespan cannot be used to store cross request application state. Save points will not save and restore application-scoped managed beans since they are not passivated in failover scenarios. Therefore, the application is always responsible for making sure that all required application-scoped state is available. Potential naming conflicts for managed beans already existing within the session scope at restore time will not occur because multiple managed beans using the same name should not be implemented within an application.</td>
</tr>
<tr>
<td>Navigation State</td>
<td>Task flow call stack, which ADF Controller maintains as one task flow calls another at runtime. The task flow call stack tracks where the end user is in the application and the navigation path for getting there. The task flow stack also identifies the starting point of any persisted data transactions originated for the end user.</td>
</tr>
<tr>
<td>ADF Model State</td>
<td>Fusion web applications use ADF Model to represent the persisted data model and business logic service providers. The ADF Model holds any data model updates made from when the current bounded task flow begins. The model layer determines any limits on the saved state lifetime. For more information, see Chapter 49, &quot;Using State Management in a Fusion Web Application.&quot;</td>
</tr>
</tbody>
</table>
if (mgr != null) {
    String id = mgr.createSavePoint();
    System.out.println("Save point is being set " + id);
    ...
}

The SavePointListener interface exposes methods that notify clients when save point events occur. The following package contains the SavePointListener interface:

```
oracle.adf.controller.savepoint
```

---

**Note:** All save points created inside a bounded task flow are deleted when the bounded task flow exits.

---

## 24.7.1 How to Add a Save Point to a Task Flow

You drag and drop a method call activity to the task flow diagram and configure it to invoke the `createSavePoint` method or to invoke a custom method if you created one.

**Before you begin:**

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Section 24.7, "Using Save Points in Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

You will need to complete this task:

- Confirm that your Fusion web application leaves the value of the `jbo.locking.mode` property set to the default value `optimistic`. This is required if you use a save point in a Fusion web application. The value `pessimistic` causes an old session to lock until the session has timed out. In pessimistic mode, if you run an application and change data without committing changes to the database, you may get an error when you create a save point and try to restore it at a later point. For information about the `jbo.locking.mode` property, see Section 49.11.1, "How to Confirm That Applications Use Optimistic Locking."

**To add a save point to a task flow:**

1. In the Applications window, double-click the bounded task flow where you want to add a save point.

2. In the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop a **Method Call** onto the diagram.

3. In the Properties window, expand the **General** node and write an EL expression in the **Method** field to specify the save point method that the method call activity invokes. If needed, select **Method Expression Builder** in the dropdown menu that you invoke from the icon that appears when you hover over the property field.

If you use the Expression Builder to specify the `createSavePoint` method exposed by the `currentViewPort` node of ADF Controller Objects, the resulting EL expression is similar to the following:

```
#{controllerContext.currentViewPort.createSavePoint}
```
4. Use a control flow to connect the method call activity with other activities in the bounded task flow.
   For more information, see Section 20.4.1, "How to Add a Control Flow Rule to a Task Flow."

5. Optionally, configure save point options in the Fusion web application’s adf-config.xml file to determine, for example, if implicit save points can be created for the application.
   For more information, see Section 24.7.7, "How to Enable Implicit Save Points."

24.7.2 What Happens When You Add Save Points to a Task Flow

JDeveloper generates entries similar to those shown in Example 24–8 in the task flow’s source file when you configure a method call activity to invoke the createSavePoint method.

Example 24–8  Method Call Metadata to Invoke the createSavePoint Method

```xml
<method-call id="methodCall1">
  <method id="__3">#{controllerContext.currentViewPort.createSavePoint}</method>
</method-call>
```

24.7.3 How to Restore a Save Point

Use the save point restore activity to restore a previously persisted save point for an application. The save point restore activity uses the save point that was originally created by invoking the createSavePoint method to identify the save point to restore.

You can obtain a list of the current persisted save points with createSavePoint. However, ADF Controller does not determine which save points to restore. A user must select the save point from a list or the application developer must select it programmatically. The savepoint ID is then passed to a save point restore activity to perform the restore.

Before you begin:

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Section 24.7, "Using Save Points in Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To add a save point restore activity to a bounded or unbounded task flow:

1. In the Applications window, double-click the task flow where you want to add the save point restore activity.

2. In the ADF Task Flow page of the Components window, from the Components panel, in the Activities group, drag and drop a Save Point Restore onto the diagram.

3. In the Properties window, expand the General section and write an EL expression in the Save Point ID field that, when evaluated, retrieves the save point that was originally created when the createSavePoint method was invoked.
If you use the Expression Builder to specify the `getSavePoint` method of ADF Controller Objects, the resulting EL expression is similar to the following:

```el
#{SessionScope.myBean.savepointID}
```

### 24.7.4 What Happens When You Restore a Save Point
JDeveloper generates entries similar to Example 24–9 in the task flow’s source file when you add a save point restore activity that gets a save point ID.

**Example 24–9  Metadata for a Save Point Restore Activity in a Task Flow**

```xml
<save-point-restore id="savePointRestore1">
  <save-point-id id="_4">#{sessionScope.myBean.savepointID}</save-point-id>
</save-point-restore>
```

### 24.7.5 How to Use the Save Point Restore Finalizer
When using the save point restore activity, you may need to invoke application-specific logic as part of restoring the application state. You can write an EL expression for the Save Point Restore Finalizer property of a bounded task flow that specifies a finalizer method. The bounded task flow invokes the specified method after the task flow’s state has been restored. It performs any necessary logic to make sure that the application’s state is correct before proceeding with the restore.

**Before you begin:**
It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Section 24.7, "Using Save Points in Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

**To use the save point restore finalizer:**
1. In the Applications window, double-click the bounded task flow that you want to use a save point restore finalizer.
2. In the Structure window, right-click the node for the bounded task flow (task-flow-definition) and choose Go to Properties.
3. In the Properties window, expand the General section, and select Expression Builder in the dropdown list that you invoke from the icon that appears when you hover over the Save Point Restore Finalizer property field.
4. Write an EL expression that specifies the finalizer method to invoke.

### 24.7.6 What Happens When a Task Flow Invokes a Save Point Restore Finalizer
JDeveloper generates entries similar to Example 24–10 in the task flow’s source file when you write an EL expression for the Save Point Restore Finalizer property.

**Example 24–10  Metadata to Invoke a Save Point Restore Finalizer**

```xml
<task-flow-definition id="task-flow-definition1">
  <save-point-restore-finalizer id="_2">#{sessionScope.MyBean.invokeFinalizer}</save-point-restore-finalizer>
</task-flow-definition>
```
24.7.7 How to Enable Implicit Save Points

A save point in a task flow can be categorized as *implicit* or *explicit*. An explicit save point requires an end user action before a bounded or unbounded task flow creates a save point. For example, an end user clicks a button that invokes a method call activity that, in turn, creates a save point.

An implicit save point can only originate from a bounded task flow. It includes everything from when the originating task flow creates a save point. It occurs when data is saved automatically because:

- A session times out due to end user inactivity.
- An end user logs out without saving the data.
- An end user closes the only browser window, thus logging out of the application.
- An end user navigates away from the current application using control flow rules (for example, uses a link component to go to an external URL) and having unsaved data.

Enabling implicit save points requires you to add an element to your Fusion web application’s adf-config.xml file and to make the bounded task flow critical. You configure the adf-config.xml file in your application and the bounded task flow(s) for which you want to create implicit save points. Enabling implicit save points involves a performance cost because your Fusion web application has to do extra work that it would otherwise not do. This is why you have to explicitly enable implicit save points in your application and specify the task flows to which it applies.

**Before you begin:**

It may be helpful to have an understanding of what save point options you can configure for a task flow. For more information, see Section 24.7, “Using Save Points in Task Flows.”

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, “Additional Functionality for Complex Task Flows.”

**To enable implicit save points:**

1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click adf-config.xml.

2. In the overview editor, click the Controller navigation tab and then expand the Savepoints section and select the Enable Implicit Savepoints checkbox. JDeveloper generates the following entry in the adf-config.xml file:

   `<adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
   ...
   <enable-implicit-savepoints>true</enable-implicit-savepoints>
   </adf-controller-config>

   For more information about the adf-config.xml file, see Section A.9, "adfc-config.xml."

3. In the Applications window, double-click the bounded task flow.

4. In the editor window, click the Overview tab.

5. In the overview editor, click the Behavior navigation tab and select the Critical checkbox.
24.7.8 What You May Need to Know About Enabling Implicit Save Points

If multiple windows are open when the implicit save point is created, a different save point is created for each browser window. This includes everything from the root view port of the browser window on down. You can write an EL expression for the Method property of a method call activity to retrieve the list of implicit save points using the `savePointManager` node under ADF Controller Objects. The resulting EL expression is similar to the following:

```java
ControllerContext.savePointManager.listSavePointIds
```

Implicit save points are generated only if a critical task flow is present in any of the page flow stacks for any view port under the current root view port. An implicit save point is not generated if the request is for an ADF Controller resource, such as:

- Task flow call activity
- Task flow return activity
- Save point restore activity
- A dialog

Implicit save points are deleted when the task flow at the bottom of the stack completes or a new implicit save point is generated, whichever comes earlier.

24.7.9 What You May Need to Know About the Time-to-Live Period for a Save Point

An application-level property (`savepoint-expiration`) that is defined in the `adf-config.xml` file determines the period between when a task flow creates a save point and when the save point manager removes it (time-to-live period). The default value is 86400 seconds (24 hours).

You can change the time-to-live period for individual save points by calling the `setSavePointTimeToLive` method on an instance of `SavePointManager` from the following package:

```java
oracle.adf.controller.savepoint
```

An instance of `SavePointManager` can be obtained as follows:

```java
SavePointManager mgr = ControllerContext.getInstance().getSavePointManager();
```

**Example 24–11** shows the syntax for the `setSavePointTimeToLive` method.

**Example 24–11** Syntax for the `setSavePointTimeToLive` Method

```java
public void setSavePointTimeToLive(long timeInSeconds) {
    
}
```

If you supply a value for the `setSavePointTimeToLive` method argument (`timeInSeconds` in **Example 24–11**) equal to or less than zero, the default value is used (86400).

The `SavePointManager` defines methods that help you manage save points. For example, it defines `getSavePoint` and `removeSavePoint` methods that can retrieve and remove save points. Note that the `removeSavePoint` method does not get called automatically when a save point expires. You must explicitly call the `removeSavePoint` method to remove save points (including expired save points) from the `ORADFCSAVPT` database table. Alternatively, Oracle ADF provides a SQL script (`adfc_cleanup_save_point_table.sql`) that removes expired save points. For more information, see Section 24.6.3, "What You May Need to Know About the Database Table for Save Points."
Consider calling the `setSavePointTimeToLive` method at the same time that you call the method to create save points, as illustrated in Example 24–7. For more information about the `SavePointManager`, see the `Java API Reference for Oracle ADF Controller`.

### 24.8 Using Train Components in Bounded Task Flows

You can create a task flow as a train. This allows you to create a user interface where you navigate end users through a multistep process. ADF Faces provides the user interface components that render the train functionality in the task flow view activities that appears to the end user. These components are the `train` and `trainButtonBar` components. Figure 24–8 shows a runtime view of the `edit-customer-task-flow-definition.xml` task flow from the Summit ADF task flow sample application. This task flow uses the `train` and `trainButtonBar` components to navigate an end user through the task of editing a customer’s data.

**Figure 24–8  Train and Train Button Bar Components in a Task Flow**

The `train` component in Figure 24–8 renders three train stops. Each stop corresponds to a page fragment in the `edit-customer-task-flow-definition.xml` task flow where the end user can enter and review information to complete the task of editing a customer’s data. Figure 24–8 shows the Address train stop where the end user enters an address for postage. The other stops are:

- General Information
- Comments

The Train Button Bar component, also shown in Figure 24–8, is optional and provides additional controls to navigate between the train stops. This component can be used in conjunction with the train component to provide multiple ways to navigate through train stops.

Bounded task flows and task flow templates can make use of these train components if you select the `Create Train` checkbox on the dialogs provided by JDeveloper to create a bounded task flow or a task flow template. A bounded task flow or a task flow template can render one train only. If you want to use multiple trains, create a separate bounded task flow or task flow template for each train.

**Figure 24–9** displays an extract from the design-time view of the task flow where you can see the view activities that render at runtime as train stops in Figure 24–8.

The dotted lines connecting the view activities indicates the sequence in which the end user navigates between the view activities when the view activities render as train stops.
Using Train Components in Bounded Task Flows

**Creating Complex Task Flows**

Figure 24–9  Task Flow Configured to Render as a Train

JDeveloper displays a context menu with options to change the position of the activity when your right-click a view activity or task flow call activity that is configured as a train stop, as illustrated in Figure 24–10.

Figure 24–10  Context Menu to Edit a Train Stop

Configure a task flow call activity as a train stop when you want to group a number of activities as a train stop or call a child train stop. For example, there are cases when other task flow activities, such as router and method call activities, should be considered part of a train stop along with the corresponding view activity. A method call activity might need to precede a view activity for initialization purposes. When grouped this way, the activities can be performed as a set each time the train stop is visited. For more information, see Section 24.8.3, "Grouping Task Flow Activities to Execute Between Train Stops."

Branching using router activities and control flow cases is supported on the task flow diagram containing the train, as well as in child bounded task flows called from the train.

### 24.8.1 Creating a Task Flow as a Train

You need to configure a bounded task flow to use train components before you can implement the type of functionality discussed in Section 24.8, "Using Train Components in Bounded Task Flows." Use one of the methods outlined in the following list to configure a bounded task flow to use train components:

- Select the Create Train checkbox in the dialog that appears when you create a new bounded task flow or task flow template.

For more information, see Section 20.2, "Creating a Task Flow" or Section 24.9, "Creating Task Flow Templates."

- Right-click an existing bounded task flow in the diagram and choose Train > Create Train.
Open an existing bounded task flow in the overview editor, click the Behavior navigation tab and select the Train checkbox.

Once you have configured the bounded task flow to use train components, you drag and drop the task flow activities that you want to render in the train to the diagram in the bounded task flow.

24.8.1.1 How to Create a Train in a Bounded Task Flow

You drag and drop the task flow activities that you want to render in the train to the diagram for the bounded task flow.

Before you begin:

It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see Section 24.8.1, "Creating a Task Flow as a Train."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

You will need to complete this task:

Configure the bounded task flow to use train components, as described in Section 24.8, "Using Train Components in Bounded Task Flows."

To create a train in a bounded task flow:

1. In the Applications window, double-click the bounded task flow or task flow template where you want to render train stops.

2. Drag each view activity or JSF page you want to include in the train to the diagram for the bounded task flow.

   - If you drag a JSF page, JDeveloper automatically adds a view activity to the diagram. You drag a JSF page that you want to include from the Applications window to the diagram for the bounded task flow.

   - If you drag a view activity to the diagram, you can double-click it to invoke the dialog to create a new JSF page. To drag a view activity, in the ADF Task Flow page of the Components window, from the Component panel, in the Activities group, drag and drop a View onto the diagram.

   You can reorder the train stop sequence at a later point. For more information, see Section 24.8.4, "Disabling the Sequential Behavior of Train Stops in a Train."

3. In the diagram for the bounded task flow, double-click each view activity that you want to define as a train stop.

   A dialog appears to create a new JSF page if the view activity is not yet associated with a JSF page. Use the dialog to create a new JSF page.

   If the view activity is already associated with a JSF page, the JSF page opens.

4. In the ADF Faces page of the Components window, from the General Controls panel, in the Location group, drag a Train, and, optionally, a Train Button Bar component and drop it on the JSF page.

   You must manually add each Train and Train Button Bar component that you want to appear in a task flow view activity. Consider using a page template. For more information, see Section 26.2, "Using Page Templates."
24.8.1.2 What Happens When You Create a Task Flow as a Train
JDeveloper writes the `<train/>` element to the source file for the bounded task flow or task flow template that you enable as a train, using one of the methods outlined in Section 24.8.1, "Creating a Task Flow as a Train."

JDeveloper writes entries to the JSF page where you add `train` and `trainButtonBar` components. Example 24–12 shows code snippets from the GeneralInfo.jsf page fragment in the Summit ADF task flow sample application. Both types of train component bind to instances of the train model object (trainModel).

Example 24–12 Metadata for Train Components in a JSF Page

```xml
<af:train value="#{controllerContext.currentViewPort.taskFlowContext.trainModel}"
    id='t1'/>
...
<af:trainButtonBar value="#{controllerContext.currentViewPort.taskFlowContext.trainModel}"
    id='tbb1'/>
```

Dotted lines appear between each view activity that you add to the bounded task flow and define as a train stop, as illustrated in Figure 24–9. The dotted lines indicate the order in which the bounded task flow navigates through the train stops. JDeveloper defines the sequence in the order that you add the view activities to the bounded task flow. You can change the sequence. For more information, see Section 24.8.4, "Disabling the Sequential Behavior of Train Stops in a Train." You can also skip a train stop. For more information, see Section 24.8.6, "Configuring a Train to Skip a Train Stop."

24.8.2 Invoking a Child Bounded Task Flow from a Train Stop
An alternative approach to grouping task flow activities in one train stop, as described in Section 24.8.3, "Grouping Task Flow Activities to Execute Between Train Stops," is to create another bounded task flow as a train that you invoke from your current bounded task flow. This bounded task flow is referred to as a child bounded task flow. You configure the parent bounded task flow to invoke it using a task flow call activity. To implement this functionality, you:

- Create a child bounded task flow as a train
- Add the task flow activities that you want end users to access from the train stop on the parent bounded task flow to the child bounded task flow
- Designate a task flow call activity as a train stop in the parent bounded task flow to invoke the child bounded task flow
- Add a task flow return activity to the child bounded task flow that returns control to the parent bounded task flow once the child bounded task flow finishes execution

Task flow activities in the child bounded task flow execute together regardless of whether the end user visits the train stop for the first time or returns at a later point. Nonview task flow activities in the child bounded task flow typically precede the view activity in the child bounded task flow’s flow control. You can invoke a child bounded task flow from a bounded task flow that itself is a child to another bounded task flow.

24.8.2.1 How to Invoke a Child Bounded Task Flow From a Train Stop
You create a bounded task flow as a train, add task flow activities to it, and configure a task flow call activity on the parent bounded task flow to invoke it.
**Before you begin:**

It may be helpful to have an understanding of the configuration options that you can configure for a child bounded task flow that you invoke from a train. For more information, see Section 24.8.2, "Invoking a Child Bounded Task Flow from a Train Stop."

You may also find it helpful to read about the additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

You will need to complete this task:

Create a bounded task flow as a train. This is a child bounded task flow that is to be invoked from a task flow call activity in the parent task flow. Add the task flow activities that you require to it. For more information, see Section 24.8.1, "Creating a Task Flow as a Train."

**To invoke a child bounded task flow from a train stop:**

1. In the Applications window, double-click the bounded task flow that is the child bounded task flow configured as a train.

2. In the ADF Task Flow page of the Components window, from the ADF Task Flow panel, in the Activities group, drag and drop a **Task Flow Return** onto the diagram.

3. Configure the task flow return activity to return control to the parent task flow when the child bounded task flow finishes execution.

   For more information, see Section 21.7, "Using Task Flow Return Activities."

4. In the Applications window, double-click the parent bounded task flow that is going to invoke the child bounded task flow.

   For more information, see Section 24.8.1, "Creating a Task Flow as a Train."

5. In the ADF Task Flow page of the Components window, from the ADF Task Flow panel, in the Activities group, drag and drop a **Task Flow Call** onto the diagram.

6. Configure the task flow call activity to invoke the child bounded task flow that you configured in Steps 1 to 3.

   For more information, see Section 21.6, "Using Task Flow Call Activities."

**24.8.3 Grouping Task Flow Activities to Execute Between Train Stops**

You can group task flow activities together to form a single train stop. For example, a train stop that renders as **Address** at runtime might group together the following task flow activities:

- defineAddress view activity
- createAddress method call activity
- addressDetails view activity

Each time a user visits the runtime **Address** train stop, the task flow would provide access to the task flow activities listed previously. The defineAddresses view activity renders the train stop and the associated defineAddresses.jsff page fragment. The defineAddresses.jsff page fragment, in turn, exposes a button to invoke the createAddress method call activity. This method call activity validates user input in the Address page and defines an outcome that (optionally) passes control to the addressDetails view activity. The addressDetails view activity renders...
the Address Information page at runtime where an end user may choose to enter additional addresses.

**Figure 24–11  Task Flow Activities Grouped into One Train Stop**

The train considers all task flow activities that lead from the first nonview activity through the next view activity to be part of the train. Make sure that all task flow activities, except for view and task flow call activities, for the train stop follow the view or task flow call activity that you define as a train stop.

You can also group task flow activities to execute between train stops. **Figure 24–12** shows a possible configuration where a method call activity (doSomethingBeforePage2) invokes before control flow passes to page2. The callMethodBeforePage2 wildcard control flow rule passes control to the doSomethingBeforePage2 method call activity. This method call activity defines a fixed outcome (continue) that passes control to the next train stop (page2) in the train.
24.8.4 Disabling the Sequential Behavior of Train Stops in a Train

By default, train stops are sequential. This means end users can select a train stop only after visiting the previous train stop in the train. Figure 24–13 shows a train component that a registration task flow renders. End users cannot visit the Payment options and Review train stops until they first visit the Address train stop. All train stops in this train are sequential.

You can change this default behavior (make a train stop nonsequential) by configuring the view activity that renders the train stop to make it nonsequential.

24.8.4.1 How to Disable the Sequential Behavior of a Train

You write a value for the task flow view activity’s sequential property that evaluates to false at runtime.
Before you begin:
It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see Section 24.8, "Using Train Components in Bounded Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To disable the sequential behavior of a train stop:
1. In the Applications window, double-click the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Properties window, expand the Train Stop section and write a value in the Sequential field to determine if the train stop is sequential or nonsequential.
   Write false or write an EL expression that resolves to false at runtime to make the train stop nonsequential. For example, write an EL expression similar to the following:
   
   `#{myTrainModel.isSequential}`

24.8.4.2 What Happens When You Disable the Sequential Behavior of a Train Stop
JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in Example 24–13.

Example 24–13  Metadata to Disable the Sequential Behavior of a Train Stop

```
<view id="paymentOptionDetails">
  <page>/account/paymentOptionDetails.jsff</page>
  <train-stop id="__1">
    <sequential>#{myTrainModel.isSequential}</sequential>
  </train-stop>
</view>
```

Figure 24–14 shows the corresponding runtime view when the value specified for sequential evaluates to false. End users can now navigate directly to payment options by clicking the Payment options train stop.

Figure 24–14  Train with a Nonsequential Train Stop

24.8.5 Changing the Label of a Train Stop
You can configure a train stop to display a label that you define. The label that you define can be a static value or a value in a resource bundle that you reference using an EL expression, for example. For more information about using localized strings, see the “Internationalizing and Localizing Pages” chapter of Developing Web User Interfaces with Oracle ADF Faces.
24.8.5.1 How to Change the Label of a Train Stop
You change the label of a train stop by configuring a value for the view activity’s Display Name property.

Before you begin:
It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see Section 24.8, "Using Train Components in Bounded Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To change the label of a train stop:
1. In the Applications window, double-click the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Properties window, expand the Description section and write a value in the Display Name to specify the label that the train stop renders at runtime.
   Write a literal value or write an EL expression that references a value in a resource bundle to render at runtime.

24.8.5.2 What Happens When You Change the Label of a Train Stop
JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in Example 24–14 from the edit-customer-task-flow-definition.xml bounded task flow in the Summit ADF task flow sample application.

Example 24–14 Metadata to Change the Label of a Train Stop

```xml
<view id="GeneralInfo">
    <page>/customers/GeneralInfo.jsff</page>
    <train-stop>
        <display-name>General Information</display-name>
        <sequential>false</sequential>
    </train-stop>
</view>
```

At runtime, the Fusion web application displays the value you specified for the display-name property as the label for the train stop.

24.8.6 Configuring a Train to Skip a Train Stop
You can configure a train so that it skips an individual train stop. At runtime, the Fusion web application disables the train stop that you configure to skip. The end user can only navigate to the next train stop in the train.

Implement this functionality if you want the train to execute at a train stop other than the first train stop. For example, configure train stops 1 and 2 to skip if you want to execute train stop 3 first. Use this approach rather than defining the view activity associated with the train stop as the default activity, as discussed in Section 20.2.3, "What You May Need to Know About the Default Activity in a Bounded Task Flow."
24.8.6.1 How to Configure a Train to Skip a Train Stop
You write a value for the view activity’s skip property that evaluates to true at runtime.

Before you begin:
It may be helpful to have an understanding of the configuration options that you can configure for a train. For more information, see Section 24.8, "Using Train Components in Bounded Task Flows."
You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

To configure a train to skip a train stop:
1. In the Applications window, double-click the bounded task flow containing the view activity that renders the train stop.
2. In the diagram for the bounded task flow, select the view activity.
3. In the Properties window, expand the Train Stop and write a value in the Skip field to determine if the train navigates to the train stop or skips it.
   Write true or write an EL expression that resolves to true at runtime to make the train skip the train stop. For example, write an EL expression similar to the following:
   #{myTrainModel.shouldSkip}

24.8.6.2 What Happens When You Configure a Train to Skip a Train Stop
JDeveloper writes an entry to the source file for the bounded task flow, as illustrated in Example 24–15.

Example 24–15 Metadata to Make a Train Skip a Train Stop

Example 24–15 shows the corresponding runtime view when the value specified for skip evaluates to true. End users must now navigate to the next train stop in the train (Payment options) if the train is sequential.

Figure 24–15 Train Configured to Skip a Train Stop

24.9 Creating Task Flow Templates
You can create task flow templates for yourself or other application developers to use as a starting point when creating new bounded task flows. Unbounded task flows
Creating Task Flow Templates

cannot be created using task flow templates. A bounded task flow created from a task flow template will have definitions for the same set of task flow activities, control flows, input parameters, and managed beans as the task flow template. For example, Figure 24–16 shows a bounded task flow that has been created from a task flow template. The view1 and view2 view activities plus the goToView2 control flow in this bounded task flow have been defined in the task flow template while the start and view3 view activities have been defined in the bounded task flow itself.

Figure 24–16  Bounded Task Flow Displaying Activities Defined in Task Flow Template

An example use case for a task flow template is where you define a task flow activity as an exception handler on a bounded task flow. The task flow activity could be a view activity associated with a page that you display to end users when an exception occurs. Rather than define this view activity in each bounded task flow, you define it in a task flow template and select the task flow template when you create new bounded task flows. For more information about exception handling, see Section 24.5, "Handling Exceptions in Task Flows."

You can base a new task flow template on an existing task flow template. You can also refactor an existing bounded task flow to create a new task flow template. For more information, see Section 20.6.4, "How to Convert Bounded Task Flows."

When you create a bounded task flow or another task flow template based on a task flow template, you can specify that subsequent changes you make to a task flow template be automatically propagated to bounded task flows and templates. To do this, you select the Update the Task Flow When the Template Changes checkbox in the dialog that you use to create a bounded task flow or a template. Subsequent changes that you make to the task flow template (add new view activities, for example) get propagated to the bounded task flows. You can change, update, or disassociate the parent task flow template of a child bounded task flow or task flow template at any point during development of the child.

At runtime, the contents of a child bounded task flow or a child task flow template combine with the contents of the parent task flow template if you selected the Update the Task Flow When the Template Changes checkbox when creating the child. The child task flow and task flow template override the parent task flow template when conflict occurs, even if you selected the Update the Task Flow When the Template Changes checkbox when creating the child task flow or task flow template. For example, you create a parent task flow template to use as a train, as described in Section 24.8, "Using Train Components in Bounded Task Flows," and then create a bounded task flow based on this task flow template. Later, you disable the train component on the parent task flow template. The child task flow overrides the parent task flow template and continues to execute as a train.
Table 24–3 describes in more detail how ADF Controller resolves conflicts between parent task flow templates and child task flows and child task flow templates.

<table>
<thead>
<tr>
<th>Bounded Task Flow Metadata</th>
<th>Combination Algorithm</th>
</tr>
</thead>
<tbody>
<tr>
<td>Default activity</td>
<td>Child bounded task flow or child task flow template overrides parent task flow template.</td>
</tr>
<tr>
<td>Transaction</td>
<td>Child bounded task flow or child task flow template overrides parent task flow template as an entire block of metadata, including all subordinate elements.</td>
</tr>
<tr>
<td>Task flow reentry</td>
<td>Child bounded task flow or child task flow template overrides parent task flow template as an entire block of metadata, including all subordinate elements.</td>
</tr>
</tbody>
</table>
| Control flow rules         | Combination algorithm occurs at the control flow case level, not the control flow rule level. Control flow cases fall into the following categories:  
  ■ Both from action and from outcome specified  
  ■ Only from action specified  
  ■ Only from outcome specified  
  ■ Neither from action nor from outcome specified  
  Each of these categories is merged additively. The child bounded task flow or template overrides parent task flow template for identical matches within each of the four categories. |
| Input parameter definitions| Child bounded task flow or child task flow template overrides parent task flow template for identical input parameter definition names. |
| Return value definitions   | Child bounded task flow or child task flow template overrides parent task flow template for identical return value definition names. |
| Activities                 | Child bounded task flow or child task flow template overrides parent task flow template for identical activity IDs. |
| Managed beans              | Child bounded task flow or child task flow template overrides parent task flow template for identical managed bean names. |
| Initializer                | Child bounded task flow or child task flow template overrides parent task flow template. |
| Finalizer                  | Child bounded task flow or child task flow template overrides parent task flow template. |
| Critical                   | Child bounded task flow or child task flow template overrides parent task flow template. |
| Use page fragments         | Child bounded task flow or child task flow template overrides parent task flow template. |
| Exception handler          | Child bounded task flow or child task flow template overrides parent task flow template. |
| Security - permission      | Child bounded task flow or child task flow template overrides parent task flow template.  
  Privilege maps are additive. Child bounded task flow or child task flow template overrides parent task flow template for identical privilege map operations. |
| Security - transport       | Child bounded task flow or child task flow template overrides parent task flow template. |
Validations at both design time and runtime verify that the resulting parent-child extension hierarchy does not involve cycles of the same task flow template.

### 24.9.1 How to Create a Task Flow Template

You create a task flow template by selecting ADF Task Flow Template from the New Gallery.

**Before you begin:**

It may be helpful to have an understanding of what task flow template options you can configure. For more information, see Section 24.9, "Creating Task Flow Templates."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

**To create a task flow template:**

1. In the Applications window, right-click the project where you want to create the task flow template and choose New > From Gallery.

2. In the New Gallery, expand Web Tier, select JSF/Facelets and then ADF Task Flow Template, and click OK.

3. In the Create ADF Task Flow Template dialog, choose the appropriate options:
   - **File Name**: Accept the default value proposed by JDeveloper or enter a new file name. The value is used to name the XML source file for the task flow template you create. The source file includes the activities and control flow rules that are in the task flow template. The default name for the XML source file is `task-flow-template.xml`.
   - **Create with Page Fragments**: Leave this checkbox selected (the default) if you expect that a bounded task flow based on the template will be used as an ADF region. Clear the checkbox if you want to add JSF pages instead of JSF page fragments to a task flow based on the task flow template.

4. Click OK.

### 24.9.2 What Happens When You Create a Task Flow Template

As shown in Example 24–16, an XML file is created each time you create a new task flow template using JDeveloper. You can find the XML file in the Applications window in the location that you specified in the Directory field of the Create ADF Task Flow Template dialog, for example, `.../WEB-INF`.

The contents of the XML source file for the task flow template can be similar to those of a bounded task flow. One difference is the inclusion of the `<task-flow-template>` tag.

**Example 24–16 Task flow template source file**

```xml
<?xml version="1.0" encoding="windows-1252" ?>
```
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2" id="__1">
  <task-flow-template id="task-flow-template">
    <default-activity>view1</default-activity>
    <view id="view1">view1.jsff</view>
  </task-flow-template>
</adfc-config>

24.9.3 What You May Need to Know About Task Flow Templates

If you use a task flow template that contains bindings, you must change the component IDs of task flows based on the task flow template. Doing this makes sure that the IDs are unique. Task flows generated from the template inherit the same ID as the template. This may cause an exception at runtime. For more information, see Section 26.2.1, "How to Use ADF Data Binding in ADF Page Templates."

If your Fusion web application has configured ADF security, you have to make grants on both the task flow template and task flows that use the template. Usually, the grant on the task flow template is to the anonymous-role application role so that the grant that really matters is on the task flow, but not always. For more information about ADF security, see Section 41, "Enabling ADF Security in a Fusion Web Application."

24.10 Creating a Page Hierarchy Using Task Flows

Creating a page hierarchy is a useful way of organizing the JSF pages in your Fusion web application so that end users can more easily navigate the application. End users access information on the pages by navigating a path of links. Figure 24–17 shows a sample page hierarchy.

Figure 24–17  Page Hierarchy

To navigate this hierarchy, an end user clicks links on each page to drill down or up to another level of the hierarchy. For example, clicking Human Resources on the Fusion App home page displays the Human Resources page hierarchy shown in Figure 24–17. Clicking the link on the Benefits tab displays the page hierarchy shown in Figure 24–18.
The user can click links on the Benefits page to display other pages, for example, the Medical, Dental or Vision pages. The breadcrumbs on each page indicate where the current page fits in the hierarchy. The user can click each node in a breadcrumb to navigate to other pages in the hierarchy. The bold tab labels match the path to the current page shown by the breadcrumbs.

Pages referenced by view activities in a bounded task flow can also be included in any page hierarchy that you generate. Figure 24–19 shows the runtime view of a page hierarchy that renders view activities referenced by a bounded task flow.

You can use ADF Controller with an XMLMenuModel implementation to create the previously discussed page hierarchies. If you do, JDeveloper generates the following for you:

- Control flow metadata that determines the view or page to display when an end user selects a menu item
- An XMLMenuModel metadata file
- Default navigation widgets such as Previous and Next buttons
- Breadcrumbs
- Managed bean configuration

If you decide not to use ADF Controller, you can create the page hierarchy using an XMLMenuModel implementation. For more information about this method of building a page hierarchy, see the "Using a Menu Model to Create a Page Hierarchy” section in Developing Web User Interfaces with Oracle ADF Faces.
24.10.1 How to Create a Page Hierarchy

Create an unbounded task flow or open an existing one. Add view activities or bounded task flows to the unbounded task flow. Each view activity or bounded task flow that you add to the unbounded task flow contains references to pages to appear in the proposed page hierarchy. Use JDeveloper’s Create ADF Menu Model dialog to generate an XMLMenuModel metadata file. Organize the item nodes in the generated XMLMenuModel metadata file to create the page hierarchy you want. Connect submenus to parent menus to finalize the hierarchy.

Figure 24–20 shows an example page hierarchy that consists of view activities:

- The top-level menu (Home Page) is the root parent page. It contains a single tab that links to the Human Resources submenu.
  
  In JDeveloper, Home Page page is represented as an item node and Human Resources page as a shared node.

- Human Resources has four tab links to Payroll, Time, Labor, and Benefits pages.
  
  In this menu, Human Resources is a group node that references child item nodes (Payroll, Time, and Labor) and a shared node (Benefits) that references the Benefits submenu.

- Benefits is a group node that references child item nodes (Medical, Dental, and Vision) pages.

Figure 24–20 Menu Hierarchy

![Menu Hierarchy Diagram]

Note: It is possible to create the entire menu hierarchy in one menu model. However, breaking a menu hierarchy into submenus makes maintenance easier. In addition, breaking the menu hierarchy into smaller submenu models enables each separate development organization to develop its own menu. These separate menus can later be combined using shared nodes to create the complete menu hierarchy.

Figure 24–21 shows the corresponding design-time view in JDeveloper of the unbounded and bounded task flows that render the page hierarchy shown in Figure 24–19. The unbounded task flow (adfc-config.xml) contains a view activity (view1) and a task flow call activity (task-flow-definition) that invokes the bounded task flow (task-flow-definition.xml) shown in the lower part of Figure 24–21.
24.10.1.1 How to Create an XMLMenuModel Metadata File

You use JDeveloper’s Create ADF Menu Model dialog to generate an XMLMenuModel metadata file once you have defined what menus (unbounded task flows) and nodes (pages) you want to appear in the final page hierarchy.

Before you begin:
It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see Section 24.10, "Creating a Page Hierarchy Using Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

You will need to complete these tasks:

1. Create an unbounded task flow for each menu in the final page hierarchy.
   For example, to achieve the page hierarchy illustrated in Figure 24–20, you create two unbounded task flows (Human Resources menu and Benefits menu).
   For more information about creating an unbounded task flow, see Section 20.2.1, "How to Create a Task Flow."

   **Tip:** Prefix the name of the file for unbounded task flows that you create with `adfc-` to help you to identify the file as the source of an unbounded task flow, as opposed to a bounded task flow.

2. Add view activities that reference pages to each unbounded task flow. The pages referenced by the view activities correspond to the menu nodes in the menu.
   For example, the Benefits menu contains one group node (benefits) and three item nodes (medical, dental and vision) so you add four view activities to the unbounded task flow for the Benefits menu, as illustrated in Figure 24–22.
Creating a Page Hierarchy Using Task Flows

Creating Complex Task Flows

24-49

Do not add view activities for menus that include other menus using shared nodes. For example, the Human Resources menu in Figure 24–20 has a tab called Benefits that references the Benefits menu using a shared node. The bounded task flow for the Benefits menu already includes a view activity for Benefits so there is no need to add a view activity to the bounded task flow for the Human Resources menu.

For more information about view activities, see Section 21.2, "Using View Activities."

---

**Note:** If the page hierarchy includes pages referenced by a bounded task flow, add a task flow call activity to the unbounded task flow that calls the bounded task flow.

---

**To create the XMLMenuModel metadata file:**

1. In the Applications window, right-click the file(s) for each of the unbounded task flows you created and choose Create ADF Menu Model.

2. In the Create ADF Menu Model dialog, enter a file name for the XMLMenuModel metadata file and a directory to store it.

3. Click OK.

---

**24.10.1.2 How to Create a Submenu with a Hierarchy of Group and Child Nodes**

You open the XMLMenuModel metadata file you created and convert the item nodes that you want to make group nodes to group nodes. You then create a hierarchy where a group node is a parent to one or more item nodes.

**Before you begin:**

It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see Section 24.10, "Creating a Page Hierarchy Using Task Flows."

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, "Additional Functionality for Complex Task Flows."

---

**To create a submenu with a hierarchy of group and item nodes:**

1. In the Applications window, double-click the XMLMenuModel metadata file. An item node appears in the Structure window for each view activity in the unbounded task flow. By default, no hierarchy is defined.

2. In the Structure window, drag and drop the item nodes to become child nodes of the item node that you are going to convert to a group node.

Each item node that you convert to a group node must have at least one child item node. For example, to create the menu hierarchy in Figure 24–20, you convert the
item node for Benefits to a group node, you drag and drop the item nodes for Medical, Dental, and Vision so that they become child nodes of the Benefit item node.

3. In the Structure window, right-click the parent item node and choose **Convert To groupNode**.

4. In the groupNode Properties dialog, in the id field, enter a new identifier or accept the default value.

   The identifier must be unique among all of the nodes in all of the XMLMenuModel metadata files. It is good practice to specify a value that identifies the node. For example, if you change the Benefits node to a group node, you can update its default ID, `itemNode_benefits`, to `groupNode_benefits`.

5. In the idref field, enter the ID of one of the other nodes in the menu, for example, `itemNode_Medical`.

   The value you enter can be an ID of a child item node that is a group node or an item node.

6. Enter or change the existing default value in the label field to match what you want to appear at runtime.

   For example, you might change `label_benefits` to `Benefits`.

7. Accept the rest of the default values in the fields and click **Finish**.

   A Confirm Convert dialog asks if you want to delete the action and focusViewID attributes on the groupNode element. Group nodes do not use these attributes, always click **OK**.

8. Click OK

### 24.10.1.3 How to Attach a Menu Hierarchy to Another Menu Hierarchy

You use a shared node element to link two menus together. For example, the Human Resources menu shown in the menu hierarchy in Figure 24–20 contains four submenus (Payroll, Time, Labor, and Benefits). The Benefits submenu is itself a menu with submenu entries. In the XMLMenuModel metadata file for the Human Resources menu, you convert the item node for the Benefits submenu to a shared node. You write an EL expression for an attribute (ref) of the newly created shared node that references the XMLMenuModel metadata file for the Benefits menu.

**Before you begin:**

It may be helpful to have an understanding of what page hierarchy options you can configure. For more information, see Section 24.10, “Creating a Page Hierarchy Using Task Flows.”

You may also find it helpful to read about additional functionality that you can add using other task flow features. For more information, see Section 24.1.2, “Additional Functionality for Complex Task Flows.”

**To attach a menu hierarchy to another hierarchy using a shared node:**

1. In the Applications window, double-click the XMLMenuModel metadata file for the menu that is going to reference the other menu.

2. In the Structure window, select a node, right-click and select the appropriate menu options to insert a `sharedNode` element.
3. In the Insert sharedNode dialog, in the ref field, enter an EL expression to reference the XMLMenuModel metadata file for the other menu.

4. Click OK.

---

**Note:** If your page hierarchy has more than one unbounded task flow, make sure that the file name for each additional unbounded task flow appears as a value for the <metadata-resources> element in the adfc_config.xml file. For more information, see Section 24.10.2, "What Happens When You Create a Page Hierarchy."

---

### 24.10.2 What Happens When You Create a Page Hierarchy

Changes occur in a number of different files when you create a page hierarchy.

#### Changes to the adfc-config.xml File

When you create a new unbounded task flow, JDeveloper automatically adds a reference in the adfc-config.xml file to the source file for the newly created unbounded task flow. In Example 24–17, adfc-unbounded_tflow.xml is the name of the source file for a newly created unbounded task flow.

**Example 24–17  Unbounded task flow referenced by adfc-config.xml**

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2"
 id="__1">
 <metadata-resource id="__2">
  /WEB-INF/adfc-unbounded_tflow.xml
 </metadata-resource>
</adfc-config>
```

For more information about adfc-config.xml, see Section A.9, "adfc-config.xml."

At runtime, the Fusion web application loads the adfc-config.xml file when it first starts. The adfc-config.xml file can contain:

- ADF navigation metadata for an unbounded task flow
- ADF activity metadata for an unbounded task flow
- Managed bean definitions used by ADF activities

#### XMLMenuModel Metadata File

JDeveloper generates an XMLMenuModel metadata file with nodes for each of the view activities that you added to the unbounded task flow, as illustrated in Example 24–4.

**Example 24–18  Example XMLMenuModel Metadata File**

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<menu xmlns="http://myfaces.apache.org/trinidad/menu">
 <groupNode id="groupNode_benefits" label="Benefits" idref="itemNode_medical">
  <itemNode id="itemNode_medical" label="label_medical" actions="adfMenu_medical" focusViewId="/medical"/>
  <itemNode id="itemNode_dental" label="label_dental" action="adfMenu_dental" focusViewId="/dental"/>
  <itemNode id="itemNode_vision" label="label_vision" action="adfMenu_vision" focusViewId="/vision"/>
 </groupNode>
</menu>
```
Diagram for an Unbounded Task Flow

JDeveloper updates the file for the unbounded task flow with the control flow rules and managed beans used to navigate the page hierarchy. Figure 24–23 shows the updated unbounded task flow in the diagrammer that corresponds to the unbounded task flow in Figure 24–22.

Figure 24–23  Updated Unbounded Task Flow
This chapter describes how to create dialogs in your Fusion web application. It describes how you can use ADF Controller and task flows to create dialogs or, alternatively, use the ADF Faces dialog framework. This chapter includes the following sections:

- Section 25.1, "About Using Dialogs in Your Application"
- Section 25.2, "Running a Bounded Task Flow in a Modal Dialog"
- Section 25.3, "Using the ADF Faces Dialog Framework Instead of Bounded Task Flows"

25.1 About Using Dialogs in Your Application

Use dialogs if you want to show information to end users in a secondary browser window external to the browser window that displays the end user’s current page. For example, you want to display help information to end users to assist them with a task in the primary browser window or you want end users to choose a value from a list of values. The help information example is a use case where a modeless dialog is appropriate. A modeless dialog allows end users work in both the primary window and the dialog at the same time. For the use case where you want an end user to choose a value, a modal dialog is more appropriate. A modal dialog prevents an end user accessing the page that invoked the dialog until they execute an action requested by the dialog (for example, choose a value).

Use the ADF Faces dialog framework if you want to configure modeless dialogs for your end users. If you plan to configure modal dialogs for your end users, configure an ADF Controller bounded task flow to invoke one or more dialogs.

25.1.1 Using Dialogs in Your Application Use Cases and Examples

Section 25.2, "Running a Bounded Task Flow in a Modal Dialog" describes how you can run a bounded task flow in a modal dialog to retrieve input from an end user, and return to a view activity that called the bounded task with the retrieved input. If your application does not use ADF Controller task flows or you want to use modeless dialogs, Section 25.3, "Using the ADF Faces Dialog Framework Instead of Bounded Task Flows," describes how you can use the ADF Faces dialog framework to render one or more pages in a dialog.

25.1.2 Additional Functionality for Using Dialogs in Your Application

You may find it helpful to understand other Oracle ADF features before you configure or use dialogs in your application. Additionally, you may want to read about what you
can do with the dialogs you configure. Following are links to other functionality that may be of interest.

- If your application uses ADF Controller task flows, you may find it helpful to understand more about the features that task flows offer. For more information, see Chapter 20, "Getting Started with ADF Task Flows."

- For more information about ADF Faces components, see Developing Web User Interfaces with Oracle ADF Faces.

- You can also write custom code for your dialogs using the APIs provided by Oracle ADF. Make sure when you write custom code that you do not import packages that are marked internal, as in this example:

  ```java
  import oracle.adfinternal.controller.*;
  ```

  For information about the APIs that you can use to write custom code, see the following reference documents:

  - Java API Reference for Oracle ADF Controller
  - Java API Reference for Oracle ADF Faces

### 25.2 Running a Bounded Task Flow in a Modal Dialog

You can configure a bounded task flow to run in a modal dialog, retrieve input from an end user, and return to the view activity that called the bounded task flow with the retrieved input. The bounded task flow that you configure must reference pages, not page fragments.

Figure 25–1 shows an example of the configuration required from the Summit sample application for ADF task flows. The task flow in create-edit-orders-task-flow-definition contains a view activity (Orders) from where the end user invokes the orders-select-many-items.xml task flow that renders a modal dialog. For more information, see Section 25.2.1, "How to Run a Bounded Task Flow in a Modal Dialog."

When the end user closes the dialog, control and any modified values return to the launch page in the calling task flow in create-edit-orders-task-flow-definition. For more information, see Section 25.2.2, "How to Return a Value From a Modal Dialog."

In addition, you can configure the application to refresh part of the launch page after the modal dialog returns control. For more information, see Section 25.2.3, "How to Refresh a Page After a Modal Dialog Returns."
25.2.1 How to Run a Bounded Task Flow in a Modal Dialog

You add a view activity and a task flow call activity to an existing task flow. The view activity invokes a page where an end user can invoke an action that, in turn, invokes the bounded task flow to appear in a modal dialog.

Before you begin:
It may be helpful to have an understanding of how the attributes you configure affect the functionality of a bounded task flow in a modal dialog. For more information, see Section 25.2, "Running a Bounded Task Flow in a Modal Dialog."
Running a Bounded Task Flow in a Modal Dialog

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 25.1.2, "Additional Functionality for Using Dialogs in Your Application."

To run a bounded task flow in a modal dialog box:
1. In the Applications window, double-click the existing task flow.
2. In the diagram for the task flow, double-click the view activity to open the associated page.
3. Select the command component that the end user clicks at runtime to invoke the bounded task flow as a modal dialog box (for example, a button component).
4. In the Properties window, expand the Common section and enter the control flow case to invoke the bounded task flow in the Action field.
   For example, selectmultipleitems in Figure 25–1.
5. From the UseWindow dropdown list, select true to invoke the bounded task flow in a popup dialog.
6. In the diagram for the existing task flow, select the task flow call activity.
7. In the Properties window, expand the Behavior section and select true from the Run As Dialog dropdown list to run the bounded task flow as a dialog.
   The bounded task flow that the task flow activity calls can now behave as a dialog; it can be invoked by the command component you configured in Steps 3 to 5 and can return a value to the view activity that renders the command component, as described in Section 25.2.2, "How to Return a Value From a Modal Dialog." Note that you need to make these other changes to run a bounded task flow in a modal dialog. Setting the run-as-dialog attribute to true is not sufficient.
8. Select external-window (the default value) from the Display Type dropdown list if you want to render the dialog in an external browser window or inline-popup if you want to render the dialog in the same browser window.

25.2.2 How to Return a Value From a Modal Dialog

You can configure a bounded task flow that renders in a modal dialog to return a value to the view activity that invoked the bounded task flow when the end user dismisses the modal dialog. The returned value can, for example, be displayed in an input component on the page associated with the view activity.

You must configure the bounded task flow that is called by the task flow call activity to declare input parameters and return values. For more information, see Section 22.3, "Passing Parameters to a Bounded Task Flow."

You specify a method binding for a method with one argument (a return event) as the value for the returnListener attribute of the command component (for example, a button component). The returnListener attribute sets this value in the input component on the page associated with the view activity. Specify a backing bean for the input component and set the input component’s partialTrigger attribute to the ID of the command component.

You also need to specify:
- A return value definition on the called bounded task flow to indicate where to take the return value from upon exit of the called bounded task flow.
- Return values on the task flow call activity in the existing task flow to indicate where the existing task flow can find return values.
For more information, see Section 22.4, "Configuring a Return Value from a Bounded Task Flow."

For more information about creating backing beans, input components, and command components, see the "Using Input Components and Defining Forms" chapter in Developing Web User Interfaces with Oracle ADF Faces.

Before you begin:
It may be helpful to have an understanding of how the attributes you configure affect the functionality of bounded task flows in modal dialogs. For more information, see Section 25.2, "Running a Bounded Task Flow in a Modal Dialog."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 25.1.2, "Additional Functionality for Using Dialogs in Your Application."

You will need to complete this task:
Configure a bounded task flow to run in a modal dialog. For more information, see Section 25.2.1, "How to Run a Bounded Task Flow in a Modal Dialog."

To specify a return value:
1. In the Applications window, double-click the task flow that contains the task flow call activity to invoke the bounded task flow to render in a modal dialog.

2. In the diagram editor, select the task flow call activity.

3. In the Properties window, expand the Behavior section and select true from the Run As Dialog dropdown list.

4. In the Dialog Return Value field, enter the name of the return value definition you specified for the target bounded task flow.

   For information about how to specify the return value definition on a bounded task flow, see Section 22.4, "Configuring a Return Value from a Bounded Task Flow."

5. In the Applications window, double-click the page that launches the modal dialog.

6. In the design editor, select the input component and, in the Properties window, expand the Behavior section to specify an EL expression in the PartialTriggers field.

   The EL expression you specify identifies the command component, accepts the return value of the command component, and specifies a backing bean. For example, enter an EL expression with syntax similar to the following:
   
   #{pageFlowScope.backingBean.gotoModalDialog}

   where gotoModalDialog identifies the command component.

7. In the design editor, select the command component and, in the Properties window, expand the Behavior section and enter an EL expression that references a return listener method in the page's backing bean as a value in the ReturnListener field.

   The return listener method you specify processes the return event that is generated when an end user dismisses the modal dialog. In the Summit ADF task flow sample application, the command component in the Orders.jsff page fragment specifies the following EL expression:

   #{viewScope.OrdersBackingBean.onShuttleTaskFlowReturn}
25.2.3 How to Refresh a Page After a Modal Dialog Returns

You can configure the page from where end users invoke a modal dialog to refresh after end users close the modal dialog. You may want to configure this behavior if the modal dialog returns a value or end users edit existing data in the page through controls in the modal dialog.

You implement this functionality by configuring the command component that invokes the modal dialog to listen for a return event. When it receives the return event, it invokes a backing bean method that executes a partial page render event on your page. Example 25–1 shows a button component that invokes a modal dialog and listens for a return event.

Example 25–1 ReturnListener Attribute Referencing a Backing Bean Method

```xml
<af:button text="Edit"
    id="b1" binding="#{backingBeanScope.backing_launch_page.b1}"
    action="edit" useWindow="true"
    returnListener="#{backingBeanScope.backing_launch_page.backFromPopup}"/>
```

The button component’s returnListener attributes listens for the return event from invoking the modal dialog. When it receives the return event, it invokes a backing bean method similar to Example 25–2:

Example 25–2 Backing Bean Method to Invoke a Partial Page Event

```java
public void backFromPopup(ReturnEvent returnEvent) {
    AdfFacesContext adfFacesContext;
    adfFacesContext = AdfFacesContext.getCurrentInstance();
    adfFacesContext.addPartialTarget(this.getF1());
}
```

The backing bean method (backFromPopup) takes the return event as an argument and, in our example, invokes a partial page render event on a form in the page.

Before you begin:

It may be helpful to have an understanding of how you configure other options for modal dialogs that you invoke from a page associated with a view activity in a task flow. For more information, see Section 25.2, "Running a Bounded Task Flow in a Modal Dialog."

You may also find it helpful to understand other functionality that can be added using other task flow and dialog framework features. For more information, see Section 25.1.1, "Using Dialogs in Your Application Use Cases and Examples."

To refresh a page after a modal dialog returns:

1. In the Applications window, double-click the task flow that invokes the bounded task flow that renders in a modal dialog.
2. In the diagram, double-click the view activity that references the page where your end user invokes a command component to launch the modal dialog.
3. In the design editor, select the command component.
4. In the Properties window, expand the Behavior section and, from the ReturnListener field under the Secondary Window label, select Edit from the icon that appears when you hover over the property field to specify the name of the backing bean method that you want JDeveloper to generate.
5. In the Edit Property: ReturnListener dialog, click **New** beside the **Managed Bean** field.

6. In the Create Managed Bean dialog, name the bean and the class, set the bean’s scope, and click **OK**.

7. In the Edit Property: ReturnListener dialog, click **New** beside the **Method** field.

8. In the Create Method dialog, name the method and click **OK**.

9. In the Edit Property: ReturnListener dialog, click **OK**.

10. In the Applications window, expand **Application Sources** and then expand the package that contains the backing bean class and method that you created in Steps 3 to 9.

11. Write a method body similar to **Example 25–2** to invoke a partial page render event on your page.

### 25.2.4 What You May Need to Know About Dialogs in an Application that Uses Task Flows

If your Fusion web application renders modeless dialogs (non modal dialogs without task flows) and also uses ADF Controller features, such as task flows, you specify the `dialog:syntax` in the control flow rules of the application’s adfc-config.xml file rather than the faces-config.xml file. Specify `dialog:syntax` in navigation rules within the faces-config.xml file if your Fusion web application does not use ADF Controller features, as described in Section 25.3, "Using the ADF Faces Dialog Framework Instead of Bounded Task Flows."

**Example 25–3** shows an example of what you can specify in the adfc-config.xml file.

#### Example 25–3  adfc-config.xml file with dialog:syntax

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2" id="__ 1">
  <view id="view1"
       <page>/view1.jsf</page>
  </view>
  <view id="dialog">
    <page>/dialog/untitled1.jsf</page>
  </view>
  <control-flow-rule>
    <from-activity-id>test</from-activity-id>
    <control-flow-case>
      <from-outcome>dialog:test</from-outcome>
      <to-activity-id>dialog</to-activity-id>
    </control-flow-case>
  </control-flow-rule>
</adfc-config>
```

### 25.3 Using the ADF Faces Dialog Framework Instead of Bounded Task Flows

You can use the ADF Faces dialog framework to create modal and modeless dialogs in an application that does not use ADF Controller and task flows. The dialog framework enables you to display a page or series of pages in a new browser window instead of displaying it in the same window (using the same view ID) as the current page. There
Using the ADF Faces Dialog Framework Instead of Bounded Task Flows

may also be cases where you want to use a series of inline dialogs, that is, dialogs that are part of the parent page, but that have a flow of their own, but that do not use a separate view ID. This is important for applications that do not support popups such as, for example, applications that run on client devices or that use the Active Data Service described in Chapter 47, "Using the Active Data Service." Ordinarily, you would need to use JavaScript to open the dialog and manage the process. With the dialog framework, ADF Faces makes it easy to open a new browser window as well as manage dialogs and processes without using JavaScript.

**Note:** If your application uses the Fusion technology stack with ADF Controller, then you should use task flows to create dialogs launched in a separate window, or multiple dialog processes. For more information, see Section 25.2, "Running a Bounded Task Flow in a Modal Dialog."

Consider a simple application that requires users to log in to see their orders. Figure 25–2 shows the page flow for the application, which consists of five pages: login.jspx, orders.jspx, new_account.jspx, account_details.jspx, and error.jspx.

![Figure 25–2 Page Flow of an External Dialog Sample Application](image)

When an existing user logs in successfully, the application displays the Orders page, which shows the user's orders, if any. When a user does not log in successfully, the Error page displays in a separate popup dialog window, as shown in Figure 25–3.
Using the ADF Faces Dialog Framework Instead of Bounded Task Flows

**Figure 25–3  Error Page Popup**

![Error Page Popup](image)

Error

You have entered an incorrect username or password. Please try again or register a new user account.

* Username
* Password

Cancel

On the Error page there is a Cancel button. When the user clicks Cancel, the popup dialog closes and the application returns to the Login page and the original flow, as shown in Figure 25–4.

**Figure 25–4  Login Page**

![Login Page](image)

Login Page

* Username
* Password

Log in  New user?

When a new user clicks the New User link on the Login page, the New Account page displays in a popup dialog in a new window, as shown in Figure 25–5.
Using the ADF Faces Dialog Framework Instead of Bounded Task Flows

Figure 25–5  New Account Page in a Separate Window

![New Account Page in a Separate Window](image)

After entering information such as first name and last name, the user then clicks the Details button to display the Account Details page in the same popup dialog, as shown in Figure 25–6. In the Account Details page, the user enters other information and confirms a password for the new login account. There are two buttons on the Account Details page: Cancel and Done.

Figure 25–6  Account Details Page in a Popup Dialog

![Account Details Page in a Popup Dialog](image)

If the new user decides not to proceed with creating a new login account and clicks Cancel, the popup dialog closes and the application returns to the Login page. If the new user clicks Done, the popup dialog closes and the application returns to the Login page where the Username field is now populated with the user’s first name, as shown in Figure 25–7. The new user can then proceed to enter the new password and log in successfully.
Using the ADF Faces Dialog Framework Instead of Bounded Task Flows

Figure 25–7 LogIn Page with Username Field Populated

Login Page

* Username: Jane
* Password

Log in New user?

Note: The dialog framework should not be used to have more than one dialog open at a time, or to launch dialogs that have a life span outside of the life span of the base page.

To make it easy to support dialog page flows in your applications, ADF Faces has built in the dialog functionality to action components (such as commandMenuItem and button). For ADF Faces to know whether or not to open a page in a new flow from an action component, the following conditions must exist:

- There must be a JSF navigation rule with an outcome that begins with dialog:
- The command component’s action outcome must begin with dialog:
- The useWindow attribute on the command component must be true.

Note: If the useWindow attribute is false, or if you configure the popup to be a separate window (and not inline) and the client device does not support popups, ADF Faces automatically shows the page in the current window instead of using a popup window; code changes are not required to facilitate this action.

The page that displays in a dialog is an ordinary JSF page, but for purposes of explaining how to implement external dialogs in this chapter, a page that displays in a popup dialog is called the dialog page, and a page from which the dialog is opened is called the originating page. A dialog process starts when the originating page opens a dialog (which can contain one dialog page or a series of dialog pages), and ends when the user dismisses the dialog and returns to the originating page.

To create a dialog page flow in an application:

1. Define a JSF navigation rule for opening a dialog.
2. Create the JSF page from which a dialog is opened.
3. Create the dialog page and return a dialog value.
4. Optional: Pass a value into a dialog.
5. Handle the return value.

The tasks can be performed in any order.

25.3.1 How to Define a JSF Navigation Rule for Opening a Dialog

You manage the navigation into a dialog flow by defining a standard JSF navigation rule with a special dialog: outcome.
To define a navigation rule to open a dialog:

1. In the Applications window, expand the WEB-INF node and double-click `adfc-config.xml`.

2. In the diagram editor, create a page flow for your originating page and dialog pages.
   
   For more information, see Section 20.4.1, "How to Add a Control Flow Rule to a Task Flow."

3. When creating navigation rules to the dialog pages, the outcome must begin with `dialog:`. For example, in the login sample application shown in Figure 25–2, the outcome from the Login page to the New Account dialog page is `dialog:newAccount`.

At runtime, the dialog navigation rules on their own simply show the specified pages in the originating page. But when used with command components with `dialog:` action outcomes and with `useWindow` attributes set to `true`, ADF Faces opens the pages in dialogs.

25.3.2 How to Create the JSF Page That Opens a Dialog

In the originating page, you need to use a command component to launch the dialog. The command component’s action value needs to be the outcome to the dialog that is to be launched.

Before you begin:

It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see Section 25.1, "About Using Dialogs in Your Application."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 25.1.2, "Additional Functionality for Using Dialogs in Your Application."

You will need to complete this task:

You also need to create the JSF page that opens a dialog. For more information, see the "Creating a View Page" section in Developing Web User Interfaces with Oracle ADF Faces.

To create the JSF Page that opens a dialog:

1. In the Applications window, double-click the JSF page.

2. In the ADF Faces page of the Components window, from the General Controls panel, drag and drop a command component (for example, a Button) onto the JSF page.

   For more information about adding a command component to a page, see the "Using Buttons and Links for Navigation" section in Developing Web User Interfaces with Oracle ADF Faces.

   Note the following when setting the attributes on the command component:

   - **Action**: Set the action attribute to the outcome that navigates to the dialog, as created in Section 25.3.1, "How to Define a JSF Navigation Rule for Opening a Dialog."

     **Tip**: The action value can be either a static string or the return of a method on a managed bean.
For example, the action attribute on the command component of the Login page is bound to a method that determines whether to navigate to the Orders page or to the Error dialog page, based on the returned outcome. If the method returns `dialog:error`, the error dialog opens. If the method returns `success`, the user navigates to the Orders page.

- **ActionListener**: As an alternative to setting the action attribute, configure the `actionListener` attribute to invoke the `launchDialog` method from an instance of the following class:

  ```java
  oracle.adf.view.rich.context.AdfFacesContext
  ```

  For more information about the `launchDialog` method and the `AdfFacesContext` class, see the Java API Reference for Oracle ADF Faces.

- **UseWindow**: Set to `true` to have the dialog open.

  **Tip**: When set to `false`, ADF Faces shows the dialog page in the current window after preserving all of the state of the current page. You do not have to write any code to facilitate this.

- **WindowHeight** and **WindowWidth**: Set the desired size of the dialog window. These values will set the `contentWidth` and `contentHeight` attributes on the popup component for the dialog.

  **Tip**: While the user can change the values of these attributes at runtime, the values will not be retained once the user leaves the page unless you configure your application to use change persistence. For information about enabling and using change persistence, see the "Allowing User Customization on JSF Pages" chapter in Developing Web User Interfaces with Oracle ADF Faces.

- **PartialSubmit**: Set to `true`. This prevents the originating page from reloading (and hence being visible only momentarily) when the popup dialog is displayed.

- **WindowEmbedStyle**: Set to `inlineDocument` if you want the dialog to open in a popup that belongs to the originating page. Set to `window` if you want the dialog to open in a separate browser.

- **WindowModalityType**: Set to `applicationModal` if you want the dialog to be modal. Modal dialogs do not allow the user to return to the originating page until the dialog has been dismissed. Set to `modeless` if you want the user to be able to go back and forth between the originating page and the dialog.

When a command component is about to open a dialog, it delivers a `LaunchEvent` event. The `LaunchEvent` event stores information about the component that is responsible for opening a popup dialog, and the root of the component tree to display when the dialog process starts. A `LaunchEvent` can also pass a map of parameters into the dialog. For more information, see Section 25.3.5, "How to Pass a Value into a Dialog."

### 25.3.3 How to Create the Dialog Page and Return a Dialog Value

A dialog page is just like any other JSF page, with one exception. In a dialog page, you must provide a way to tell ADF Faces when the dialog process finishes, that is, when the user dismisses the dialog or series of dialogs.
For example, the New Account page and Account Details page belong in the same dialog process. A dialog process can have as many pages as you desire, you only need to notify the framework that the dialog process has ended once.

You do this declaratively using the returnActionListener tag as a child to the command component used to close the dialog. However, if you need to provide a return value or other action event processing, you can bind the actionListener attribute on the command component to a method that calls the AdfFacesContext.returnFromDialog() method. This method lets you send back a return value in the form of a java.lang.Object or a java.util.Map of parameters. You do not have to know where you are returning the value to - ADF Faces automatically takes care of it.

At runtime, the AdfFacesContext.returnFromDialog() method tells ADF Faces when the user dismisses the dialog. This method can be called whether the dialog page is shown in a popup dialog or in the main window. If a popup dialog is used, ADF Faces automatically closes it.

Before you begin:
It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see Section 25.1, "About Using Dialogs in Your Application."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 25.1.2, "Additional Functionality for Using Dialogs in Your Application."

To close a dialog window and optionally return a value:
1. In the Applications window, double-click the dialog page.

2. In the ADF Faces page of the Components window, from the General Controls panel, drag and drop a command component (for example, a Button) onto the dialog page.

   For more information about adding a command component to a page, see the "Using Buttons and Links for Navigation" section in Developing Web User Interfaces with Oracle ADF Faces.

3. If the command component will be used to close the window, in the Properties window, expand the Behavior section and select true from the Immediate dropdown list.

4. If the command component will be used to navigate to another page in the dialog process, configure the command component as though it were standard navigation. To do this, in the Properties window, expand the Common section and select false from the UseWindow dropdown list. This causes the next page to display in the same dialog window, preserving the state of the previous page.

5. If you need to end the dialog process and close the dialog, but do not need to return a value, in the Components window, from the Operations panel, in the Listeners group, drag a Return Action Listener and drop it as a child to the command component.

   The returnActionListener tag calls the returnFromDialog method on the AdfFacesContext object - no backing bean code is needed.

   No attributes are used with the af:returnActionListener tag. The immediate attribute on the af:button component is set to true if the user clicks Cancel without entering values in the required Password and Confirm Password fields, the default JSF ActionListener can execute during the Apply
Using the ADF Faces Dialog Framework Instead of Bounded Task Flows

Using Dialogs in Your Application

Request Values phase instead of the Invoke Application phase, thus bypassing input validation. For more information, see the "Using the JSF Lifecycle with ADF Faces" chapter in Developing Web User Interfaces with Oracle ADF Faces.

6. If you need to end the dialog process and do need to return a value, create a method on a managed bean that handles the action event and returns the needed values using the returnFromDialog method on the current instance of AdfFacesContext.

**Note:** The AdfFacesContext.returnFromDialog() method returns null. This is all that is needed in the backing bean to handle the Cancel action event.

For example, when the user clicks Done on the Account Details page, the process ends and returns the user input values. Example 25–4 shows the code for the event handler method to which the Done button binds. The method gets the customer information, then either creates a Faces message for an incorrect password, or sets the values on the new customer object and return that object.

**Example 25–4 Action Listener Method for the Done Button in a Managed Bean**

```java
public void done(ActionEvent e)
{
    AdfFacesContext afContext = AdfFacesContext.getCurrentInstance();
    String firstname = afContext.getPageFlowScope().get("firstname").toString();
    String lastname = afContext.getPageFlowScope().get("lastname").toString();
    String street = afContext.getPageFlowScope().get("street").toString();
    String zipCode = afContext.getPageFlowScope().get("zipCode").toString();
    String country = afContext.getPageFlowScope().get("country").toString();
    String password = afContext.getPageFlowScope().get("password").toString();
    String confirmPassword = afContext.getPageFlowScope().get("confirmPassword").toString();
    if (!password.equals(confirmPassword))
    {
        FacesMessage fm = new FacesMessage();
        fm.setSummary("Confirm Password");
        fm.setDetail("You've entered an incorrect password. Please verify that you've entered a correct password!");
        FacesContext.getCurrentInstance().addMessage(null, fm);
    }
    else
    {
        //Get the return value
        Customer cst = new Customer();
        cst.setFirstName(firstname);
        cst.setLastName(lastname);
        cst.setStreet(street);
        cst.setPostalCode(zipCode);
        cst.setCountry(country);
        cst.setPassword(password);
        // And return it
        afContext.getCurrentInstance().returnFromDialog(cst, null);
    }
}
```
25.3.4 What Happens at Runtime: How to Raise the Return Event from the Dialog

When the dialog is dismissed, ADF Faces generates a return event (ReturnEvent). The AdfFacesContext.returnFromDialog() method sends a return value as a property of the return event. The return event is delivered to the return listener (ReturnListener) that is registered on the command component that opened the dialog (for example, the New User link on the Login page). How you handle the return value is described in Section 25.3.7, "How to Handle the Return Value."

25.3.5 How to Pass a Value into a Dialog

To pass a value into a dialog, you use a LaunchListener listener bound to a handler method for the LaunchEvent. You can use the getDialogParameters() method to add a parameter to a Map using a key-value pair.

Before you begin:
It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see Section 25.1, "About Using Dialogs in Your Application."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 25.1.2, "Additional Functionality for Using Dialogs in Your Application."

To pass a value into a dialog:

1. In the Applications window, double-click the JSF page that contains the command component used to navigate to the dialog page.
2. In the design editor, select the command component used to navigate to the dialog page.
3. In the Properties window, expand the Behavior section.
4. From the icon that appears when you hover over the LaunchListener property field, select Edit.
5. In the Edit Property: LaunchListener dialog, click New beside the Managed Bean field.
6. In the Create Managed Bean dialog, name the bean and the class, set the bean’s scope, and click OK.
7. In the Edit Property: LaunchListener dialog, click New beside the Method field.
8. In the Create Method dialog, name the method and click OK and click OK to close the Edit Property: LaunchListener dialog.
9. In the Applications window, expand Application Sources and then expand the package that contains the bean class and method that you created in Steps 3 to 8.
10. In the source editor, write a handler method for the LaunchEvent that uses the getDialogParameters method to get the parameters from a dialog.

For example, in the sample application, a new user can enter a name in the Username field on the Login page, and then click the New User? link. When the New Account dialog page displays in a popup dialog, the First Name input field is automatically populated with the name that was entered in the Login page. To accomplish this, you create a handler that uses the getDialogParameters method to put the value of the username field into the dialog, as shown in Example 25–5.
Example 25–5  LaunchEvent Listener Method for the New User Link in a Backing Bean

```java
public void handleLaunch(LaunchEvent event)
{
    //Pass the current value of the field into the dialog
    Object usr = username;
    event.getDialogParameters().put("firstname", getUsername());
}

// Use by inputText value binding
private String username;
public String getUsername()
{
    return username;
}
public void setUsername(String username)
{
    this.username = username;
}
```

11. In the Applications window, double-click the dialog page.

12. On the dialog page, use the `pageFlowScope` object to retrieve the key and value via a special EL expression in the format `#{pageFlowScope.someKey}`, as shown in Example 25–6

Example 25–6  Input Field on the New Account Page

```xml
<af:inputText label="First name" value="#{pageFlowScope.firstname}"/>
```

25.3.6 What Happens at Runtime: How the LaunchEvent is Handled

In ADF Faces, a process always gets a copy of all the values that are in the `pageFlowScope` of the page from which a dialog is launched. When the `getDialogParameters()` method has added parameters to a `Map`, those parameters also become available in `pageFlowScope`, and any page in the dialog process can get the values out of `pageFlowScope` by referring to the `pageFlowScope` objects via EL expressions.

---

**Note:** Unlike `sessionScope`, `pageFlowScope` values are visible only in the current page flow or process. If the user opens a new window and starts navigating, that series of windows has its own process; values stored in each window remain independent. Clicking on the browser's Back button automatically resets `pageFlowScope` to its original state. When you return from a process the `pageFlowScope` is back to the way it was before the process started. To pass values out of a process you use `AdfFacesContext.returnFromDialog()`, `sessionScope` or `applicationScope`.

---

25.3.7 How to Handle the Return Value

To handle a return value once the dialog is dismissed, you define a return listener on the command component that launched the dialog. For example, in the sample application, once a new user enters information, that information needs to be handled once the dialog process is complete.
Before you begin:
It may be helpful to have an understanding of how the attributes you configure affect the functionality of the ADF Faces dialog framework. For more information, see Section 25.1, “About Using Dialogs in Your Application.”

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 25.1.2, “Additional Functionality for Using Dialogs in Your Application.”

To handle the return value:
1. In the Applications window, double-click the JSF page that contains the command component used to navigate to the dialog page.
2. In the design editor, select the command component used to navigate to the dialog page.
3. In the Properties window, expand the Behavior section.
4. From the icon that appears when you hover over the ReturnListener property field, select Edit.
5. In the Edit Property: ReturnListener dialog, click New beside the Managed Bean field.
6. In the Create Managed Bean dialog, name the bean and the class, set the bean’s scope, and click OK.
7. In the Edit Property: ReturnListener dialog, click New beside the Method field.
8. In the Create Method dialog, name the method and click OK and click OK to close the Edit Property: LaunchListener dialog.
9. In the Applications window, expand Application Sources and then expand the package that contains the bean class and method that you created in Steps 3 to 8.
10. In the source editor, write a handler method for the returnEvent. You use the getReturnValue() method to retrieve the return value, because the return value is automatically added as a property of the ReturnEvent.

Example 25–7 shows the code for the return listener method that handles the return value.

Example 25–7  Return Listener Method for the New User Link in a Backing Bean

```java
public void handleReturn(ReturnEvent event) {
    if (event.getReturnValue() != null) {
        Customer cst;
        String name;
        String psw;
        cst = (Customer)event.getReturnValue();
        name = cst.getFirstName();
        psw = cst.getPassword();
        CustomerList.getCustomers().add(cst);
        inputText1.setSubmittedValue(null);
        inputText1.setValue(name);
        inputText2.setSubmittedValue(null);
        inputText2.setValue(psw);
    }
}
```
25.3.8 What Happens at Runtime: How the Launching Component Handles the ReturnEvent

At runtime in the sample application, when ADF Faces delivers a ReturnEvent to the ReturnListener registered on the link component, the handleReturn() method is called and the return value is processed accordingly. The new user is added to a customer list, and as a convenience to the user any previously submitted values in the Login page are cleared and the input fields are populated with the new information.
Part V contains the following chapters:

- Chapter 26, "Getting Started with Your Web Interface"
- Chapter 27, "Understanding the Fusion Page Lifecycle"
- Chapter 28, "Creating a Basic Databound Page"
- Chapter 29, "Creating ADF Databound Tables"
- Chapter 30, "Using Command Components to Invoke Functionality in the View Layer"
- Chapter 31, "Displaying Master-Detail Data"
- Chapter 32, "Creating Databound Selection Lists and Shuttles"
- Chapter 33, "Creating ADF Databound Search Forms"
- Chapter 34, "Using More Complex Databound ADF Faces Components"
- Chapter 35, "Creating Databound Graph and Gauge Components"
- Chapter 36, "Creating Databound Pivot Table and Pivot Filter Bar Components"
- Chapter 37, "Creating Databound Geographic and Thematic Map Components"
- Chapter 38, "Creating Databound Gantt Chart and Timeline Components"
- Chapter 39, "Creating Databound Hierarchy Viewer, Treemap, and Sunburst Components"
- Chapter 40, "Using Contextual Events"
This chapter describes getting started with ADF data controls to create databound UI components, using ADF Faces components in the Fusion web application. It describes how to use page templates and page fragments to build a page. It also describes how to use managed beans to store logic for the page.

This chapter includes the following sections:

- Section 26.1, "About Developing a Web Application with ADF Faces"
- Section 26.2, "Using Page Templates"
- Section 26.3, "Creating a Web Page"
- Section 26.4, "Using a Managed Bean in a Fusion Web Application"

### 26.1 About Developing a Web Application with ADF Faces

Most of what you need to know to get started with your web interface is covered in Developing Web User Interfaces with Oracle ADF Faces. However, using the ADF Model layer for data binding instead of JSF managed beans provides additional functionality, such as the ability to declaratively bind components to your business services. For more information on what ADF Model can provide, see Chapter 17, "Using ADF Model in a Fusion Web Application."

This chapter provides a high-level overview of the web interface development process as detailed in the Faces guide, and also provides information about the additional functionality available when you use ADF Model data binding.

Following the development process outlined in Chapter 1, "Introduction to Building Fusion Web Applications with Oracle ADF", developing a web application with ADF Faces and using ADF Model for data binding involves the following steps:

- Creating ADF Faces templates for your pages (optional)
- Creating the individual pages and page fragments for regions to be used within a page
- Creating any needed managed beans

Additionally, the lifecycle of a Fusion web application is different from that of a standard JSF or ADF Faces application. For more information about how the lifecycle works, see Chapter 27, "Understanding the Fusion Page Lifecycle."

Managed beans are Java classes that give you the flexibility to add UI level code to your pages and task flows. You can use them for functions such as front end data manipulation and event handling.
ADF Faces page templates provides structure, consistency, and reusability for building web pages. You can create a page template and apply it to several pages for a consistent look and feel. It saves you time and effort because you do not need to layout the same elements each time you create a page.

### 26.1.1 Page Template and Managed Beans Use Cases and Examples

In the `create-edit-orders-task-flow-definition`, the `ShuttleBean` is used for code to support a shuttle component to shuttle the available products from the leading list to the selected products in the trailing list. The managed bean contains the code necessary to populate the available products list and the selected products list. Figure 26–1 shows the managed beans used in the `create-edit-orders-task-flow-definition`.

![Figure 26–1 Managed Beans in the create-edit-orders-task-flow-definition](image)

### 26.1.2 Additional Functionality for Page Templates and Managed Beans

You may find it helpful to understand other Oracle ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- For more information about using page templates, see Chapter 17, "Using ADF Model in a Fusion Web Application," and the "How to Create a Page Template" section of Developing Web User Interfaces with Oracle ADF Faces.

- For more information about managed beans in a standard JSF application, see the Java EE tutorial on the Oracle Technology Network website (http://www.oracle.com/technetwork/java/javaee/overview/index.html). For more information about managed beans and scope values, see Section 27.3, "About Object Scope Lifecycles."

### 26.2 Using Page Templates

As you design the flow of your application, you can begin to think about the design of your pages. To ensure consistency throughout your application, you use ADF page templates. These page templates provide structure and consistency for other developers building web pages. Page templates typically contain static areas which cannot be changed when they are used, and dynamic areas, where developers can place content specific to the page they are building.
For example, a page template can provide a top area for branding and navigation, a bottom area for copyright information, and a center area for the main content of the page. Page developers do not need to do anything to the branding and copyright information when they use the template. They need only to develop the main content area.

In addition to using ADF Faces components to build a page template, you can add attributes to the template definition. These attributes provide placeholders for specific information that the page developer needs to provide when using the page template. For instance, if you have added an attribute for a welcome message and when page developers use this page template, they can add a different welcome message for each page.

You can also add facet references to the page template. These references act as placeholders for content on the page. Figure 26–2 shows a rendition of how facets can be used in a page template.

![Facets in the Page Template](image)

In this page template, facet references are used inside four different `panelSplitter` components. When the home page was created using this page template, the navigational links were placed in the Header facet and the accordion panels that hold the navigation trees and search panels were placed in the Start facet. The cart summary was placed in the End facet, and the main portion of the page was placed in the Center facet. The copyright information was placed in the Bottom facet.

When you choose to add databound components to a page template, an associated page definition file and the other metadata files that support ADF Model layer data binding are created. Each component is bound in the same fashion as for standard JSF pages, as described in Chapter 17, "Using ADF Model in a Fusion Web Application." You can also create model parameters for the page template. The values for these parameters can then be set at runtime by the calling page.
For example, if you wanted a list of products to appear on each page that uses the page template, you could drag and drop the Name attribute of the ProductVO collection as a list. Or, if you wanted the pages to display the currently selected product Id, you could create a model parameter for the page template that would evaluate to that product’s Id.

**Note:** Page templates are primarily a project artifact. While they can be reused between projects and applications, they are not fully self-contained and will always have some dependencies to external resources, for example, any ADF data binding, Strings from a message bundle, images, and managed beans.

If a page template does not contain databound components, it can be referenced dynamically by the calling page using an EL expression. That is, the page template to be used can be determined at runtime. For instance, a page may use templateA or templateB based on user selection. When you add a page template to a page, an `af:pageTemplate` tag is added to the page. The `af:pageTemplate` tag includes a `viewId` attribute that specifies the page template the page will use. You can set `viewId` with an EL expression to a managed bean method that returns the page template Id, as shown in Example 26–1.

**Example 26–1 Page with Dynamic Page Template (not Databound Page Template Only)**

```xml
<af:pageTemplate
   id="pt1"
   viewId="#{myBean.templateViewId}'
```

If the page template has databound components, setting the `viewId` with an EL expression is not enough. Because databound components require access to the binding container, you must specify the page template as well as its associated binding container.

For databound page templates, you use the `pageTemplateModel` to manage both the page template Id and the associated binding container. In the JSF page, instead of using the `viewId` attribute, you set the `value` attribute to the `pageTemplateModel`. You must also modify the page executable section of the calling page’s page definition file and create a managed bean with methods to process the page template Ids. For detailed instructions, see Section 26.2.3, "How to Add a Databound Page Template to a Page Dynamically."

### 26.2.1 How to Use ADF Data Binding in ADF Page Templates

Creating a page template for use in an application that uses ADF Business Components and ADF Model layer data binding is the same as creating a standard ADF Faces page template, as documented in the "Using Page Templates" section of *Developing Web User Interfaces with Oracle ADF Faces*. Once you create the template, you can drag and drop items from the Data Controls panel. JDeveloper automatically adds the page definition file when you drag and drop items from this panel.

The Create a Page Template wizard also allows you to create model parameters for use by the template.

**Before you begin:**

It may help to understand the options that are available to you when you create a basic page template. For more information, see Section 26.2, "Using Page Templates."
You may also find it useful to understand additional functionality that can be used with page templates. For more information, see Section 26.1.2, "Additional Functionality for Page Templates and Managed Beans."

You will need to complete this task:

Create a page template that uses ADF Business Components and ADF Model layer data binding by following the instructions in the "How to Create a Page Template" section of Developing Web User Interfaces with Oracle ADF Faces. However, do not complete the dialog.

**To add model parameters to a template:**

1. In the Data Binding page of the Create a Page Template wizard, select **Create Page Definition File**.

   **Note:** You only need to select this checkbox if you wish to add parameters. JDeveloper automatically adds the page definition file when you drag and drop items from the Data Controls panel.

2. Click the **Add** icon.
3. Enter the following for the parameter:
   - **Id:** Enter a name for the parameter.
   - **Value:** Enter a value or an EL expression that can resolve to a value. If needed, click the Invoke Expression Builder (...) button to open the Expression Builder. You can use this to build the expression. For more information about EL expressions and the EL expression builder, see Chapter 17.8, "Creating ADF Data Binding EL Expressions."
   - **Option:** Select the option that determines how the parameter value will be specified.
     - **optional:** The binding definition's value is used only if the parameter is not specifically set by the caller. This is the default.
     - **final:** The binding definition has the expression to access the value that should be used for this parameter.
     - **mandatory:** The parameter value has to be set by the caller.
   - **Read Only:** Select if the parameter's value is to be read-only and should not be overwritten

4. Create more parameters as needed. Use the order buttons to arrange the parameters into the order in which you want them to be evaluated.

You can now use the Data Controls panel to add databound UI components to the page, as you would for a standard JSF page, as described in the remaining chapters in this part of the book.

**Note:** If your template contains any method actions bound to a method iterator, you cannot change the value of the **refresh** attribute on the iterator to anything other than **Default**. If set to anything other than **Default**, the method will not execute.
26.2.2 What Happens When You Use ADF Model Layer Bindings on a Page Template

When you add ADF databound components to a template or create model parameters for a template, a page definition file is created for the template, and any model parameters are added to that file.

---

**Note:** This section describes what happens for a statically assigned page template. For information about dynamic templates, see Section 26.2.3, "How to Add a Databound Page Template to a Page Dynamically."

---

Example 26–2 shows what the page definition file for a template for which you created a productId model parameter might look like.

**Example 26–2  Model Parameters in a Page Definition for a Template**

```xml
<parameters>
  <parameter id="productId" readonly="true" value="#{bindings.productId.inputValue}"/>
</parameters>

<executables/>
<bindings/>
```

Parameter binding objects declare the parameters that the page evaluates at the beginning of a request. For more information about binding objects and the ADF lifecycle, see Chapter 17, "Using ADF Model in a Fusion Web Application." However, since a template itself is never executed, the page that uses the template (the calling page) must access the binding objects created for the template (including parameters or any other type of binding objects created by dragging and dropping objects from the Data Controls panel onto the template).

In order to access the template’s binding objects, the page definition file for the calling page must instantiate the binding container represented by the template’s page definition file. As a result, a reference to the template’s page definition is inserted as an executable into the calling page’s page definition file, as shown in Example 26–3.

**Example 26–3  Reference to Template’s Page Definition as an Executable**

```xml
<executables>
  <page path="oracle.summit.view.pageDefs.MyTemplatePageDef" id="pageTemplateBinding"/>
</executables>
```

In this example, the calling page was built using the MyTemplate template. Because the page definition file for the MyTemplate template appears as an executable for the calling page, when the calling page’s binding container is instantiated, it will in turn instantiate the MyTemplatePageDef’s binding container, thus allowing access to the parameter values or any other databound values.

Because there is an ID for this reference (in this case, pageTemplateBinding), the calling page can have components that are able to access values from the template. When you create a JSF page from a template, instead of you having to repeat the code contained within the template, you can use the af:pageTemplate tag on the calling page. This tag contains the path to the template JSF page.

Additionally, when the template contains any ADF data binding, the value of that tag is the ID set for the calling page’s reference to the template’s page definition, as shown
in Example 26–4. This binding allows the component access to the binding values from the template.

**Example 26–4  Page Template Page Definition Reference**

```xml
<af:pageTemplate viewId="/MyTemplate.jspx" value="#{bindings.pageTemplateBinding}"/>
```

### 26.2.3 How to Add a Databound Page Template to a Page Dynamically

You can dynamically add a page template without databound components by using an EL expression to select the page template. For more information on how to do this, see Section 26.2, "Using Page Templates."

You can also statically add a page template with databound components. For more information on how to do this, see Section 26.2.1, "How to Use ADF Data Binding in ADF Page Templates."

This section describes how to dynamically add a page template with databound components to a page. For more information, see Section 26.2, "Using Page Templates."

You use the `pageTemplateModel` to dynamically manage a page template and its binding container. You use an EL expression in the page definition file to set the page template `id`. You create managed bean methods to return the page template `id`.

**Before you begin:**

It may help to understand the options that are available to you when you create a basic page template. For more information, see Section 26.2, "Using Page Templates."

You may also find it useful to understand additional functionality that can be used with page templates. For more information, see Section 26.1.2, "Additional Functionality for Page Templates and Managed Beans."

You will need to complete this task:

Create a page template that uses ADF Business Components and ADF Model layer data binding as described in Section 26.2.1, "How to Use ADF Data Binding in ADF Page Templates."

**To add a databound page template to a page dynamically:**

1. In the JSF page source editor, remove the `viewId` attribute and change the `value` attribute to the `pageTemplateModel`. You do not need to create a `pageTemplateModel` explicitly. You can use the `pageTemplateModel` from the corresponding page definition file’s page executable binding. For example, for a page executable binding called `pageTemplate1`, you would add the following line under the `af:pageTemplate` tag:

   ```xml
   value="#{bindings.pageTemplate1.templateModel}"/>
   ```

2. In the page definition file `<executable>` section, make the following changes to the `<page>` section:

   - Remove the `path` attribute. It is no longer needed. The `pageTemplateModel` manages databound components’ access to the binding container.
   - Change the `id` attribute to the page executable binding. In this example, it is `pageTemplate1`.
   - Add a `Refresh` attribute and set it to `ifNeeded`.
Using Page Templates

- Add a `viewId` attribute and set it to an EL expression with a managed bean method that returns the current page template id.

For example, for a page executable binding of `pageTemplate1`, the `id` attribute would also be `pageTemplate1`:

```xml
<executables>
  <page id="pageTemplate1">
    <viewId="#{myBean.templateViewId}"
    Refresh="ifNeeded"/>
    ...
  </page>
</executables>
```

3. Create a `pageFlowScope` managed bean with a method that returns the current page template id.

The managed bean code should be similar to that of Example 26–5. In this example, `getTemplateViewId()` obtains the user's page template selection and returns the page template id. `setMDTemplateViewId()` sets the page template to be `MDPageTemplate` and `setPopupTemplateViewId()` sets the page template to be `PopupPageTemplate`.

**Example 26–5 Managed Bean Code to Process Page Templates Dynamically**

```java
public class myClass {
    final private String MDPageTemplate = "/MDPageTemplate.jspx";
    final private String PopupPageTemplate = "/PopupPageTemplate.jspx";
    private String templateViewId;

    public myClass() {
        super();
        templateViewId = MDPageTemplate;
    }
    public String getTemplateViewId() {
        return templateViewId;
    }
    public void setMDTemplateViewId(ActionEvent ae) {
        templateViewId = MDPageTemplate;
    }
    public void setPopupTemplateViewId(ActionEvent ae) {
        templateViewId = PopupPageTemplate;
    }
}
```

26.2.4 What Happens at Runtime: How Pages Use Templates

When a page is created using a template that contains ADF data binding, the following happens:

1. The calling page follows the standard JSF/ADF lifecycle, as documented in Chapter 27, "Understanding the Fusion Page Lifecycle." As the page enters the Restore View phase, the URL for the calling page is sent to the binding context, which finds the corresponding page definition file.

2. During the Initialize Context phase, the binding container for the calling page is created based on the page definition file.

3. During the Prepare Model phase, the page template executable is refreshed. At this point, the binding container for the template is created based on the template’s page definition file, and added to the binding context.
4. The lifecycle continues, with UI components and bindings from both the page and the template being processed.

26.3 Creating a Web Page

You can create pages either by double-clicking a view activity in a task flow or by using the New Gallery. When creating the page (or dropping a view activity onto a task flow), you can choose to create the page as a JSF JSP or as a JSF JSP fragment. JSF fragments provide a simple way to create reusable page content in a project, and are what you use when you wish to use task flows as regions on a page. When you modify a JSF page fragment, the JSF pages that consume the page fragment are automatically updated.

**Note:** Although JDeveloper supports XHTML files to be used in applications that use Facelets, the faces-config.xml and adfc-config.xml diagrammers do not support XHTML. In order to add navigation to these files, you have to manually edit the code by clicking the Source tab.

When you begin adding content to your page, you typically use the Components window and Data Controls panel of JDeveloper. The Components window contains all the ADF Faces components needed to declaratively design your page. Once you have the basic layout components placed on the page, you can then drag and drop items from the Data Controls panel to create ADF Model databound UI components. The remaining chapters in this part of the book explain in detail the different types of databound components and pages you can create using ADF Model data binding.

26.3.1 How to Create a Web Page

You create web pages using the Create JSF Page dialog.

**Before you begin:**
It may be helpful to have an understanding of the different options when creating a page. For more information, see Section 26.3, "Creating a Web Page."

**To create a web page:**
1. In the Applications window, right-click the node (directory) where you would like the page to be saved, and choose New > Page.
2. Complete the Create JSF Page dialog. For help, click Help in the dialog.

For more information on the templates available and what happens when you create the page, see "Creating a View Page" section in Developing Web User Interfaces with Oracle ADF Faces.

26.3.2 What You May Need to Know About Creating Blank Web Pages

When you create a new blank web page, the generated code might differ depending on the type of project you are working in and the tag libraries that have been imported in the project. For example, if you are working in a project created from the Custom Project template and you select the Create Blank Page option in the Create JSF page dialog, the generated code might not include ADF Faces tags as it would under similar circumstances in the UI project of an ADF Fusion Web Application workspace.
If you want to create a page without a pre-defined layout that includes ADF Faces tags, it might be easiest to select the **Copy Quick Start Layout** option in the Create JSF page dialog and select a simple layout. Selecting this option will trigger the importing of the ADF Faces tag library into the project. In addition, any subsequent pages that you create in the project, even those created with the **Create Blank Page** option selected, will use ADF Faces tags.

### 26.3.3 What You May Need to Know About Securing a Web Page

When creating web pages, you should have a plan for how you will apply security to them.

To secure a web page within the ADF Security framework, you actually secure the page’s page definition file. If the page is within a bounded task flow, you secure the bounded task flow (and the security policies applied to that bounded task flow apply to all of the pages within the task flow). If a page is within a bounded task flow, you should **not** apply security policies to the page definition file, as that could enable a user to access the page directly.

For more information on securing web pages, see Section 41.5, "Defining ADF Security Policies."

### 26.4 Using a Managed Bean in a Fusion Web Application

Managed beans are Java classes that you register with the application using various configuration files. When the JSF application starts up, it parses these configuration files, and the beans listed within them are made available. The managed beans can be referenced in an EL expression, allowing access to the beans’ properties and methods. Whenever a managed bean is referenced for the first time and it does not already exist, the Managed Bean Creation Facility instantiates the bean by calling the default constructor method on it. If any properties are also declared, they are populated with the declared default values.

Often, managed beans handle events or some manipulation of data that is best handled at the front end. For a more complete description of how managed beans are used in a standard JSF application, see the Java EE tutorial on the Oracle Technology Network website (http://www.oracle.com/technetwork/java/javaee/overview/index.html).

**Best Practice:** Use managed beans to store logic that is related to the UI rendering only. All application data and processing should be handled by logic in the business layer of the application. Similar to how you store data-related logic in the database using PL/SQL rather than a Java class, the rule of thumb in a Fusion web application is to store business-related logic in the middle tier. This way, you can expose this logic as business service methods, which can then become accessible to the ADF Model layer and be available for data binding.

In an application that uses ADF data binding and ADF task flows, managed beans are registered in different configuration files from those used for a standard JSF application. In a standard JSF application, managed beans are registered in the `faces-config.xml` configuration file. In a Fusion web application, managed beans can be registered in the `faces-config.xml` file, the `adfc-config.xml` file, or a task flow definition file. Which configuration file you use to register a managed bean depends on what will need to access that bean, whether or not it needs to be
customized at runtime, what the bean’s scope is, and in what order all the beans in the application need to be instantiated. Table 26-1 describes how registering a bean in each type of configuration file affects the bean.

**Note:** Fusion web applications take advantage of the functionality provided by ADF task flows. Managed beans accessed within the task flow definition must be registered in that task flow’s definition file and not in the `faces-config.xml` file.

<table>
<thead>
<tr>
<th>Managed Bean Placement</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>adfc-config.xml</td>
<td>Managed beans can be of any scope. However, any backing beans for page fragments or declarative components should use <code>BackingBean</code> scope. For more information regarding scope, see Section 27.3, “About Object Scope Lifecycles.”</td>
</tr>
<tr>
<td></td>
<td>When executing within an unbounded task flow, <code>faces-config.xml</code> will be checked for managed bean definitions before the adfc-config.xml file.</td>
</tr>
<tr>
<td></td>
<td>Lookup precedence is enforced per scope. Request-scoped managed beans take precedence over session-scoped managed beans. Therefore, a request-scoped managed bean named <code>foo</code> in the adfc-config.xml file will take precedence over a session-scoped managed bean named <code>foo</code> in the current task flow definition file.</td>
</tr>
<tr>
<td></td>
<td>Already instantiated beans take precedence over new instances being instantiated. Therefore, an existing session-scoped managed bean named <code>foo</code> will always take precedence over a request-scoped bean named <code>foo</code> defined in the current task flow definition file.</td>
</tr>
</tbody>
</table>
Using a Managed Bean in a Fusion Web Application

As a general rule for Fusion web applications, a bean that may be used in more than one page or task flow, or one that is used by pages within the main unbounded task flow (adfc-config.xml), should be registered in the adfc-config.xml configuration file. A managed bean that will be used only by a specific task flow should be registered in that task flow’s definition file. There should be no beans registered in the faces-config.xml file.

<table>
<thead>
<tr>
<th>Managed Bean Placement</th>
<th>Effect</th>
</tr>
</thead>
<tbody>
<tr>
<td>Task flow definition file</td>
<td>Managed bean can be of any scope. However, managed beans of pageFlow scope or view scope that are to be accessed within the task flow definition must be defined within the task flow definition file. Any backing beans for page fragments in a task flow should use BackingBean scope.</td>
</tr>
<tr>
<td></td>
<td>Managed bean definitions within task flow definition files will be visible only to activities executing within the same task flow.</td>
</tr>
<tr>
<td></td>
<td>When executing within a bounded task flow, faces-config.xml will be checked for managed bean definitions before the currently executing task flow definition. If no match is found in either location, adfc-config.xml and other bootstrap configuration files will be consulted. However, this lookup in other adfc-config.xml and bootstrap configuration files will only occur for session- or application-scoped managed beans.</td>
</tr>
<tr>
<td></td>
<td>Lookup precedence is enforced per scope. Request-scoped managed beans take precedence over session-scoped managed beans. Therefore, a request-scoped managed bean named foo in the adfc-config.xml file will take precedence over a session-scoped managed bean named foo in the current task flow definition file.</td>
</tr>
<tr>
<td></td>
<td>Already instantiated beans take precedence over new instances being instantiated. Therefore, an existing session-scoped managed bean named foo will always take precedence over a request-scoped bean named foo registered in the current task flow definition file.</td>
</tr>
<tr>
<td></td>
<td>Customizations are allowed.</td>
</tr>
<tr>
<td>faces-config.xml</td>
<td>Managed beans can be of any scope other than pageFlow scope or view scope.</td>
</tr>
<tr>
<td></td>
<td>When searching for any managed bean, the faces-config.xml file is always consulted first. Other configuration files will be searched only if a match is not found. Therefore, beans registered in the faces-config.xml file will always win any naming conflict resolution.</td>
</tr>
<tr>
<td></td>
<td>No customizations can be made.</td>
</tr>
</tbody>
</table>

As a general rule for Fusion web applications, a bean that may be used in more than one page or task flow, or one that is used by pages within the main unbounded task flow (adfc-config.xml), should be registered in the adfc-config.xml configuration file. A managed bean that will be used only by a specific task flow should be registered in that task flow’s definition file. There should be no beans registered in the faces-config.xml file.

**Note:** If you create managed beans from dialogs within JDeveloper, the bean is registered in the adfc-config.xml file, if it exists.

For example, in the Summit sample application for Oracle ADF, the ShuttleBean is a managed bean used by the showshuttle page to handle the selections in the shuttle component on that page. Because it is used solely within the...
create-edit-orders-task-flow-definition task flow, it is registered in the
create-edit-orders-task-flow-definition definition file.

You can create a managed bean for use within a task flow (either the default
adfc-config flow or any bounded task flow). For more information regarding
managed beans and how they are used as backing beans for JSF pages, see the
"Creating and Using Managed Beans" section in Developing Web User Interfaces with
Oracle ADF Faces.

26.4.1 How to Use a Managed Bean to Store Information

Within the editors for a task flow definition, you can create a managed bean and
register it with the JSF application at the same time.

Before you begin:
It may help to understand the options that are available to you when you create a
managed bean. For more information, see Section 26.4, "Using a Managed Bean in a
Fusion Web Application."

You may also find it useful to understand additional functionality that can be used
with managed beans. For more information, see Section 26.1.2, "Additional
Functionality for Page Templates and Managed Beans."

You will need to complete this task:

Create the configuration file (if it doesn’t already exist) that you want the managed
bean to be associated with. This can be faces-config.xml,
adfc-config.xml, or a bounded task flow definition file.

To create a managed bean for adfc-config.xml or a task flow:

1. In the Applications window, double-click either the adfc-config.xml file or any
other task flow definition file.

2. In the overview editor, click the Managed Beans navigation tab. Figure 26–3
shows the editor for the adfc-config.xml file.

Figure 26–3 Managed Beans in the adfc-config.xml File

3. In the Managed Bean page, click the Add icon to add a row to the Managed Beans
table.

4. In the fields, enter the following:

   Name: A name for the bean.
Using a Managed Bean in a Fusion Web Application

- **Class**: If the corresponding class has already been created for the bean, use the browse (...) button for the **managed-bean-class** field to search for and select the class. If a class does not exist, enter the name you’d like to use. Be sure to include any package names as well. You can then use the drop-down menu to choose **Generate Class**, and the Java file will be created for you.

- **Scope**: The bean’s scope. For more information about the different object scopes, see Section 27.3, "About Object Scope Lifecycles."

---

**Note**: When determining what scope to register a managed bean with or to store a value in, keep the following in mind:

- Always try to use the narrowest scope possible.

- If your managed bean takes part in component binding by accepting and returning component instances (that is, if UI components on the page use the binding attribute to bind to component properties on the bean), then the managed bean must be stored in **BackingBean** scope. If it can’t be stored in one of those scopes (for example, if it needs to be stored in **sessionScope** for high availability reasons), then instead of using component binding, you need to use the **ComponentReference API**. For more information, see the “What You May Need to Know About Component Bindings and Managed Beans” section of *Developing Web User Interfaces with Oracle ADF Faces*.

- Use the **sessionScope** scope only for information that is relevant to the whole session, such as user or context information. Avoid using the **sessionScope** scope to pass values from one page to another.

- You can also set the scope to **none**. While not technically a scope, **none** means that the bean will not live within any particular scope, but will instead be instantiated each time it is referenced. You should set a bean’s scope to **none** when it is referenced by another bean.

---

5. You can optionally add needed properties for the bean. With the bean selected in the **Managed Beans** table, click the **Add** icon for the **Managed Properties** table. Enter a property name (other fields are optional).

---

**Note**: While you can declare managed properties using this editor, the corresponding code is not generated on the Java class. You will need to add that code by creating private member fields of the appropriate type and then using the **Generate Accessors** menu item on the context menu of the source editor to generate the corresponding getter and setter methods for these bean properties.

---

26.4.2 What Happens When You Create a Managed Bean

When you use the configuration editor to create a managed bean and elect to generate the Java file, JDeveloper creates a stub class with the given name and a default
Using a Managed Bean in a Fusion Web Application

Getting Started with Your Web Interface

constructor. **Example 26–6** shows the code added to the `MyBean` class stored in the view package.

**Example 26–6  Generated Code for a Managed Bean**

```java
package view;

public class MyBean {
    public MyBean() {
        // constructor
    }
}
```

You now need to add the logic required by your task flow or page. You can then refer to that logic using an EL expression that refers to the `managed-bean-name` value given to the managed bean. For example, to access the `myInfo` property on the bean, the EL expression would be:

```el
#{my_bean.myInfo}
```

JDeveloper also adds a `managed-bean` element to the appropriate task definition file. **Example 26–7** shows the `managed-bean` element created for the `MyBean` class.

**Example 26–7  Managed Bean Configuration on the adfc-config.xml File**

```
<managed-bean>
    <managed-bean-name>my_bean</managed-bean-name>
    <managed-bean-class>view.MyBean</managed-bean-class>
    <managed-bean-scope>session</managed-bean-scope>
</managed-bean>
```

26.4.3 How to Set Managed Bean Memory Scopes in a Server-Cluster Environment

Typically, in an application that runs in a clustered environment, a portion of the application's state is serialized and copied to another server or a data store at the end of each request so that the state is available to other servers in the cluster.

**Note:** If the managed bean will be calling `set` and `get` methods on ADF Faces components, you cannot serialize the managed beans because ADF Faces components are not serializable. You will need to access the ADF Faces components in another way.

When you are designing an application to run in a clustered environment, you must:

- Ensure that all managed beans with a lifespan longer than one request are serializable (that is, they implement the `java.io.Serializable` interface). Specifically, beans stored in session scope, page flow scope, and view scope need to be serializable.

  **Tip:** To identify failures with objects stored in page flow scope and view scope, use `writeObject()`. This method provides additional information in an exception about the object and scope that failed to serialize. Additional information might be a region's page flow scope and the key of the object.

- Make sure that the framework is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).
When a value within a managed bean in either view scope or page flow scope is modified, the application needs to notify the framework so that it can ensure that the bean's new value is replicated.

In Example 26–8, an attribute of an object in view scope is modified.

**Example 26–8  Code That Modifies an Object in viewScope**

```java
Map<String, Object> viewScope = AdfFacesContext.getCurrentInstance().getViewScope();
MyObject obj = (MyObject)viewScope.get("myObjectName");
obj.setFoo("newValue");
```

Without additional code, the framework will be unaware of this change and it will not know that a new value needs to be replicated within the cluster. To inform the framework that an object in an ADF scope has been modified and that replication is needed, use the `markScopeDirty()` method, as shown in Example 26–9. The `markScopeDirty()` method accepts only `viewScope` and `pageFlowScope` as parameters.

**Example 26–9  Additional Code to Notify Oracle ADF of Changes to an Object**

```java
ControllerContext ctx = ControllerContext.getInstance();
ctx.markScopeDirty(viewScope);
```

This code is needed for any request that modifies an existing object in one of the ADF scopes. If the scope itself is modified by the scope's `put()`, `remove()`, or `clear()` methods, it is not necessary to notify the framework.

If an application is not deployed to a clustered environment, the tracking of changes to ADF memory scopes is not needed, and by default, this functionality is disabled. To enable ADF Controller to track changes to ADF memory scopes and replicate the page flow scope and view scope within the server cluster, set the `<adf-scope-ha-support>` parameter in the `adf-config.xml` file to `true`. Because scope replication has a small performance overhead, it should be enabled only for applications running in a server-cluster environment.

Example 26–10 shows `adf-scope-ha-support` set to `true` in the `adf-config.xml` file.

**Example 26–10  adf-scope-ha-support Parameter in the adf-config.xml File**

```xml
<?xml version="1.0" encoding="US-ASCII" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
xmlns:adfc="http://xmlns.oracle.com/adf/controller/config">
<adfc:adf-controller-config>
...
<adfc:adf-scope-ha-support>true</adfc:adf-scope-ha-support>
...
</adfc:adf-controller-config>
...
</adf-config>
```
This chapter describes the ADF page lifecycle, its phases, and how to best use the lifecycle within a Fusion web application.

This chapter includes the following sections:

- Section 27.1, "About the Fusion Page Lifecycle"
- Section 27.2, "About the JSF and ADF Page Lifecycles"
- Section 27.3, "About Object Scope Lifecycles"
- Section 27.4, "Customizing the ADF Page Lifecycle"

27.1 About the Fusion Page Lifecycle

When a JSF page is submitted and a new page is requested, the JSF page request lifecycle is invoked. This lifecycle handles the submission of values on the page, validation for components on the current page, navigation to and display of the components on the resulting page, as well as saving and restoring state. The JSF lifecycle phases use a UI component tree to manage the display of the components. This tree is a runtime representation of a JSF page: each UI component tag in a page corresponds to a UI component instance in the tree.

The FacesServlet object manages the page request lifecycle in JSF applications. The FacesServlet object creates an object called FacesContext, which contains the information necessary for request processing, and invokes an object that executes the lifecycle.

In addition to the JSF lifecycle, the ADF Faces and ADF page lifecycle are also run. The ADF Faces lifecycle extends the JSF lifecycle, providing additional functionality, such as a client-side value lifecycle, a subform component that allows you to create independent submittable sections on a page without the drawbacks (for example, lost user edits) of using multiple forms on a single page, and additional scopes. For more information about both the JSF lifecycle and the ADF Faces lifecycle, including what you can do with the lifecycle for your application, see the "Using the JSF Lifecycle with ADF Faces" chapter of Developing Web User Interfaces with Oracle ADF Faces.

The ADF page lifecycle handles preparing and updating the data model, validating the data at the model layer, and executing methods on the business layer. The ADF page lifecycle uses the binding container to make data available for easy referencing by the page during the current page request.

The combined JSF and ADF page lifecycle is only one sequence within a larger sequence of events that begins when an HTTP request arrives at the application server and continues until the page is returned to the client. This overall sequence of events can be called the web page lifecycle. It follows processing through the model, view, and
controller layers as defined by the MVC architecture. The page lifecycle is not a rigidly defined set of events, but is rather a set of events for a typical use case. Figure 27–1 shows a sequence diagram of the lifecycle of a web page request using JSF and Oracle ADF in tandem.

**Figure 27–1  Lifecycle of a Web Page Request Using JSF and Oracle ADF**

The basic flow of processing a web page request using JSF and Oracle ADF happens as follows:

1. A web request for http://yoursite/yourapp/faces/some.jsp arrives from the client to the application server.

2. The `ADFBindingFilter` object looks for the ADF binding context in the HTTP session, and if it is not yet present, initializes it for the first time. Some of the functions of the `ADFBindingFilter` include finding the name of the binding context metadata file, and finding and constructing an instance of each data control.

3. The `ADFBindingFilter` object invokes the `beginRequest()` method on each data control participating in the request. This method gives the data control a notification at the start of every request so that it can perform any necessary setup.

4. The JSF `Lifecycle` object, which is responsible for orchestrating the standard processing phases of each request, notifies the `ADFPhaseListener` class during each phase of the lifecycle, so that it can perform custom processing to coordinate the JSF lifecycle with the ADF Model data binding layer. For more information about the details of the JSF and ADF page lifecycle phases, see Section 27.2, "About the JSF and ADF Page Lifecycles."
5. The **ADFPhaseListener** object creates an **ADF PageLifecycle** object to handle each request and delegates the appropriate before and after phase methods to corresponding methods in the **ADF PageLifecycle** class. If the binding container for the page has never been used before during the user's session, it is created.

6. The first time an application module data control is referenced during the request, it acquires an instance of the application module from the application module pool.

7. The **JSF Lifecycle** object forwards control to the page to be rendered.

8. The UI components on the page access value bindings and iterator bindings in the page's binding container and render the formatted output to appear in the browser.

9. The **ADFBindingFilter** object invokes the **endRequest()** method on each data control participating in the request. This method gives a data control notification at the end of every request, so that they can perform any necessary resource cleanup.

10. An application module data control uses the **endRequest** notification to release the instance of the application module back to the application module pool.

11. The user sees the resulting page in the browser.

The ADF page lifecycle also contains phases that are defined simply to notify ADF page lifecycle listeners before and after the corresponding JSF phase is executed (that is, there is no implementation for these phases). These phases allow you to create custom listeners and register them with any phase of both the JSF and ADF page lifecycles, so that you can customize the ADF page lifecycle if needed, both globally or at the page level.

### 27.2 About the JSF and ADF Page Lifecycles

Figure 27–2 shows a high-level view of the combined JSF and ADF page lifecycles.

**Figure 27–2  JSF and ADF Page Lifecycles**
Say for example, you have a page with some text displayed in an input text component and a button. When that page is first rendered, the component tree is built during the Restore View phase and then the lifecycle goes straight to the Render Response phase, as the components are rendered. When the user clicks the button, the full lifecycle is invoked. The component tree is rebuilt, the input text component extracts any new value during the Apply Request Values phase and Process Validations phase, and if there is an error, for example due to validation, then the lifecycle jumps to the Render Response phase. Otherwise, the model is then updated with the new value during the Update Model phase, and then any application processing associated with the button (such as navigation), is executed during the Invoke Application phase.

Figure 27–3 shows the details of how the JSF and ADF Faces and ADF Model phases integrate in the lifecycle of a page request.

**Figure 27–3 Lifecycle of a Page Request in a Fusion Web Application**

In a JSF application that uses ADF Model, the phases in the page lifecycle are as follows:

- **Restore View**: The URL for the requested page is passed to the bindingContext object, which finds the page definition file that matches the URL. The component tree of the requested page is either newly built or restored. All the component
tags, event handlers, converters, and validators on the submitted page have access to the `FacesContext` instance. If the component tree is empty, (that is, there is no data from the submitted page), the page lifecycle proceeds directly to the Render Response phase.

If any discrepancies between the request state and the server-side state are detected, an error will is thrown and the page lifecycle jumps to the Render Response phase.

- **JSF Restore View**: Provides before and after phase events for the Restore View phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Restore View phase. The Initialize Context phase of the ADF Model page lifecycle listens for the `after(JSF Restore View)` event and then executes. ADF Controller uses listeners for the before and after events of this phase to synchronize the server-side state with the request. For example, it is in this phase that browser back button detection and bookmark reference are handled. After the before and after listeners are executed, the page flow scope is available.

- **Initialize Context**: The page definition file is used to create the `bindingContainer` object, which is the runtime representation of the page definition file for the requested page. The `LifecycleContext` class used to persist information throughout the ADF page lifecycle phases is instantiated and initialized with values for the associated request, binding container, and lifecycle.

- **Prepare Model**: The ADF page lifecycle enters the Prepare Model phase by calling the `BindingContainer.refresh(PREPARE_MODEL)` method. During the Prepare Model phase, `BindingContainer` page parameters are prepared and then evaluated. If parameters for a task flow exist, they are passed into the flow. Next, any executables that have their refresh property set to `prepareModel` are refreshed based on the order of entry in the page definition file’s `<executables>` section and on the evaluation of their `RefreshCondition` properties (if present). When an executable leads to an iterator binding refresh, the corresponding data control will be executed, and that leads to execution of one or more collections in the service objects. If an iterator binding fails to refresh, a JBO exception will be thrown and the data will not be available to display. For more information about the `RefreshCondition` property, see Section A.8, “pageNamePageDef.xml.”

If the incoming request contains no POST data or query parameters, then the lifecycle forwards to the Render Response phase.

If the page was created using a template, and that template contains bindings using ADF Model, the template’s page definition file is used to create the binding container for the template. The container is then added to the binding context.

If any `taskFlow` executable bindings exist (for example, if the page contains a region), the `taskFlow` binding creates an ADF Controller `ViewPortContext` object for the task flow, and any nested binding containers for pages in the flow are then executed.

- **Apply Request Values**: Each component in the tree extracts new values from the request parameters (using its decode method) and stores those values locally. Most associated events are queued for later processing. If you have set a component’s `immediate` attribute to `true`, then the validation, conversion, and events associated with the component are processed during this phase and the lifecycle skips the Process Validations, Update Model Values, and Invoke Application phases. Additionally, any associated iterators are invoked. For more information about ADF Faces validation and conversion, see the “Validating and Converting Input” chapter in *Developing Web User Interfaces with Oracle ADF Faces*. 

...
■ JSF Apply Request Values: Provides before and after phase events for the Apply Request Values phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Apply Request Values phase.

■ Process Validations: Local values of components are converted and validated on the client. If there are errors, the lifecycle jumps to the Render Response phase. At the end of this phase, new component values are set, any validation or conversion error messages and events are queued on FacesContext, and any value change events are delivered. Exceptions are also caught by the binding container and cached.

■ JSF Process Validations: Provides before and after phase events for the Process Validations phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Process Validations phase.

■ Update Model Values: The component’s validated local values are moved to the model and the local copies are discarded. For any updateable components (such as an inputText component), corresponding iterators are refreshed, if the refresh condition is set to the default (deferred) and the refresh condition (if any) evaluates to true.

If you are using a backing bean for a JSF page to manage your UI components, any UI attributes bound to a backing bean property will also be refreshed in this phase.

■ JSF Update Model Values: Provides before and after phase events for the Update Model Values phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Update Model Values phase.

■ Validate Model Updates: The updated model is now validated against any validation routines set on the model. Exceptions are caught by the binding container and cached.

■ Invoke Application: Any action bindings for command components or events are invoked.

■ JSF Invoke Application: Provides before and after phase events for the Invoke Application phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Invoke Application phase.

■ Metadata Commit: Changes to runtime metadata are committed. This phase stores any runtime changes made to the application using the Metadata Service (MDS). For more information about using MDS to persist runtime changes, see Chapter 45, "Customizing Applications with MDS."

■ Initialize Context (only if navigation occurred in the Invoke Application lifecycle): The Initialize Context phase listens for the beforeJSFRenderResponse event to execute. The page definition file for the next page is initialized.

■ Prepare Model (only if navigation occurred in the Invoke Application lifecycle): Any page parameters contained in the next page’s definition are set.

■ Prepare Render: The binding container is refreshed to allow for any changes that may have occurred in the Apply Request Values or Validation phases. Any iterators that correspond to read-only components (such as an outputText component) are refreshed. Any dynamic regions are switched, if needed. The prepareRender event is sent to all registered listeners, as is the afterJSFRenderResponse event.
About the JSF and ADF Page Lifecycles

Understanding the Fusion Page Lifecycle

- Render Response: The components in the tree are rendered as the Java EE web container traverses the tags in the page. State information is saved for subsequent requests and the Restore View phase.

In order to lessen the wait time required to display both a page and any associated data, certain ADF Faces components such as the table component, use data streaming for their initial request. When a page contains one or more of these components, the page goes through the normal lifecycle. However, instead of fetching the data during that request, a special separate request is run. Because the page has just rendered, only the Render Response phase executes for the components that use data streaming, and the corresponding data is fetched and displayed. If the user’s action (for example scrolling in a table), causes a subsequent data fetch another request is executed. Collection-based components, such as tables, trees, tree tables, and data visualization components all use data streaming.

- JSF Render Response: Provides before and after phase events for the Render Response phase. You can create a listener and register it with the before or after event of this phase, and the application will behave as if the listener were registered with the Render Response phase.

27.2.1 What You May Need to Know About Partial Page Rendering and Iterator Bindings

ADF Faces provides an optimized lifecycle that you can use when you want the page request lifecycle (including conversion and validation) to be run only for certain components on a page, usually for components whose values have changed.

One way to use the optimized lifecycle is to manually set up dependencies so that the events from one component act as triggers for another component, known as the target. When any event occurs on the trigger component, the lifecycle is run on any target components, as well as on any child components of both the trigger and the target, causing only those components to be rerendered. This is considered a partial page rendering (PPR)

Example 27–1 shows radio buttons as triggers and a panelGroupLayout component that contains the output text to be the target (the panelGroupLayout component must be the target because the outputText component may not always be rendered).

Example 27–1 Example of Partial Page Rendering

```xml
<af:form>
   <af:inputText label="Required Field" required="true"/>
   <af:selectBooleanRadio id="show" autoSubmit="true" text="Show"
      value="#{validate.show}"/>
   <af:selectBooleanRadio id="hide" autoSubmit="true" text="Hide"
      value="#{validate.hide}"/>
   <af:panelGroupLayout partialTriggers="show hide" id="panel">
      <af:outputText value="You can see me!" rendered="#{validate.show}"/>
   </af:panelGroupLayout>
</af:form>
```

Note: Instead of displaying prepareRender as a valid phase for a selection, JDeveloper displays renderModel, which represents the refresh(RENDER_MODEL) method called on the binding container.
Because the `autoSubmit` attribute is set to `true` on the radio buttons, when they are selected, a `SelectionEvent` is fired. Because the `panelGroupLayout` component is set to be a target for both radio components, when that event is fired, only the `selectOneRadio` (the trigger), the `panelGroupLayout` component (the trigger’s target), and its child component (the `outputText` component) are processed through the lifecycle. Because the `outputText` component is configured to render only when the `Show` radio button is selected, the user is able to select that radio button and see the output text, without having to enter text into the required input field above the radio buttons.

Instead of having to set partial triggers and targets within code manually, the ADF Faces framework provides automatic PPR. Automatic PPR happens when an event has a corresponding event root component, or when the component itself is an event root. An event root component determines the boundaries of PPR. For example, the `attributeChangeEvent` considers the `inputText` component that invokes the event, its event root. Therefore, in the previous example, when the value changes for the `inputText` component, because it is the initial boundary for the PPR, the lifecycle would be run only on that `inputText` component and any child components.

Along with event roots, by default for Fusion web applications, automatic PPR also occurs for all UI components associated with the same iterator binding. All associated components refresh whenever any one of them has a value change event. This functionality is controlled by setting the `changeEventPolicy` attribute for iterators to `ppr`. By default, this is set globally.

For example, say you create a number of `inputText` components using the Data Controls panel (for example, when you create a form). When the `attributeChangeEvent` occurs on one of those `inputText` components, because the other `inputText` components are associated with the same iterator, all those `inputText` components will also be refreshed.

Another example might be a page that contains a `panelSplitter` component, where the left part of the splitter contains a form to create a new customer (created by dropping a form using the `Customer` collection), and the right part of the splitter contains instructions for using the form. Because the bindings for the `inputText` components that make up the form are all associated with the `Customer` iterator, anytime the form is submitted and a value for one of the `inputText` components has changed, only the `inputText` components associated with the `Customer` will be processed through the lifecycle. The rest of the page, including the instructions in the right side of the splitter, will not be refreshed.

**Note:** In order for automatic PPR to happen, the event and event root component must be listed in Table 5-1 of the “Events and Partial Page Rendering” section of *Developing Web User Interfaces with Oracle ADF Faces*. If it is not listed, you will need to set up PPR manually, as described in the “Using Partial Triggers” section of the same guide.

For example, say you create a form and a table from the same data control collection. The form shows the details for a row of data, while the table shows all rows in a collection, with the row currently displayed in the form shown as selected. When you click the `Next` button on the form, you want the table to refresh to show the new row as selected. Because the selection event is not supported by automatic PPR, the table will not refresh, even though the table and form both use the same iterator. You will need to set the `Next` and `Previous` buttons to be triggers of PPR for the target table.
About the JSF and ADF Page Lifecycles

Note: Only UI components that have a control binding defined in the page definition file associated with the configured iterator will be refreshed.

If you directly access the iterator from a managed bean and expose iterator values to UI components through that bean, then automatic PPR will not happen for those UI components. In these cases, you need to configure PPR manually. For more information, see the "Using Partial Triggers" section of *Developing Web User Interfaces with Oracle ADF Faces.*

Note: The ADF Faces query components (query and quickQuery) do not support automatic PPR. If you set changeEventPolicy to be ppr globally, any iterators associated with bindings for those components, or with components or tags that don’t participate in PPR (such as behavior tags), will have the changeEventPolicy attribute set to none at runtime.

By default, all new applications use global PPR. You do not have to set it. You can however, override the setting in the page definition file for a page.

**Before you begin:**

It may be helpful to have an understanding of partial page rendering. For more information, see Section 27.2.1, "What You May Need to Know About Partial Page Rendering and Iterator Bindings.”

**To set iterator bindings to use PPR:**

1. To set a specific iterator binding to use or not use PPR, open the associated page definition file, select the iterator, and in the Properties window, set ChangeEventPolicy.

2. To set all iterator bindings to use PPR:
   a. In the Applications Resource panel, expand the Descriptors and ADF META-INF nodes, and then double click adf-config.xml.
   b. In the overview editor, click the Model navigation tab, and then select Default Change Event Policy is Partial Page Rendering (PPR).

For more information about how the ADF Faces framework uses PPR, see the "Rerendering Partial Page Content" chapter in *Developing Web User Interfaces with Oracle ADF Faces.*

**27.2.2 What You May Need to Know About Task Flows and the Lifecycle**

Task flows are initially refreshed when the parent binding container (the one associated with the page) is refreshed. This happens in the Prepare Model phase. On a subsequent request, the task flow will be refreshed during the Prepare Render phase, depending on its refresh and refreshCondition attributes and its parameter value.

Note: Any child page fragment’s page definition still handles the refresh of the bindings of the child page fragments.
Tip: If you have a region on a page that is not initially disclosed (for example, a popup dialog), the parameters still need to be available when the parent page is rendered, even though the region might not be displayed. If a region requires parameters, but those parameter values will not be available when the parent page is rendered, then you should use dynamic regions. If the parameters are null, an empty task flow can be used until the parameters for the region are ready and that region can display. To swap in an empty task flow, you set the dynamic region’s taskFlowId attribute to an empty string.

If you set an EL expression as the value of the refreshCondition attribute, it will be evaluated during the Prepare Render phase of the lifecycle. When the expression evaluates to true, the task flow will be refreshed again. When refreshCondition evaluates to false, the behavior is the same as if the refreshCondition had not been specified.

Note: If the variable bindings is used within the EL expression, the context refers to the binding container of the parent page, not the page fragment displayed within the region.

The valid values for the refresh property of a task flow executable are as follows:

- **default**: The region will be refreshed only once, when the parent page is first displayed.
- **ifNeeded**: Refreshes the region only if there has been a change to taskFlow binding parameter values. If the taskFlow binding does not have parameters, then ifNeeded is equivalent to the default. When ifNeeded is used, the refreshCondition attribute is not considered.

Note: Setting the refresh attribute to ifNeeded takes precedence over any value for the refreshCondition attribute. Also note that ifNeeded is not supported when you pass parameters to the taskFlow binding using a dynamic parameter Map. Instead, use refreshCondition="#{EL.Expression}".

Because the only job of the taskFlow binding is to refresh its parameters, setting Refresh to always does not make sense. If the taskFlow binding’s parameters don’t change, there is no reason to refresh the ADF region.

Note that the child page fragment’s page definition still handles the refresh of the bindings of the child page fragments.

### 27.3 About Object Scope Lifecycles

At runtime, ADF objects such as the binding container and managed beans are instantiated. Each of these objects has a defined lifespan set by its scope attribute. You can access a scope as a java.util.Map from the RequestContext API. For example, to access an object named foo in the request scope, you would use the expression #{requestScope.foo}.

Object scopes are analogous to global and local variable scopes in programming languages. The wider the scope, the higher and longer the availability of an object. During their life, these objects may expose certain interfaces, hold information, or pass
variables and parameters to other objects. For example, a managed bean defined in session scope will be available for use during multiple page requests. However, a managed bean defined in request scope will only be available for the duration of one page request.

There are six types of scopes in a Fusion web application:

- **Application scope:** The object is available for the duration of the application.
- **Session scope:** The object is available for the duration of the session.

  **Note:** There is no window uniqueness for session scope, all windows in the session share the same session scope instance. If you are concerned about multiple windows being able to access the same object (for example to ensure that managed beans do not conflict across windows), you should use a scope that is window-specific, such as page flow or view scope.

- **Page flow scope:** The object is available for the duration of a task flow. As its name suggests, page flow scope is specific to an instance of a task flow (bounded or unbounded). So if you have a page with two or more regions (created by a task flow), separate instances of the page flow scope will exist for each region. Additionally, if the user opens the page with the regions in separate browser tabs, a separate instance of the page flow scope bean will be instantiated for each browser tab.

  **Note:** Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the `pageFlowScope` scope, your expression would be `#{pageFlowScope.MyBean}`.

- **Request scope:** The object is available from the time an HTTP request is made until a response is sent back to the client.
- **Backing bean scope:** Used for managed beans for page fragments and declarative components only, the object is available from the time an HTTP request is made until a response is sent back to the client. This scope is needed for fragments and declarative components because there may be more than one page fragment or declarative component on a page, and to prevent collisions, any values must be kept in separate scope instances. Therefore, any managed bean for a page fragment or declarative component must use backing bean scope.

  **Note:** Because this is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the backing bean scope, your expression would be `#{backingBeanScope.MyBean}`.

- **View scope:** The object is available until the view ID for the current view activity changes. This scope can be used to hold values for a given page. However, unlike request scope, which can be used to store a value needed from one page to the next, anything stored in view scope will be lost once the view ID changes.
About Object Scope Lifecycles

**Note:** Both JSF and ADF Faces have an implementation of view scope. Only the ADF Faces view scope survives page redirects and refreshes. In a Fusion web application, when you use `viewScope` in an expression, it resolves to the ADF Faces view scope.

Because this view scope is not a standard JSF scope, EL expressions must explicitly include the scope to reference bean. For example, to reference the `MyBean` managed bean from the view scope, your expression would be `#{viewScope.MyBean}`.

**Note:** When you create objects (such as a managed bean) that require you to define a scope, you can set the scope to `none`, meaning that it will not live within any particular scope, but will instead be instantiated each time it is referenced.

By default, the binding container and the binding objects it contains are defined in session scope. However, the values referenced by value bindings and iterator bindings are undefined between requests and for scalability reasons do not remain in session scope. Therefore, the values that binding objects refer to are valid only during a request in which that binding container has been prepared by the ADF lifecycle. What stays in session scope are only the binding container and binding objects themselves.

**Figure 27–4** shows the time period during which each type of scope is valid.
When determining what scope to register a managed bean with, always try to use the narrowest scope possible. Only use the session scope for information that is relevant to the whole session, such as user or context information. Avoid using session scope to pass values from one task flow to another. When creating a managed bean for a page fragment or a declarative component, you must use backing bean scope.

Managed beans can be registered in either the adfc-config.xml or the configuration file for a specific task flow. For more information about using managed beans in a Fusion application, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

---

**Note:** Do not register managed beans in the faces-config.xml in a Fusion web application.

---

### 27.3.1 What You May Need to Know About Object Scopes and Task Flows

When determining what scope to use for variables within a task flow, you should use any of the scope options other than application or session scope. These two scopes will persist objects in memory beyond the life of the task flow and therefore compromise the encapsulation and reusable aspects of a task flow. In addition, application and session scopes may keep objects in memory longer than needed, causing unneeded overhead.

When you need to pass data values between activities within a task flow, you should use page flow scope. View scope should be used for variables that are needed only within the current view activity, not across view activities. Request scope should be used when the scope does not need to persist longer than the current request. It is the only scope that should be used to store UI component information. Lastly, backing bean scope must be used for backing beans in your task flow if there is a possibility that your task flow will appear in two region components or declarative components on the same page and you would like to achieve region instance isolations.

### 27.4 Customizing the ADF Page Lifecycle

The ADF lifecycle contains clearly defined phases that notify ADF lifecycle listeners before and after the corresponding JSF phase is executed. You can customize this lifecycle by creating a custom phase listener that invokes your needed code, and then registering it with the lifecycle to execute during one of these phases.

For example, if you do not want to use the default "Managed State" release level for application modules, you can set the release level from the after-prepareRender phase of the ADF lifecycle using a custom ADF page phase-listener class (for more information, see Section 49.4.5, "How to Set Release Level in an ADF PagePhaseListener").

---

**Note:** An application cannot have multiple phase listener instances. An initial ADFPhaseListener instance is, by default, registered in the META-INF/faces-config.xml configuration file. Registering, for example, a customized subclass of the ADFPhaseListener creates a second instance. In this scenario, only the instance that was most recently registered is used.

The following warning message indicates when an instance has been replaced by a newer one: "ADFc: Replacing the ADF Page Lifecycle implementation with class name of the new listener."
27.4.1 How to Create a Custom Phase Listener

To create a custom phase listener, you must create a listener class that implements the PagePhaseListener interface. You then add methods that execute code either before or after the phase that the code needs to execute.

Example 27–2 contains a template that you can modify to create a custom phase listener. See Section 4.13.1, “How to Generate Custom Classes,” for more information about creating a class in JDeveloper.

Example 27–2  Example Custom Phase Listener

```java
public class MyPagePhaseListener implements PagePhaseListener
{
    public void afterPhase(PagePhaseEvent event)
    {
        System.out.println("In afterPhase "+ event.getPhaseId());
    }

    public void beforePhase(PagePhaseEvent event)
    {
        System.out.println("In beforePhase "+ event.getPhaseId());
    }
}
```

Once you create the custom listener class, you need to register it with the phase in which the class needs to be invoked. You can either register it globally (so that the whole application can use it), or you can register it only for a single page.

27.4.2 How to Register a Listener Globally

To customize the ADF lifecycle globally, register your custom phase listener by editing the adf-settings.xml configuration file. The adf-settings.xml file is shared by several ADF components, including ADF Controller, to store configuration information.

To register the listener in adf-settings.xml:
1. In the Applications window, beneath the META-INF node, double-click the adf-settings.xml file.
2. In the editor window, click the Source tab
3. In the source editor, scroll down to
```xml
<adfc-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
  ...
  ...
  ...
  <lifecycle>
    <phase-listener>
      <listener-id>MyPagePhaseListener</listener-id>
```
5. Add values for the following elements:
   - `<listener-id>` A unique identifier for the listener (you can use the fully qualified class name)
   - `<class>` The class name of the listener

### 27.4.3 What You May Need to Know About Listener Order

You can specify multiple phase listeners in the `adf-settings.xml` and, optionally, the relative order in which they are called. When registering a new listener in the file, you determine the position in the list of listeners using two parameters:

- **beforeIdSet**: The listener is called before any of the listeners specified in `beforeIdSet`
- **afterIdSet**: The listener is called after any of the listeners specified in `afterIdSet`

**Example 27–3** contains an example configuration file in which multiple listeners have been registered for an application.

**Example 27–3  adf-settings.xml Configuration File with Multiple Listener Registration**

```xml
<lifecycle>
  <phase-listener>
    <listener-id>MyPhaseListener</listener-id>
    <class>view.myPhaseListener</class>
    <after-id-set>
      <listener-id>ListenerA</listener-id>
      <listener-id>ListenerC</listener-id>
    </after-id-set>
    <before-id-set>
      <listener-id>ListenerB</listener-id>
      <listener-id>ListenerM</listener-id>
      <listener-id>ListenerY</listener-id>
    </before-id-set>
  </phase-listener>
</lifecycle>
```

In the example, `MyPhaseListener` is a registered listener that executes after listeners A and C but before listeners B, M, and Y. To execute `MyPhaseListener` after listener B, move the `<listener-id>` element for listener B under the `<after-id-set>` element.

### 27.4.4 How to Register a Lifecycle Listener for a Single Page

To customize the lifecycle of a single page, you set the `ControllerClass` attribute on the page definition file. This listener will be valid only for the lifecycle of the particular page described by the page definition. For more information about the page
Customizing the ADF Page Lifecycle

definition file and its role in a Fusion web application, see Section 17.7, "Working with Page Definition Files."

You specify a different controller class depending on whether it is for a standard JSF page or a page fragment.

To customize the ADF Lifecycle for a single page or page fragment:
1. In the Applications window, right-click the page or page fragment and choose Go To Page Definition.
2. In the Structure window, select the page definition node.
3. In the Properties window, click the icon that appears when you hover over the ControllerClass field, and choose Edit.
4. Click the Hierarchy tab and navigate to the appropriate controller class for the page or page fragment. Following are the controller classes to use for different types of pages:
   - Standard JSF page - specify `oracle.adf.controller.v2.lifecycle.PageController`
     If you need to receive afterPhase/beforePhase events, specify `oracle.adf.controller.v2.lifecycle.PagePhaseListener`
   - Page fragment - specify `oracle.adf.model.RegionController`

Tip: You can specify the value of the page definition's ControllerClass attribute as a fully qualified class name or you can enter an EL expression that resolves to a class directly in the ControllerClass field.

When using an EL expression for the value of the ControllerClass attribute, the Structure window may show a warning indicating that e "#{YourExpression}" is not a valid class. You can safely ignore this warning.
This chapter describes how to create databound forms in the Fusion web application with data modeled from ADF Business Components, using ADF data controls and ADF Faces components. It describes how to create text fields from individual attributes, generate entire forms from collections for editing and creating new records, and create dynamic forms.

This chapter includes the following sections:

- Section 28.1, "About Creating a Basic Databound Page"
- Section 28.2, "Creating Text Fields Using Data Control Attributes"
- Section 28.3, "Creating Basic Forms Using Data Control Collections"
- Section 28.4, "Creating Command Components Using Data Control Operations"
- Section 28.5, "Incorporating Range Navigation into Forms"
- Section 28.6, "Creating a Form to Edit an Existing Record"
- Section 28.7, "Using Parameters to Create a Form"
- Section 28.8, "Creating an Input Form"
- Section 28.9, "Creating a Form with Dynamic Components"
- Section 28.10, "Modifying the UI Components and Bindings on a Form"

### 28.1 About Creating a Basic Databound Page

You can create UI pages that allow you to display and collect information using data controls created for your business services. For example, using the Data Controls panel, you can drag an attribute for an item, and then choose to display the value either as output text or as an input text field with a label. JDeveloper creates all the necessary JSF tags and binding code needed to display and update the associated data. For more information about the Data Controls panel and the declarative binding experience, see Chapter 17, "Using ADF Model in a Fusion Web Application."

In addition to being able to drop individual attributes, you can drop all attributes for an object at once as a form or table. This chapter includes information on creating forms that display values, forms that allow users to edit values, and forms that collect values (input forms). For information on creating tables, see Chapter 29, "Creating ADF Databound Tables."

Once you drop the UI components, you can then drop built-in operations as command UI components that allow you to navigate through the records in a collection or that allow users to operate on the data, such as committing, deleting, or creating a record.
For example, you can create a button that allows users to delete data objects displayed in the form. You can also modify the default components to suit your needs.

### 28.1.1 ADF Databound Form Use Cases and Examples

You use forms when you need to collect or display a row of data. For example, the Summit sample application for Oracle ADF contains a panel that allows users to update information about their customers as shown in Figure 28–1. This form was created by dragging and dropping the Customers collection from the Data Controls panel and then selecting the fields to display.

**Figure 28–1  Customer General Information Form in the Summit ADF Sample Application**

When you create a form, you can also choose to add navigation, so that the user can navigate quickly between records, as shown in Figure 28–2.

**Figure 28–2 Navigate Between Records in a Form**

You can also add command buttons that invoke processing on the row displayed in the form. For example, you can change values for a record and save those changes in an edit form, or you can create an input form that allows users to create a new record. Figure 28–3 shows an input form where a user can create a new order.

**Figure 28–3 Input Form**
28.1.2 Additional Functionality for Databound Pages

You may find it helpful to understand other Oracle ADF features before you implement your databound pages. Following are links to other functionality that you may find useful.

- **ADF view objects**: Much of how the components display and function in the form is controlled by the corresponding view objects. For more information, see Chapter 5, "Defining SQL Queries Using View Objects."

- **ADF application modules**: The Data Controls panel, from which you drag databound components to your pages, is populated with representations of view objects that you have added to application modules. For more information, see Chapter 13, "Implementing Business Services with Application Modules."

- **Adapter-based data controls**: If you are using other types of business services, such as EJB components or web services, you can create data controls for those business services as described in Developing Applications with Oracle ADF Data Controls.

- **ADF Model and data binding**: When you create forms in an ADF web application, you use ADF Model and data binding. For more information, see Chapter 17, "Using ADF Model in a Fusion Web Application."

- **ADF Faces**: You also use ADF Faces UI components. For detailed information about developing with ADF Faces, see Developing Web User Interfaces with Oracle ADF Faces.

- **Advanced UI controls**: Basic forms use input and output components. You can also use more advanced components, such as lists, tables, trees, search forms, LOV components, graphs, gauges, treemaps, and more. For more information, see the remaining chapters in Part V, "Creating a Databound Web User Interface".

- **Task flows**: If your form takes part in a transaction, for example an input form, then you may need to use an ADF task flow to invoke certain operations before or after the form is rendered. For more information, see Part IV, "Creating ADF Task Flows".

- **Page lifecycle**: For information about how forms work with the page lifecycle, see Chapter 27, "Understanding the Fusion Page Lifecycle."

- **Validation**: You may want certain fields to be validated before they are submitted to the data store. For more information, see Chapter 11, "Defining Validation and Business Rules Declaratively" and Chapter 18, "Using Validation in the ADF Model Layer."

- **Active data**: If your application uses active data, then you can have the data in your UI components update automatically, whenever the data in the data source changes. For more information, see Chapter 47, "Using the Active Data Service."

### 28.2 Creating Text Fields Using Data Control Attributes

JDeveloper allows you to create text fields declaratively in a WYSIWYG development environment for your JSF pages, meaning you can design most aspects of your pages without needing to look at the code. When you drag and drop items from the Data
Controls panel, JDeveloper declaratively binds ADF Faces text UI components to attributes on a data control using an attribute binding.

28.2.1 How to Create a Text Field

To create an individual text field that can display or update an attribute, you drag and drop an attribute of a collection from the Data Controls panel. For ADF Business Components, the Data Controls panel is populated with elements of your data model that you have defined in one or more application modules.

Before you begin:

It may be helpful to have a general understanding of using data control attributes to create text fields. For more information, see Chapter 28.2, "Creating Text Fields Using Data Control Attributes."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.
- Create a JSF page as described in Section 26.3, "Creating a Web Page."

To create a databound text field:

1. From the Data Controls panel, select an attribute from a collection. For a description of the icons that represent attributes and other objects in the Data Controls panel, see Section 17.4, "Using the Data Controls Panel."

For example, Figure 28–4 shows the LastName attribute under the Customers collection of the BackOfficeAppModuleDataControl data control in the Summit ADF sample application. This is the attribute to drop to display, update, or insert the customer’s last name.

Figure 28–4 Attributes Associated with a Collection in the Data Controls Panel

2. Drag the attribute onto the page, and from the context menu choose the type of UI component to display or collect the attribute value, as shown in Figure 28–5.
Creating Text Fields Using Data Control Attributes

Creating a Basic Databound Page

For an attribute, you are given the following choices:

- **Text:**
  - **ADF Input Text w/ Label:** Creates an ADF Faces inputText component in which the label attribute is populated. In addition, a nested validator component is created, which you can use to add client-side validation.
  - **Tip:** For more information about the various attributes of the inputText component, see the “Using Input Components and Defining Forms” chapter of Developing Web User Interfaces with Oracle ADF Faces.
  - **ADF Input Text:** Creates an ADF Faces inputText component without a label. In addition, a nested validator component is generated, which you can use for client-side validation.
  - **ADF Output Text w/ Label:** Creates a panelLabelAndMessage component that holds an ADF Faces outputText component. The label attribute on the panelLabelAndMessage component is populated.
  - **ADF Output Text:** Creates an ADF Faces outputText component.
  - **ADF Output Formatted w/Label:** Same as ADF Output Text w/Label, but uses an outputFormatted component instead of an outputText component. The outputFormatted component allows you to add a limited amount of HTML formatting. For more information, see the "Displaying Output Text and Formatted Output Text" section of Developing Web User Interfaces with Oracle ADF Faces.
  - **ADF Output Formatted:** Same as ADF Output Formatted w/Label, but without the label.
  - **ADF Label:** An ADF Faces outputLabel component.

- **List of Values:** Creates ADF LOV lists. For more information about how these lists work for Business Components, see Section 5.12, "Working with List of Values (LOV) in View Object Attributes." For more information on how these lists work for adapter-based data controls, see “Creating List of Values Objects” in Developing Applications with Oracle ADF Data Controls. For more information about using the lists on a JSF page, see Section 32.3, "Creating a Selection List."

- **Single selections:** Creates single selection lists. For more information about creating lists on a JSF page, see Section 32.3, "Creating a Selection List."
Creating Text Fields Using Data Control Attributes

### 28.2.2 What Happens When You Create a Text Field

Among other things, when you drag an attribute onto a JSF page and drop it as a UI component, a page definition file is created for the page (if one does not already exist). For a complete account of what happens when you drag an attribute onto a page, see Section 17.4.2, "What Happens When You Use the Data Controls Panel." Bindings for the iterator and attributes are created and added to the page definition file. Additionally, the necessary JSPX or JSF page code for the UI component is added to the JSF page.

#### 28.2.2.1 Iterator Bindings Created in the Page Definition File

Whenever you create UI components on a page by dropping an item that is part of a collection from the Data Controls panel (or you drop the whole collection as a form or table), JDeveloper creates an iterator binding if it does not already exist. An iterator binding references an iterator for the data collection, which facilitates iterating over its data objects. It also manages currency and state for the data objects in the collection. An iterator binding does not actually access the data. Instead, it simply exposes the object that can access the data and it specifies the current data object in the collection. Other bindings then refer to the iterator binding in order to return data for the current object or to perform an action on the object’s data. Note that the iterator binding is not an iterator. It is a binding to an iterator. In the case of ADF Business Components, the actual iterator is the default row set iterator for the default row set of the view object instance in the application module’s data model.

For example, if you drop the `LastName` attribute of the `Customers` collection, JDeveloper creates an iterator binding for the `Customers` collection.

**Tip:** There is one iterator binding created for each collection. This means that when you drop two attributes from the same collection (or drop the collection twice), they use the same binding. One advantage of this behavior is that the currency of components stays in sync. For example, if the page has a table and a form dropped from the same collection, the form will show the record of the selected row in the table. If you need the binding to behave differently for the different components, you need to manually create separate iterator bindings.

The iterator binding’s `rangeSize` attribute determines how many rows of data are fetched from a data control each time the iterator binding is accessed. This attribute gives you a relative set of 1-n rows positioned at some absolute starting location in the overall row set. When you create the iterator binding by dragging an attribute or collection on to a page, the attribute is initially set to 25. For more information about
Creating Text Fields Using Data Control Attributes

Example 28–1 shows the iterator binding created when you drop an attribute from the Customers collection.

Example 28–1  Page Definition Code for an Iterator Binding for an Attribute Dropped from a Collection

```xml
<executables>
  <iterator Binds="Customers" RangeSize="25"
    DataControl="BackOfficeAppModuleDataControl"
    id="Customers"/>
</executables>
```

For information regarding the iterator binding element attributes, see Appendix B, "Oracle ADF Binding Properties."

This metadata allows the ADF binding container to access the attribute values. Because the iterator binding is an executable, by default, it is invoked when the page is loaded, thereby allowing the iterator to access and iterate over the Customers collection. This means that the iterator will manage all the Customers objects in the collection, including determining the current Customers object or range of Customers objects.

28.2.2.2 Value Bindings Created in the Page Definition File

When you drop an attribute from the Data Controls panel, JDeveloper creates an attribute binding that is used to bind the UI component to the attribute’s value. This type of binding presents the value of an attribute for a single object in the current row in the collection. Value bindings can be used both to display and to collect attribute values.

For example, if you drop the LastName attribute under the Customers collection as an ADF Output Text w/Label widget onto a page, JDeveloper creates an attribute binding for the LastName attribute. This allows the binding to access the attribute value of the current record. Example 28–2 shows the attribute binding for LastName created when you drop the attribute from the Customers collection. Note that the attribute value references the iterator named CustomersIterator.

Example 28–2  Page Definition Code for an Attribute Binding

```xml
<bindings>
  ...  
  <attributeValues IterBinding="CustomersIterator"
    id="LastName"
    AttrNames>
    <Item Value="LastName"/>
  </AttrNames>
  </attributeValues>
</bindings>
```

For information regarding the attribute binding element properties, see Appendix B, "Oracle ADF Binding Properties."

28.2.2.3 Component Tags Created in JSF Page

When you create a text field by dropping an attribute from the Data Controls panel, JDeveloper creates the UI component associated with the widget dropped by writing the corresponding tag to the JSF page.
For example, when you drop the `LastName` attribute as an Output Text w/Label widget, JDeveloper inserts the tags for a `panelLabelAndMessage` component and an `outputText` component. It creates an EL expression that binds the `label` attribute of the `panelLabelAndMessage` component to the `label` property of hints created for the `LastName`'s binding. This expression evaluates to the `label` hint set on the view object (for more information about hints, see Section 5.13, "Defining UI Hints for View Objects"). It creates another expression that binds the `outputText` component’s `value` attribute to the `inputValue` property of the `LastName` binding, which evaluates to the value of the `LastName` attribute for the current row. An ID is also automatically generated for both components.

**Tip:** JDeveloper automatically generates IDs for all ADF Faces components. You can override these values as needed.

**Example 28–3** shows the code generated on the JSF page when you drop the `LastName` attribute as an Output Text w/Label widget.

```xml
<af:panelLabelAndMessage label="#{bindings.LastName.hints.label}" id="plam1">
    <af:outputText value="#{bindings.LastName.inputValue}" id="ot1"/>
</af:panelLabelAndMessage>
```

If instead you drop the `LastName` attribute as an Input Text w/Label widget, JDeveloper creates an `inputText` component. As **Example 28–4** shows, the value is bound to the `inputValue` property of the `LastName` binding. Additionally, the following properties are also set:

- **label**: Bound to the object’s `label` UI hint.
- **required**: Bound to the object’s `mandatory` property.
- **columns**: Bound to the object’s `displayWidth` UI hint, which determines how wide the text box will be.
- **maximumLength**: Bound to the object’s `precision` property, which determines the maximum number of characters per line that can be entered into the field.
- **shortDesc**: Bound to the `tooltip` UI hint.

In addition, JDeveloper nests a `validator` tag within the `inputText` component. You can use this tag to create client-side validation rules to supplement any validation rules that exist in the model or business service layers.

For further information regarding the `validator` and `converter` tags, see the "Validating and Converting Input" chapter of *Developing Web User Interfaces with Oracle ADF Faces*.

**Example 28–4** *JSF Page Code for an Attribute Dropped as an Input Text w/Label*

```xml
<af:inputText value="#{bindings.LastName.inputValue}"
    label="#{bindings.LastName.hints.label}"
    required="#{bindings.LastName.hints.mandatory}"
    columns="#{bindings.LastName.hints.displayWidth}"
    maximumLength="#{bindings.LastName.hints.precision}"
    shortDesc="#{bindings.LastName.hints.tooltip}" id="it1">
    <f:validator binding="#{bindings.LastName.validator}"/>
</af:inputText>
```

You can change any of these values to suit your needs. For example, the `mandatory` control hint on the view object is set to `false` by default, which means that the
required attribute on the component will evaluate to false as well. You can override this value by setting the required attribute on the component to true. If you decide that all instances of the attribute should be mandatory, then you can change the control hint on the view object, and all instances will then be required. For more information about these properties, see Appendix B, ”Oracle ADF Binding Properties.” For more information on changing these properties at the entity object level, see Section 4.10, ”Setting Attribute Properties.” For more information on changing these properties at the view object level, see Section 5.2.4, ”How to Edit a View Object.”

28.3 Creating Basic Forms Using Data Control Collections

Instead of dropping each of the individual attributes of a collection to create a form, you can drop the collection node to create a form from multiple attributes in the collection.

For example, you could create a page that displays basic information about customers in the Summit ADF sample application by dragging and dropping the Customers collection.

You can also create forms that provide more functionality than simply displaying data from a collection. For information about creating a form that allows a user to update data, see Section 28.6, ”Creating a Form to Edit an Existing Record.” For information about creating forms that allow users to create a new object for the collection, see Section 28.8, ”Creating an Input Form.” You can also create search forms. For more information, see Chapter 33, ”Creating ADF Databound Search Forms.”

28.3.1 How to Create a Form Using a Data Control Collection

When you create a form using a data control, you bind the UI components to the attributes on the corresponding object in the data control. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

Before you begin:

It may be helpful to have an understanding of basic databound forms. For more information, see Section 28.3, ”Creating Basic Forms Using Data Control Collections.”

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, ”Additional Functionality for Databound Pages.”

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, ”Creating and Modifying an Application Module.” Alternatively, if you are using another type of business service, create a data control for that business service as described in ”Exposing Business Services with Data Controls” in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, ”Creating a Web Page.”

To create a basic form:

1. From the Data Controls panel, select the collection that represents the data you wish to display. Figure 28–6 shows the Customers collection for the BackOfficeAppModuleDataControl data control.
Creating Basic Forms Using Data Control Collections

Figure 28–6  CustomerVO Object in the Data Controls Panel

2. Drag the collection onto the page, and from the context menu choose ADF Form.

Figure 28–7  Context Menu When Dropping a Collection to a Page

3. In the Create Form dialog, configure your form.
   - You can exclude attributes from appearing in the form.
   - If you do not select the Read-Only Form checkbox, ADF inputText components are used for most attributes. Each inputText component has the
Creating Basic Forms Using Data Control Collections

Creating a Basic Databound Page

label attribute populated. By default, the label obtains its value from a binding to the label property on the associated binding object. Attributes that are dates use the InputDate component.

If a control type control hint has been created for an attribute, or if the attribute has been configured to be a list, then the component set by the hint is used instead.

InputText components contain a validator tag that allows you to set up client-side validation for the attribute. If the attribute is a number or a date, a converter is also included.

Tip: For more information about the various attributes of the inputText component, see the "Using Input Components and Defining Forms" chapter of Developing Web User Interfaces with Oracle ADF Faces.

- If you select the Read-Only Form checkbox, read-only outputText components are used. Since the form is meant to display data, no validator tags are added (though converters are included). Attributes of type Date use the outputText component when in a read-only form. All components are placed inside panelLabelAndMessage components, which have the label attribute populated, and are placed inside a panelFormLayout component. This ensures that the labels are aligned appropriately with the outputText components at runtime.

- You can elect to include navigational controls that allow users to navigate through all the data objects in the collection. For more information, see Section 28.5, "Incorporating Range Navigation into Forms."

- You can also include a Submit button to submit the HTML form and apply the data in the form to the bindings as part of the JSF/ADF page lifecycle. For additional help in using the dialog, click Help.

4. If you are building a form that allows users to update data, you now need to drag and drop an operation that will commit the changes to update the record. For more information, see Section 28.6, "Creating a Form to Edit an Existing Record."

Note: If you select the Fields Generated at Runtime in the Create Form dialog, the attributes to display are determined at runtime based on configuration of the business service. For more information, see Section 28.9, "Creating a Form with Dynamic Components."

28.3.2 What Happens When You Create a Form Using a Data Control Collection

Dropping an object as a form from the Data Controls panel has a similar effect as dropping a single attribute, except that multiple attribute bindings and associated UI components are created and all UI components are placed inside a panelFormLayout component. The attributes on the UI components (such as value) are bound to properties on that attribute’s binding object (such as inputValue) or to the values of control hints set on the corresponding business object. Example 28–5 shows some of the code generated on the JSF page when you drop the Customers collection as a default ADF Form.
Example 28–5  Code on a JSF Page for an Input Form

```xml
<af:panelFormLayout id="pfl1">
    <af:inputText value="#{bindings.Id.inputValue}" label="#{bindings.Id.hints.label}" required="#{bindings.Id.hints.mandatory}" columns="#{bindings.Id.hints.displayWidth}" maximumLength="#{bindings.Id.hints.precision}" shortDesc="#{bindings.Id.hints.tooltip}" id="it1">
        <f:validator binding="#{bindings.Id.validator}"/>
        <af:convertNumber groupingUsed="false" pattern="#{bindings.Id.format}"/>
    </af:inputText>
    <af:inputText value="#{bindings.Name.inputValue}" label="#{bindings.Name.hints.label}" required="#{bindings.Name.hints.mandatory}" columns="#{bindings.Name.hints.displayWidth}" maximumLength="#{bindings.Name.hints.precision}" shortDesc="#{bindings.Name.hints.tooltip}" id="it2">
        <f:validator binding="#{bindings.Name.validator}"/>
    </af:inputText>
    <af:inputText value="#{bindings.Phone.inputValue}" label="#{bindings.Phone.hints.label}" required="#{bindings.Phone.hints.mandatory}" columns="#{bindings.Phone.hints.displayWidth}" maximumLength="#{bindings.Phone.hints.precision}" shortDesc="#{bindings.Phone.hints.tooltip}" id="it3">
        <f:validator binding="#{bindings.Phone.validator}"/>
    </af:inputText>
</af:panelFormLayout>
```

For more information about the code that is generated when you drop an item from the Data Controls panel, see Section 28.2.2, "What Happens When You Create a Text Field."

When you choose to create an input form using an object that contains a defined list of values (LOV), then a selectOneChoice component is created instead of an inputText component. For example, the CustomerVO view object contains defined LOVs for the CountryId and CreditRatingId attributes. When you drop the Customers data control object as an ADF Form, a dropdown list showing all values is created for each LOV (instead of an empty input text field). For more information about how these lists work, see Section 5.12, "Working with List of Values (LOV) in View Object Attributes." For more information on how these lists work for adapter-based data controls, see “Creating List of Values Objects” in Developing Applications with Oracle ADF Data Controls. For more information about using the lists on a JSF page, see Section 32.3, "Creating a Selection List."

Note: If the object contains a structured attribute (an attribute that is neither a Java primitive type nor a collection), that attribute will not appear in the dialog, and it will not have a corresponding component in the form. You will need to create those fields manually.
28.4 Creating Command Components Using Data Control Operations

In addition to providing a representation of your data objects, the Data Controls panel also has nodes that represent standard operations for use in a form. These built-in operations enable you to declaratively handle common form functions such as navigating between records and committing changes to a database. Most operations are available for individual data collections in a data control. The Commit and Rollback operations are available on the whole data control. When you drag an operation from the Data Controls panel to a page, you are prompted to choose what kind of command component to create, such as a button or a link.

Figure 28–8 shows the operations available for the Countries collection in the Summit ADF sample application.

**Figure 28–8 Data Control Collection Operations**

This section shows how to create command components from built-in data control operations. For information on other ways you can use command components in a databound page, see Chapter 30, "Using Command Components to Invoke Functionality in the View Layer."

28.4.1 How to Create Command Components From Operations

To create a command component based on a data control operation, you drag and drop the operation from the Data Controls panel to a page.

**Before You Begin:**

It may be helpful to have a general understanding of using data control operations to create command components. For more information, see Chapter 28.4, "Creating Command Components Using Data Control Operations."

You will need to complete these tasks:
■ Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

■ Create a JSF page as described in Section 26.3, "Creating a Web Page."

To create a command component from an operation:
1. From the Data Controls panel, drag the operation onto the page.
2. From the ensuing context menu, choose either ADF Button or ADF Link.

28.4.2 What Happens When You Create Command Components Using Operations

When you drop an operation to create a command component, JDeveloper:

■ Defines an action binding in the page definition file for the associated operation
■ Configures the iterator binding to use partial page rendering for the collection
■ Inserts code in the JSF page for the command component

28.4.2.1 Action Bindings Created for Operations

Action bindings execute business logic. For example, they can invoke operations on the action binding object. These operations operate on the iterator or on the data control itself.

Like value bindings, action bindings for operations contain a reference to the iterator binding when the action binding is bound to one of the iterator-level actions, such as Next or Previous. These types of actions are performed by the iterator, which determines the current object and can therefore determine the correct object to display when a navigation button is clicked. Action bindings to actions that are not at the iterator level, such as custom methods on an application module or the commit or rollback operations, will not contain this reference.

Action bindings use the RequiresUpdateModel property, which determines whether or not the model needs to be updated before the action is executed. In the case of navigation operations, by default this property is set to true, which means that any changes made at the view layer must be moved to the model before navigation can occur.

Example 28–6 shows the action bindings for the navigation operations.

Example 28–6  Page Definition Code for an Operation Action Binding

```xml
<action IterBinding="CustomersIterator" id="First" RequiresUpdateModel="true" Action="first"/>
<action IterBinding="CustomersIterator" id="Previous" RequiresUpdateModel="true" Action="previous"/>
<action IterBinding="CustomersIterator" id="Next" RequiresUpdateModel="true" Action="next"/>
<action IterBinding="CustomersIterator" id="Last" RequiresUpdateModel="true" Action="last"/>
```

28.4.2.2 Iterator RangeSize Attribute Defined

Iterator bindings have a rangeSize attribute that the binding uses to determine the number of data objects to make available for the page for each iteration. This attribute
helps in situations when the number of objects in the data source is quite large. Instead of returning all objects, the iterator binding returns only a set number, which then become accessible to the other bindings. Once the iterator reaches the end of the range, it accesses the next set. Example 28–7 shows the default range size for the Customers iterator.

**Example 28–7  RangeSize Attribute for an Iterator**

```xml
<iterator Binds="Customers" RangeSize="25"
  DataControl="BackOfficeAppModuleDataControl"
  id="CustomersIterator"
  ChangeEventPolicy="ppr"/>
```

**Note:** This `rangeSize` attribute is not the same as the `rows` attribute on a table component. For more information, see Table 29–1, "ADF Faces Table Attributes and Populated Values".

When the iterator binding is initially generated, the `RangeSize` attribute is set to 25. This means that a user can view 25 objects, navigating back and forth between them, without needing to access the data source. The iterator keeps track of the current object. Once a user clicks a button that requires a new range (for example, clicking the Next button on object number 25), the binding object executes its associated method against the iterator, and the iterator retrieves another set of 25 records. The bindings then work with that set. You can change this setting as needed. You can set it to -1 to have the full record set returned. If the `RangeSize` attribute is not specified, the full record set is returned.

### 28.4.2.3 EL Expressions Created to Bind to Operations

When you create command components using data control operations, JDeveloper creates an EL expression that binds a command button’s `actionListener` attribute to the `execute` property of the action binding for the given operation.

At runtime an action binding will be an instance of the `FacesCtrlActionBinding` class, which extends the core `JUCtrlActionBinding` implementation class. The `FacesCtrlActionBinding` class adds the following methods:

- **public void execute(ActionEvent event):** This is the method that is referenced in the `actionListener` property, for example `#{bindings.First.execute}`.
  
  This expression causes the binding’s operation to be invoked on the iterator when a user clicks the button. For example, the `First` command button’s `actionListener` attribute is bound to the `execute` method on the `First` action binding.

- **public String outcome():** This can be referenced in an `Action` property, for example `#{bindings.Next.outcome}`.
  
  This can be used for the result of a method action binding (once converted to a `String`) as a JSF navigation outcome to determine the next page to navigate to.

**Note:** Using the outcome method on the action binding breaks the separation between the view-controller layer and the model layer, so it should be rarely used.
Every action binding for an operation has an enabled boolean property that Oracle ADF sets to false when the operation should not be invoked. By default, JDeveloper binds the UI component’s disabled attribute to this value to determine whether or not the component should be enabled. For example, the UI component for the First button has the following as the value for its disabled attribute:

```#{!bindings.First.enabled}```

This expression evaluates to true whenever the binding is not enabled, that is, when the operation should not be invoked, thereby disabling the button. In this example, because the framework will set the enabled property on the binding to false whenever the first record is being shown, the First button will automatically be disabled because its disabled attribute is set to be true whenever enabled is False. For more information about the enabled property, see Appendix B, "Oracle ADF Binding Properties."

Example 28–8 shows the code generated after dropping the Create and Delete operations as buttons on a page.

**Example 28–8  JSF Code For Command Buttons Bound to ADF Operations**

```xml
<af:button actionListener="#{bindings.Create.execute}" text="Create"
            disabled="#{!bindings.Create.enabled}" id="b5"/>
<af:button actionListener="#{bindings.Delete.execute}" text="Delete"
            disabled="#{!bindings.Delete.enabled}" id="b6"/>
```

### 28.4.3 What Happens at Runtime: How Action Events and Action Listeners Work

When the user clicks a command component, the form is submitted and then an action event is fired. Action events might affect only the user interface (for example, a link to change the locale, causing different field prompts to display), or they might involve some logic processing in the back end (for example, a button to navigate to the next record). That event object then takes information about the current data object from the iterator and then passes it to the action binding’s method, which is bound to the command component through its actionListener attribute.

**Note:** An action listener is a class that registers to be notified when a command component fires an action event. An action listener contains an action listener method that processes the action event object passed to it by the command component.

For example, when the user clicks a Delete button that was created from the ADF Delete operation, an action event is fired. This event object stores currency information about the current data object, taken from the iterator. Because the component’s actionListener attribute is bound to the execute method of the Delete action binding, the Delete operation is invoked when the event fires. This method takes the currency information passed in the event object to determine which data object to delete.

Typically, the actionListener property’s value is in the form of an EL expression. For example, if the value of the actionListener attribute is `{bindings.Delete.execute}`, the execute() method of the Delete action binding is called.
28.4.4 What You May Need to Know About Overriding Declarative Methods

When you drop an operation or method as a command button, JDeveloper binds the button to the execute method for the operation or method. However, there may be occasions when you need to add logic before or after the existing logic. JDeveloper allows you to add logic to a declarative operation by creating a new method and property on a managed bean that provides access to the binding container. By default, this generated code executes the operation or method. You can then add logic before or after this code. JDeveloper automatically binds the command component to this new method, instead of to the execute property on the original operation or method. Now when the user clicks the button, the new method is executed. For more information, see Section 30.4, "Overriding Declarative Methods."

28.5 Incorporating Range Navigation into Forms

When you create an ADF Form, if you choose to include navigational controls, JDeveloper includes ADF Faces command components bound to existing navigational logic on the data control. This built-in logic allows the user to navigate through all the data objects in the collection. For example, Figure 28–9 shows a form that would be created if you drag the Countries collection and drop it as an ADF Form that uses navigation.

*Figure 28–9 Navigation in a Form*

<table>
<thead>
<tr>
<th>*Id</th>
<th>2</th>
</tr>
</thead>
<tbody>
<tr>
<td>Country</td>
<td>Japan</td>
</tr>
<tr>
<td>RegionId</td>
<td>4</td>
</tr>
<tr>
<td>CountryCode</td>
<td>JP</td>
</tr>
</tbody>
</table>

*Table 28–1 Built-in Navigation Operations*

| Operation   | When invoked, the associated iterator binding will...
<table>
<thead>
<tr>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>First</td>
<td>Move its current pointer to the beginning of the result set.</td>
</tr>
<tr>
<td>Last</td>
<td>Move its current pointer to the end of the result set.</td>
</tr>
<tr>
<td>Previous</td>
<td>Move its current pointer to the preceding object in the result set. If this object is outside the current range, the range is scrolled backward a number of objects equal to the range size.</td>
</tr>
<tr>
<td>Next</td>
<td>Move its current pointer to the next object in the result set. If this object is outside the current range, the range is scrolled forward a number of objects equal to the range size.</td>
</tr>
<tr>
<td>Previous Set</td>
<td>Move the range backward a number of objects equal to the range size attribute.</td>
</tr>
<tr>
<td>Next Set</td>
<td>Move the range forward a number of objects equal to the range size attribute.</td>
</tr>
</tbody>
</table>
28.5.1 How to Manually Insert Navigation Controls into a Form

By default, when you choose to include navigation when creating a form using the Data Controls panel, JDeveloper creates First, Last, Previous, and Next buttons that allow the user to navigate within the collection.

You can also add navigation buttons to an existing form manually.

Before you begin:

It may be helpful to have an understanding of navigation controls. For more information, see Section 28.5, "Incorporating Range Navigation into Forms."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

To manually add navigation buttons:

1. From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, and drag it onto the JSF page.

   For example, if you want to navigate forward through a collection of countries, you would drag the Next operation associated with the Countries collection. Figure 28–8 shows the operations associated with the Countries collection.

2. From the ensuing context menu, choose either ADF Button or ADF Link.

   Tip: You can also drop the First, Previous, Next, and Last buttons at once. To do so, drag the corresponding collection, and from the context menu, choose Navigation > ADF Navigation Buttons.

28.5.2 What Happens When You Manually Add Navigation Buttons

When you drop a navigation operation from the Data Controls panel, JDeveloper:

- Defines an action binding in the page definition file for the associated operations
- Configures the iterator binding to use partial page rendering for the collection
- Inserts code in the JSF page for the command components
- Inserts the partialSubmit attribute for the component in the JSF page and sets it to true in order to fire a partial page request when the button is clicked. For more information, see the "Using Partial Triggers" section of Developing Web User Interfaces with Oracle ADF Faces.

For more information on code generated for command components, see Section 28.4.2, "What Happens When You Create Command Components Using Operations."

Example 28–9 shows the code generated on the JSF page for navigation operation buttons.
Example 28–9  JSF Code for Navigation Buttons Bound to ADF Operations

```xml
<f:facet name="footer">
  <af:panelGroupLayout>
    <af:button actionListener="#{bindings.First.execute}" text="First"
        disabled="#{!bindings.First.enabled}"
        partialSubmit="true" id="cb1"/>
    <af:button actionListener="#{bindings.Previous.execute}" text="Previous"
        disabled="#{!bindings.Previous.enabled}"
        partialSubmit="true" id="cb2"/>
    <af:button actionListener="#{bindings.Next.execute}" text="Next"
        disabled="#{!bindings.Next.enabled}"
        partialSubmit="true" id="cb3"/>
    <af:button actionListener="#{bindings.Last.execute}" text="Last"
        disabled="#{!bindings.Last.enabled}"
        partialSubmit="true" id="cb4"/>
  </af:panelGroupLayout>
</f:facet>
```

28.5.3 What Happens at Runtime: Navigation Controls

When the user clicks a navigation control button, an action event is fired. That event object then takes information about the current data object from the iterator and then passes it to the operation’s method, which is bound to the button through its `actionListener` attribute.

For more information, see Section 28.4.3, "What Happens at Runtime: How Action Events and Action Listeners Work."

In addition, when a user clicks a navigation button, only those components associated with the same iterator as the button’s action binding are processed through the lifecycle. For more information, see Section 27.2.1, "What You May Need to Know About Partial Page Rendering and Iterator Bindings."

28.5.4 What You May Need to Know About the Browser Back Button and Navigating Through Records

You must use the navigation buttons to navigate through the records displayed in a form; you cannot use the browser’s back or forward buttons. Because navigation forms automatically use PPR, only part of the page goes through the lifecycle, meaning that when you click a navigation button, the components displaying the data are refreshed and display new data, and you actually remain on the same page. Therefore, when you click the browser’s back button, you will be returned to the page that was rendered before the page with the form, instead of to the previous record displayed in the form.

For example, say you are on a page that contains a link to view all current orders. When you click the link, you navigate to a page with a form and the first order, Order #101, is displayed. You then click Next and Order #102 is displayed. You click Next again, and Order #103 is displayed. If you click the browser’s back button, you will not be shown Order #102. Instead, you will be returned to the page that contained the link to view all current orders.
28.5.5 What You May Need to Know About the CacheResults Property

When you create a navigable form using the Data Controls panel, the CacheResults property on the associated iterator is set to true. This ensures that the iterator’s state, including currency information, is cached between requests, allowing it to determine the current object. If this property is set to false, navigation will not work.

28.6 Creating a Form to Edit an Existing Record

You can create a form that allows a user to edit the current data, and then commit those changes to the data source. To do this, you use operations that can modify data records associated with the collection or the data control itself to create command buttons. For example, you can use the Delete operation to create a button that allows a user to delete a record from the current range.

For data controls based on ADF Business Components or on EJB session beans that have an explicit commit model, it is important to note that these operations are executed only against objects in the ADF cache. You need to use the Commit operation on the root data control to actually commit any changes to the data source. You use the data control’s Rollback operation to roll back any changes made to the cached object. If the page is part of a transaction within a bounded task flow, you would most likely use these operations to resolve the transaction in a task flow return activity. For more information, see Section 24.3, "Managing Transactions in Task Flows."

28.6.1 How to Create an Edit Form

To create an edit form, you drop a collection on your page as a form and then drop the appropriate operations as command components.

Before you begin:
It may be helpful to have an understanding of creating edit forms. For more information, see Section 28.6, "Creating a Form to Edit an Existing Record."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

To create an edit form:

1. From the Data Controls panel, drag the collection for which you wish to create the form, and choose ADF Form from the context menu.

   This creates a form using inputText components, which will allow the user to edit the data in the fields.

2. In the Create Form dialog, set the fields and buttons that you would like added to the form and click OK.
3. Optionally, from the Data Controls panel, select any additional operation associated with the collection that you would like to add to the form, drag it to the page, and choose **ADF Button** or **ADF Link** from the context menu.

For example, if you want to be able to delete a country, you would select the **Delete** operation associated with the **Countries** collection. Figure 28–10 shows the operations associated with the **Countries** collection.

**Figure 28–10 Operations Associated with a Collection**

![Data Controls panel showing operations associated with the Countries collection](image)

4. Add operations to the page to save or cancel changes.

If the page is not part of a transaction within a bounded task flow, then you need to create buttons that allow the user either to commit or roll back the changes. From the Data Controls panel, drag the **Commit** and **Rollback** operations associated with the root-level data control, and drop them as either a command button or a command link. Figure 28–11 shows the commit and rollback operations for the **BackOfficeAppModuleDataControl** data control.

**Figure 28–11 Commit and Rollback Operations for a Data Control**

![Data Controls panel showing commit and rollback operations](image)

If the page is part of a transaction within a bounded task flow, then you can simply enter **Commit** and **Rollback** as the values for the transaction resolution.
when creating the task flow return activity. For more information, see Section 24.3, "Managing Transactions in Task Flows."

If you are basing the form on a data control that is based on business services other than ADF Business Components, the Commit and Rollback operations might not be available. For more information, see Section 28.6.3, "What You May Need to Know About Working With Data Controls for Stateless Business Services."

5. Optionally, change the autoSubmit property of each editable field to true.

Doing so enables any user changes to be submitted to the page when tabbing out of the field and thus enabling the Commit and Rollback operations, if they have not already been enabled by another sequence of events, such as a change to a field plus a button click.

You can access the autoSubmit property for a field by selecting the field and then scrolling to the Behavior section in the Properties window.

**Tip:** If the same page on which you create your edit form also has a table created from the same collection as the form, the table and the form use the same iterator binding, which enables the user to select the record to edit in the form by selecting a row in the table. For more information on creating databound tables, see Section 29.2, "Creating a Basic Table."

### 28.6.2 What Happens When You Create Edit Forms

For information on what happens when you drop a collection on to a page, see Section 28.3.2, "What Happens When You Create a Form Using a Data Control Collection."

Dropping any data control operation as a command button causes code generation similar to when you drop navigation operations. For more information, see Section 28.4.2, "What Happens When You Create Command Components Using Operations."

The only difference is that the action bindings for the Commit and Rollback operations do not require a reference to the iterator, because they execute a method on the application module (the data control itself), as opposed to the iterator. Note that the Rollback action has the RequiresUpdateModel property set to false. This is because the model should not be updated before the operation is executed, since all changes need to be discarded. Example 28–10 shows the action bindings generated in the page definition file for these operations.

**Example 28–10 Action Bindings for Commit and Rollback Operations**

```xml
<action id="Commit" RequiresUpdateModel="true" Action="commitTransaction"
    DataControl="BackOfficeAppModuleDataControl"/>
<action id="Rollback" RequiresUpdateModel="false"
    Action="rollbackTransaction"
    DataControl="BackOfficeAppModuleDataControl"/>
```

Table 28–2 shows the built-in non-navigation operations provided on data controls and data control objects, along with the result of invoking the operation or executing an event bound to the operation. For more information about action events, see Section 28.4.3, "What Happens at Runtime: How Action Events and Action Listeners Work."
### Table 28–2  More Built-in Operations

<table>
<thead>
<tr>
<th>Operation</th>
<th>When invoked, the associated iterator binding will...</th>
</tr>
</thead>
<tbody>
<tr>
<td>CreateInsert</td>
<td>Creates a row directly before the current row, inserts the new record into the row set, then moves the current row pointer to the new row. Note that the range does not move, meaning that the last row in the range may now be excluded from the range. For more information about using the CreateInsert operation to create objects, see Section 28.8, &quot;Creating an Input Form.&quot;</td>
</tr>
<tr>
<td>Note: CreateInsert is only available for data controls based on ADF Business Components application modules.</td>
<td></td>
</tr>
<tr>
<td>Create</td>
<td>Creates a row directly before the current row, then moves the current row pointer to the new row. Note that the range does not move, meaning that the last row in the range may now be excluded from the range. For data controls based on application modules and most other business services, the record will not be inserted into the row set, preventing a blank row should the user navigate away without actually creating data. The new row will be created when the user submits the data. For more information, see Section 29.4.5, &quot;What You May Need to Know About Create and CreateInsert.&quot; However, for JPA-based data controls, the Create operation does insert data into the row set and can be configured to persist the data. For more information, see &quot;Data Control Built-in Operations&quot; in Developing Applications with Oracle ADF Data Controls.</td>
</tr>
<tr>
<td>CreateWith Parameters</td>
<td>Same as the CreateInsert operation (the new record is inserted into the row set). However, it uses named parameters to create the object. Note: Create With Parameters is only available for data controls based on ADF Business Components application modules.</td>
</tr>
<tr>
<td>Delete</td>
<td>Deletes the current row from the cache and moves the current row pointer to the next row in the result set. Note that the range does not move, meaning that a row may be added to the end of the range. If the last row is deleted, the current row pointer moves to the preceding row. If there are no more rows in the collection, the enabled attribute is set to disabled.</td>
</tr>
<tr>
<td>RemoveRowWithKey</td>
<td>Uses the row key as a String converted from the value specified by the input field to remove the data object in the bound data collection.</td>
</tr>
<tr>
<td>SetCurrentRowWith Key</td>
<td>Sets the row key as a String converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection. For an example of when this is used, see Section 29.2.3, &quot;What You May Need to Know About Setting the Current Row in a Table.&quot;</td>
</tr>
<tr>
<td>SetCurrentRowWith KeyValue</td>
<td>Sets the current object on the iterator, given a key’s value. For more information, see Section 29.2.3, &quot;What You May Need to Know About Setting the Current Row in a Table.&quot;</td>
</tr>
<tr>
<td>ExecuteWithParams</td>
<td>Refreshes the data collection by first assigning new values to the named bind variables passed as parameters, then (re)executing the view object's query. You would use this operation in the same manner as you would use the CreateInsert operation to create an input form. For more information, see Section 28.8, &quot;Creating an Input Form.&quot; This operation appears only for view objects that have defined one or more named bind variables at design time. For more information, see Section 5.10, &quot;Working with Bind Variables.&quot; For EJB and bean data controls, this operation is only available on data control collection objects that are based on parameterized queries.</td>
</tr>
</tbody>
</table>
28.6.3 What You May Need to Know About Working With Data Controls for Stateless Business Services

When you create user interfaces based on ADF Business Components services, any data changes that a user makes are not propagated to the underlying database until the user triggers the Commit operation through a command component.

For user interfaces that are based on data controls for stateless business services, such as stateless EJB session beans or RESTful web services, the Commit and Rollback operations are not available. In such cases, you can use custom methods to handle interactions with the underlying database. In the case of EJB data controls, any persistEntity and mergeEntity methods in the session bean are exposed through the Data Controls panel, and you can create command components from them. For more information, see “About Commit Models for EJB Session Beans” in Developing Applications with Oracle ADF Data Controls.

28.7 Using Parameters to Create a Form

In Oracle ADF, there are several ways that you can create a form where the record that is displayed is determined by an input parameter. The following are some of those mechanisms:

- Create an ADF Parameter Form based on a data control collection’s ExecuteWithParams operation or on a custom method that takes parameters.
- Pass a parameter to the form through a task flow.
- Nest a setPropertyListener tag within a command component and provide application logic within a managed bean to access the parameters and invoke any needed logic.

This section covers the creation of ADF parameter forms based on the ExecuteWithParams operation. For information on passing parameters to a form through a task flow, see Chapter 22, “Using Parameters in Task Flows” and Section 23.3, “Specifying Parameters for an ADF Region.” For information on using the setPropertyListener tag, see Section 30.3, “Setting Parameter Values Using a Command Component.”

The ExecuteWithParams operation is available only for data control objects that contain parameters, such as those based on view objects containing bind variables and those based on JPA-based beans that contain named queries with parameters. For example, the Summit ADF sample application contains a view object instance called SalesPeople, which is based on the EmpVO view object, which contains the bind variable TitleIdBind. So, as shown in Figure 28–12, the SalesPeople object contains an ExecuteWithParams operation with a subnode for the TitleIdBind parameter.
View object bind variables and JPA parameterized queries allow you to supply attribute values at runtime to the view object or view criteria. The `ExecuteWithParams` operation refreshes the data collection by first assigning new values to the named bind variables passed as parameters, then (re)executing the view object’s query. For more information about bind variables in view objects, see Section 5.10, "Working with Bind Variables." For more information on named parameters in JPA queries, see "EJB Data Control Prerequisites and Considerations" in Developing Applications with Oracle ADF Data Controls.

### 28.7.1 How to Create a Form Using Parameters

To create a form using parameters, you drop the `ExecuteWithParams` operation of a collection on to a page as an ADF Parameter Form and then drop the collection itself as an ADF Form.

**Before you begin:**

It may be helpful to have an understanding of creating parameter forms. For more information, see Section 28.7, "Using Parameters to Create a Form."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

  Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Add bind variables to the view criteria definition as described in Section 5.10.2, "How to Add WHERE Clause Bind Variables to a View Object Definition."

  For JPA-based data controls you can create named queries in the session bean or service facade that specify named parameters. For more information, see "EJB Data Control Prerequisites and Considerations" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

**To create a parameter form based on the ExecuteWithParams operation:**

1. From the Data Controls panel, drag the `ExecuteWithParams` operation for the collection for which you wish to create the form, and choose ADF Parameter Form from the context menu.
2. In the Create Form dialog, select the parameters on which you want users to be able to query and click OK.

3. From the Data Controls panel, drag the corresponding collection, and drop it as the type of table or form that you want to display the results of the query based on the user input.

---

**Note:** You can also declaratively incorporate selection lists into parameter forms. To create a selection list, drag a parameter node that is a child of the `ExecuteWithParams` operation on to the form. Then drag the `ExecuteWithParams` operation and drop it as a button.

---

### 28.7.2 What Happens When You Create a Parameter Form

When you drop the `ExecuteWithParams` operation as a parameter form, JDeveloper:

- Inserts code in the JSF page for the form using `inputText` components bound to the attribute bindings, and a `button` component bound to the `ExecuteWithParams` operation.
- Defines the following in the page definition file:
  - A variable iterator for the attributes to use to access the variables (as opposed to a collection’s iterator which is used for other forms).
  - A `variableUsage` variable for each parameter to hold the data values. These variables inherit the default value and UI control hints from the view object named bind variables to which they are bound. The variables are local, meaning they live only during a single request. Though they are carried across subsequent post-backs to the same form, they are forgotten (and re-initialized) when a user navigates to some other page.
  - An action binding for the operation that contains `NamedData` elements for each parameter. Each `NamedData` element is bound to a corresponding variable. These bindings allow the operation to access the value for the parameter upon execution.
  - Attribute bindings for the associated attributes.

Example 28–11 shows the executables and bindings in the page definition file that are created by dropping the `SalesPeople` collection’s `ExecuteWithParams` operation on a page.

**Example 28–11 Executable and Binding Properties for a Parameter Form**

```xml
<executables>
  <variableIterator id="variables">
    <variableUsage DataControl="BackOfficeAppModuleDataControl"
      Binds="SalesPeople.variablesMap.TitleIdBind"
      Name="ExecuteWithParams_TitleIdBind" IsQueriable="false"/>
  </variableIterator>
  <iterator Binds="SalesPeople" RangeSize="25"
    DataControl="BackOfficeAppModuleDataControl"
    id="SalesPeopleIterator"/>
</executables>

<bindings>
  <action IterBinding="SalesPeopleIterator" id="ExecuteWithParams"
    RequiresUpdateModel="true"
    Action="executeWithParams">
    <NamedData NDName="TitleIdBind" NDType="java.lang.Integer">
```

---

You can also declaratively incorporate selection lists into parameter forms. To create a selection list, drag a parameter node that is a child of the `ExecuteWithParams` operation on to the form. Then drag the `ExecuteWithParams` operation and drop it as a button.

---

**Example 28–11 Executable and Binding Properties for a Parameter Form**

```xml
<executables>
  <variableIterator id="variables">
    <variableUsage DataControl="BackOfficeAppModuleDataControl"
      Binds="SalesPeople.variablesMap.TitleIdBind"
      Name="ExecuteWithParams_TitleIdBind" IsQueriable="false"/>
  </variableIterator>
  <iterator Binds="SalesPeople" RangeSize="25"
    DataControl="BackOfficeAppModuleDataControl"
    id="SalesPeopleIterator"/>
</executables>

<bindings>
  <action IterBinding="SalesPeopleIterator" id="ExecuteWithParams"
    RequiresUpdateModel="true"
    Action="executeWithParams">
    <NamedData NDName="TitleIdBind" NDType="java.lang.Integer">
```
When you drop the collection that will be used to display the results of the parameter form, code is generated for a basic form, as described in Section 28.3.2, "What Happens When You Create a Form Using a Data Control Collection." In addition, if you use a table to display the results, the partialTriggers property on table is set to the command button in the parameter form.

### 28.7.3 What Happens at Runtime: How Parameters are Populated

When the page is rendered, the framework checks if the page is being rendered for the first time and if the exception list has any items. If both are false, then the framework executes the `ExecuteWithParams` action binding. This action binding executes the query, taking the values of the named data elements as values for the needed parameters.

### 28.8 Creating an Input Form

You can create a form that allows a user to enter information for a new record and then commit that record to the data source. Creating a basic input form is similar to creating an edit form, except that the input form also contains the `CreateInsert` operation, which causes a blank row to be inserted into the row set which the user can then populate using a form.

You can create a simple input form by dragging and dropping a collection and the appropriate operations from the Data Controls panel on to a page. However, you might need to employ a selection of other techniques to control the user workflow and insert other form processing logic. Such techniques may include:

- Using parameters in ADF task flows to pass values with which to pre-populate given attributes of a new record. For more information, see Chapter 22.2, "Passing Parameters to a View Activity."
- Using task flow return activities to set the transaction boundary in the UI, as shown in Section 21.7, "Using Task Flow Return Activities."
- Embedding operations in task flow method calls, as shown in Section 22.3, "Passing Parameters to a Bounded Task Flow."
- Using managed beans to carry out some operations as shown in Section 30.4, "Overriding Declarative Methods."
- Incorporating the form into a region in a task flow as shown in Chapter 23, "Using Task Flows as Regions."
- Incorporating the form into a multi-step flow, as shown in Section 24.8, "Using Train Components in Bounded Task Flows."
- Placing the form inside a dialog as shown in Section 25.2, "Running a Bounded Task Flow in a Modal Dialog."
- Using save points as described in Section 24.3, "Managing Transactions in Task Flows."
The following section shows how to create a basic input form and provides information on a couple of variants.

### 28.8.1 How to Create an Input Form

Creating a basic input form involves creating an edit form and adding a command component for creating new records.

**Before you begin:**

It may be helpful to have an understanding of input forms. For more information, see Section 28.8, "Creating an Input Form."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete this task:

Create an edit form as described in Section 28.6.1, "How to Create an Edit Form."

**To create an input form:**

1. In the Data Controls panel, expand the node for the collection object on which the form is based.

2. Expand the collection’s **Operations** node and drag the **CreateInsert** operation to the edit form.

**Note:** The **CreateInsert** operation is available only for data controls based on ADF Business Components application modules. If your data control is based on another business service, use the **Create** operation instead. For more information on the differences between the two, see Table 28–2.

### 28.8.1.1 Creating an Input Form Using a Bounded Task Flow

You can use a task flow to provide the workflow for input forms. Instead of using command components to create new objects, you use a method call activity in the task flow or a method in a managed bean. Instead of using a command component to commit changes, you use a task flow return activity.

For example, you can use a method call activity in a task flow to call a data control object’s **CreateInsert** operation and then pass control to a view activity that displays a form where the user can enter the data.

**To create an input form within a bounded task flow:**

1. Create a bounded task flow as described in Section 20.2, "Creating a Task Flow."

2. In the Properties window, set the **Transaction** property to **Always Begin New Transaction**.

   For more information, see Section 24.3, "Managing Transactions in Task Flows."

3. In the bounded task flow, add a method call activity.

   For more information, see Section 21.5, "Using Method Call Activities."

4. From the Data Controls panel, drag the **CreateInsert** operation associated with the collection for which you are creating the form and drop it on the method activity.
5. With the method call activity still selected, in the Properties window, enter a string for the fixed-outcome property. After dropping the CreateInsert operation on to the method call activity, this value is set to CreateInsert, but you may want to change it to something more specific.

6. In the overview editor for the task flow, add a view activity that represents the page for the input form. For information on adding view activities, see Section 20.3, "Adding Activities to a Task Flow."

7. Add a control flow case from the method activity to the view activity.

8. With the control flow case still selected in the design editor, in the Properties window, make sure that the from-outcome property of the control flow case is the same as the value of the fixed-outcome property of the method activity set in Step 5.

9. Open the page for the view activity in the design editor, and from the Data Controls panel, drag the collection for which the form will be used to create a new record, and choose ADF Form from the context menu.

10. In the task flow, add a return activity. This return activity must execute the commit operation on the data control. For these procedures, see Section 21.7, "Using Task Flow Return Activities."

28.8.1.2 Using a Commit Button Instead of a Return Activity Within a Task Flow

Generally you should use a return activity to call the Commit operation. However, there might be cases where you need to use a command component for the Commit operation, such as when the task flow contains data managed by more than one data control or you need to commit the data before the end of the flow.

To create an input form that has a Commit button within the form:

1. Create an input form as described in Section 28.8.1.1, "Creating an Input Form Using a Bounded Task Flow," but without setting the task flow return activity.

2. In the Data Controls panel, drag the Commit operation for the data control that contains the collection associated with the input form, and drop it as a command button.

3. In the Structure window, select the command button for the commit operation.

4. In the Properties window, set the action to the outcome string that will navigate back to the method activity. You then need to add a control flow case from the page back to the activity, using the same outcome value.

5. Set the command button's disabled property to false.

   By default, JDeveloper binds the disabled attribute of the button to the enabled property of the binding, causing the button to be disabled when the enabled property is set to false. For this binding, the enabled property is false until an update has been posted. For the purposes of an input form, the button should always be enabled, since there will be no changes posted before the user needs to create the new object.

28.8.1.3 Creating an Input Form That Allows Multiple Entries in a Single Transaction

If you want the user to be able to create multiple entries before committing to the database, do the following:
To enable an input form to allow multiple entries in a single transaction:

1. Create an input form as described in Section 28.8.1.1, "Creating an Input Form Using a Bounded Task Flow"

2. In the task flow, add another control flow case from the view activity back to the method activity, and enter a value for the from-outcome method. For example, you might enter createAnother.

3. Drag and drop a command component from the Components window onto the page, and set the action attribute to the from-outcome just created. This will cause the task flow to return to the method activity and reinvoke the CreateInsert operation.

28.8.2 What Happens When You Create an Input Form

When you use an ADF Form to create an input form, JDeveloper:

- Creates an iterator binding for the collection and an action binding for the CreateInsert operation in the page definition for the method activity. The CreateInsert operation is responsible for creating a row in the row set and populating the data source with the entered data. In the page definition for the page, JDeveloper creates an iterator binding for the collection and attribute bindings for each of the attributes of the object in the collection, as for any other form. If you created command buttons or links using the Commit and Rollback operations, JDeveloper also creates action bindings for those operations.

- Inserts code in the JSF page for the form using ADF Faces inputText components, and in the case of the operations, button components.

28.8.3 What Happens at Runtime: CreateInsert Action from the Method Activity

When the CreateInsert button is clicked (or a method corresponding to that operation is called), the CreateInsert action binding is invoked, which executes the CreateInsertRow action, and a new blank instance for the collection is created.

Note: When you use a task flow method activity to the call the CreateInsert operation, the method activity’s binding container skips validation for required attributes during routing from the method activity to the view activity, allowing the blank instance to be displayed in the form on the page.

28.8.4 What You May Need to Know About Displaying Sequence Numbers

Because the Create action is executed before the page is displayed, if you are populating the primary key using sequences, the next number in the sequence will appear in the input text field, unlike the rest of the fields, which are blank. The sequence number is displayed because the associated entity class contains a method that uses an eager fetch to generate a sequence of numbers for the primary key attribute. The eager fetch populates the value as the row is created. Therefore, using sequences works as expected with input forms.

However, if instead you’ve configured the attribute’s type to DBSequence (which uses a database trigger to generate the sequence), the number would not be populated until the object is committed to the database. In this case, the user would see a negative number as a placeholder. To avoid this, you can use the following EL expression for the Rendered attribute of the input text field:
## 28.8.5 What You May Need to Know About Input Forms Backed By Stateless Services

If the data control on which your input form is based is a data control for a stateless business service, there is no built-in Commit operation for you to use to save changes back to the data source.

Instead, you need to use a custom method to save to the database. For more information, see Section 28.6.3, "What You May Need to Know About Working With Data Controls for Stateless Business Services."

## 28.9 Creating a Form with Dynamic Components

Instead of creating static databound forms where you provide tags for each component directly in the page, you can use a dynamic component to create forms where the binding metadata and the components used to display the bound content are determined at runtime.

This section provides information on creating databound dynamic forms. You can also use the dynamic component to create databound tables. For more information, see Section 29.5, "Creating a Table with Dynamic Components."

For more information on the dynamic form component, including how to create a custom data model, see "Determining Components at Runtime" in *Developing Web User Interfaces with Oracle ADF Faces*.

### 28.9.1 About Dynamic Components

ADF Faces provides the `dynamicComponent` tag that you can use to create model-driven forms and tables where the binding metadata and the tags used to display the bound content are determined at runtime.

The dynamic building of the bindings provides the following possibilities:

- Enables you to create pages where the fields displayed and the ADF Faces components used to display them are determined by the data model. Any changes to the data model, such as additional columns or changed UI hints are reflected in the page without having to redesign the page. For more information about UI hints on view objects, see Section 5.13, "Defining UI Hints for View Objects."

- Enables you to create pages based on polymorphic view objects, in which the fields available for a given record can differ depending on the record’s base entity object. Since the fields to display are determined at runtime, you do not have to include fields in the page that may not apply to certain records or do coding in the view layer to adjust the fields that are displayed for a given record. For more information about building business components that work with multiple row types, see Chapter 7, "Defining Polymorphic View Objects."

You set display information using UI hints on a view object instead of configuring the information in the Create Form or Create Table dialog when you drop the control onto the page. Then if you want to change how the data displays, you need only change it on the view object, and all dynamic components bound to that view object will change their display accordingly.
Figure 28–13 shows a dynamic form at runtime that was designed by setting UI hints for attributes on the CustomerVO view object and then dropping the Customers data control collection as a dynamic form. Among the UI hints set were LABEL and DISPLAYHINT (the latter of which can be set to hide in order to not include the given attribute in the dynamic form).

Figure 28–13 Dynamic Form Displays Based on Hints Set on the View Object

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Id</td>
<td>1</td>
</tr>
<tr>
<td>Name</td>
<td>ABC Company</td>
</tr>
<tr>
<td>Phone</td>
<td></td>
</tr>
<tr>
<td>Address</td>
<td>514 W Superior St</td>
</tr>
<tr>
<td>City</td>
<td>Kokomo</td>
</tr>
<tr>
<td>State</td>
<td></td>
</tr>
<tr>
<td>Country</td>
<td></td>
</tr>
<tr>
<td>Zip code</td>
<td>46901</td>
</tr>
<tr>
<td>Sales Rep Name</td>
<td>Magee</td>
</tr>
</tbody>
</table>

The following ADF Faces components can be rendered at runtime when you use af:dynamicComponent at design time:

- af:inputText
- af:inputDate
- af:inputListOfValues
- af:selectOneChoice
- af:selectManyChoice
- af:selectOneListbox
- af:selectManyListbox
- af:selectOneRadio
- af:selectBooleanRadio
- af:selectBooleanCheckbox
- af:selectManyCheckbox

### 28.9.2 How to Create a Dynamic Form

To create a dynamic form, you drop a collection from the data controls panel as an ADF Form and specify that the fields be generated dynamically.

**Before you begin:**

It may be helpful to have an understanding of dynamic forms. For more information, see Section 28.9, "Creating a Form with Dynamic Components."

If you want to take advantage of dynamic forms to display records that contain varying attributes, you first need to have data objects that contain that capability. For information on creating view objects with this capability, see Section 7, "Defining Polymorphic View Objects."
You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete these tasks:

■ Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

■ Create a JSF page as described in Section 26.3, "Creating a Web Page."

To create a dynamic form:

1. Set UI hints on the view object or data control structure definition file that corresponds to the collection for which you are creating the dynamic form.
   
   UI hints determine things such as the type of UI component to use to display the attribute, the label, the tooltip, whether the field should be automatically submitted, etc. You can also determine whether a given attribute is displayed or hidden. For procedures on creating UI hints, see Section 5.13, "Defining UI Hints for View Objects."

2. Optionally, for the category hint on each view object attribute, specify a category or click the New Category icon to create a new category.

   Any attributes that have the same category can be grouped together in dynamic forms that you create based on that view object.

3. Optionally, for any categories that you have created in step 2, set the UI hints for the category’s label and tooltip. These can be set in the UI Categories tab of the view object’s overview editor.

4. From the Data Controls panel, select the collection that represents the view object.

5. Drag the collection onto the page, and from the context menu, choose ADF Form.

6. In the Create Form dialog, select the Fields Generated at Runtime checkbox.

7. If you have specified any categories for attributes in step 2, select the Include Field Groups checkbox in order for the form to group the attributes according to those categories.

28.9.3 What Happens When You Create Dynamic Forms

When you drop a collection as a dynamic form on a page, the following things happen:

■ The page definition is populated with a variableIterator binding, an iterator binding to the iterator, and a tree value binding.

■ The JSF page is populated with one or more iterator and dynamicComponent tags. In addition, if the Include Field Groups option is selected, switcher and group tags are added.

28.9.3.1 Bindings Created for the Dynamic Form

The page definition file for a dynamic form contains the following executables and bindings:
Creating a Form with Dynamic Components

- **variableIterator**: an internal iterator that contains variables declared for the binding container.
- **iterator**: the iterator binding for the collection. For more information on iterator bindings, see Section 28.2.2.1, "Iterator Bindings Created in the Page Definition File."
- **tree**: the value binding for the attributes of the collection. Unlike a standard form, which has individual value bindings for each attribute set at design time, a dynamic form uses a single tree value binding to encompass the attributes that are exposed at runtime.

Tree value bindings are also used for databound tables (both standard and dynamic). For more information, see Section 29.2.2.1, "Iterator and Value Bindings for Tables."

Example 28–12 shows the bindings for a page that contains a dynamic form component based on the *Customers* collection.

**Example 28–12  Page Definition Code for a Dynamic Component**

```xml
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="SummitAppModuleDataControl.dataProvider.BackOfficeAM.Customers" DataControl="SummitAppModuleDataControl" RangeSize="25" id="CustomersIterator"/>
</executables>

<bindings>
  <tree IterBinding="CustomersIterator" id="Customers">
    <nodeDefinition DefName="oracle.summit.model.views.CustomerVO" Name="Customers0" />
  </tree>
</bindings>
```

**28.9.3.2 Tags Created for a Dynamic Form without Grouping**

In the JSF page, JDeveloper inserts an *iterator* tag, within which it nests a *dynamicComponent* tag. The *iterator* tag loops through all of the attributes that are exposed by the collection at runtime and uses the *dynamicComponent* tag to render the appropriate component for each attribute on the page.

Example 28–13 shows the code that is generated when you drop the *Customers* data control object as a dynamic form (but do not select the Include Field Groups option).

**Example 28–13  JSF Page Code for a Dynamic Form**

```xml
<af:panelFormLayout id="pf1">
  <af:iterator id="i1" value="#{bindings.Customers.attributesModel.attributes}" var="attr">
    <af:dynamicComponent id="d2" attributeModel="#{attr}" />
    value="#{bindings[attr.containerName][attr.name].inputValue}" />
  </af:iterator>
</af:panelFormLayout>
```

The value attribute of the *iterator* tag uses an EL expression that evaluates to the attributesModel.attributes property of the collection’s tree binding. The attributesModel property is used to retrieve the data object’s attributes and their metadata, such as component type, label, tooltip, and other properties of the real component to be rendered. The attributes property of attributesModel
signifies that a flat (unhierarchical) list of displayable attributes and their metadata is provided.

The attributeModel attribute of the dynamicComponent tag is bound to the EL expression #{attr}, which references the variable that is defined in the iterator’s var attribute and that serves as a pointer to the current attribute of the data control collection and its corresponding metadata. The EL expression for the dynamicComponent’s value attribute also references the variable attr.

### 28.9.3.3 Tags Created for a Dynamic Form with Grouping

If you have selected the Include Field Groups checkbox in the Create Form dialog, the generated JSF page includes the switcher and group tags, in addition to the tags described in Section 28.9.3.2, "Tags Created for a Dynamic Form without Grouping."

The switcher tag is nested directly within a an iterator tag. Within the switcher tag are nested facet tags named GROUP and ATTRIBUTE. The GROUP facet contains a group tag, within which is an outputText tag to display the group name and an iterator tag, which contains a dynamicComponent tag. The ATTRIBUTE facet only contains a dynamicComponent tag.

For each attribute that the high-level iterator iterates over, the switcher dynamically determines whether to render a group or a component for the individual attribute. If it renders a group, the iterator within the group then is used to render the components for the attributes within that group.

Example 28–14 shows the code that is generated if you create a dynamic form based on the Customers collection and choose to include field groups.

### Example 28–14  JSF Page Code for a Dynamic Form With Attribute Groups

```xml
<af:panelFormLayout id="pfl1">
  <af:iterator id="i1" value="#{bindings.Customers.attributesModel.hierarchicalAttributes}" var="attr">
    <af:switcher id="sw1" facetName="#{attr.descriptorType}" defaultFacet="ATTRIBUTE">
      <f:facet name="GROUP">
        <af:group title="#{attr.label}" id="g1">
          <af:outputText value="#{attr.name}" id="ot1"/>
          <af:iterator id="gi1" value="#{attr.descriptors}" var="nestedAttr">
            <af:dynamicComponent id="gd1" attributeModel="#{nestedAttr}"/>
          </af:iterator>
        </af:group>
      </f:facet>
      <f:facet name="ATTRIBUTE">
        <af:dynamicComponent id="ad1" attributeModel="#{attr}"/>
      </f:facet>
    </af:switcher>
  </af:iterator>
</af:panelFormLayout>
```

The value attribute of the iterator tag uses an EL expression that evaluates to the attributesModel.hierarchicalAttributes property of the collection’s tree binding. The attributesModel property is used to retrieve the data object’s attributes and their metadata, such as component type, label, tooltip, and other properties of the real component to be rendered. The hierarchicalAttributes
property signifies that a hierarchical list of displayable attributes and their metadata is provided, including any categories that have been set for any attributes in the UI hints. The attributeModel attribute of the dynamicComponent tag is set to the EL expression #{attr}, which references the variable that is defined in the iterator’s var attribute and that serves as a pointer to the current attribute (or category) of the data control collection and its corresponding metadata.

28.9.4 What Happens at Runtime: How Attribute Values Are Dynamically Determined
When a page with dynamic components is rendered, the bindings are created just as they are when items are dropped from the Data Controls panel at design time, except that they are created at runtime.

At runtime, the iterator iterates over the set of attributes and instantiates a dynamicComponent for each attribute. The dynamic component uses its attributeModel property to obtain information from the iterator about the current attribute, such as label and control type. Each dynamicComponent then renders a component based on the metadata that is returned for the attribute.

If the DISPLAYHINT UI hint for an attribute is set to Hide, no component for the attribute is rendered.

If the dynamic form is created from a data control object that is based on a polymorphic view object, the rendered components depend on the row type for the currently selected record.

28.9.5 How to Apply Validators and Converters to a Dynamic Component
By default, standard ADF Faces converters and validators are applied to the components generated at runtime when using dynamic components. For example, converterDateTime converters are applied to components based on attributes of type TimeStamp.

If you need to add more specific validation or conversion to a component, you can do so by adding ADF Faces validator and converter tags to the source for the dynamic component and use the tags’ disabled attribute to determine on which attributes the validators and converters are applied.

Before you begin:
It may be helpful to have an understanding of dynamic forms. For more information, see Section 28.9, "Creating a Form with Dynamic Components."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete this task:
Create a dynamic form as shown in Section 28.9.2, "How to Create a Dynamic Form" or a dynamic table as shown in Section 29.5.1, "How to Create a Dynamic Table."

To manually insert an ADF Faces validator or converter into a dynamic form:
1. Open the page containing the dynamic component in the source editor.
2. Within the <af:dynamicComponent> tag, insert any validator and converter components that you want to use.
3. Within the each validator and converter tag, insert the disabled attribute and bind it to an EL expression that disables the tag for all attributes except for those to which you want to apply it.
For example, the following expression would enable a validator only for the Hiredate attribute:

#{attr.name == 'Hiredate' ? false : true}

Example 28–15 shows a dynamic component with two validators and two converters applied.

**Example 28–15 Validators and Converters Applied to a Dynamic Component**

```af:panelFormLayout id="pfl1">
  <af:iterator id="i1" value="#{bindings.EmpVO1.attributesModel.attributes}" var="attr">
    <af:dynamicComponent
      value="#{bindings[attr.containerName][attr.name].inputValue}"
      attributeModel="#{attr}" id="dc1"/>
    <af:convertDateTime disabled="#{attr.name == 'Hiredate' ? false : true}" pattern="yyyy/MM/dd"/>
    <af:convertNumber disabled="#{attr.name == 'Sal' ? false : true}" pattern="#,###,###"/>
    <af:validateLength disabled="#{attr.name == 'Job' ? false : true}" maximum="10" hintMaximum="maxmum length is 10"/>
    <af:validateLongRange disabled="#{attr.name == 'Sal' ? false : true}" minimum="1000"/>
  </af:dynamicComponent>
</af:iterator>
</af:panelFormLayout>
```

### 28.9.6 What You May Need to Know About Mixing Dynamic Components with Static Components

When you create a dynamic form, you essentially create a block of components that are rendered dynamically. It is possible place static components before and after that block of components, but you can not intersperse static components within that block. Example 28–16 illustrates the granularity of mixing static and dynamic components that is possible. It consists of three group tags, the first and third of which contain static content and the second of which contains an iterator tag with a nested dynamicComponent tag.

**Example 28–16 Mixing Static Content with Dynamic Content**

```af:group title="static before dynamic" id="g1">
  <af:separator id="sp2"/>
    <f:validator binding="#{bindings.Empno.validator}"/>
    <af:convertNumber groupingUsed="false" pattern="#{bindings.Empno.format}"/>
  </af:inputText>
</af:group>
```

### 28.9.6 Mixing Static Content with Dynamic Content

```af:group title="dynamic part" id="g2">
  <af:separator id="sp3"/>
  <af:panelFormLayout id="pfl1">
    <af:iterator id="i1" value="#{bindings.EmpVO1.attributesModel.attributes}" var="attr">
      ...<af:dynamicComponent...
```

Creating a Basic Datasound Page 28-37
Creating a Form with Dynamic Components

28.9.7 How to Programmatically Set Dynamic Component Behavior

If you have any custom processing that you need to do to determine how the dynamic component is rendered, you can do so in a managed bean and then bind the dynamic component’s attributeModel property to the appropriate bean method.

Before you begin:
It may be helpful to have an understanding of dynamic forms. For more information, see Section 28.9, "Creating a Form with Dynamic Components."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete this task:
Create a dynamic form as shown in Section 28.9.2, "How to Create a Dynamic Form" or a dynamic table as shown in Section 29.5.1, "How to Create a Dynamic Table."

To programmatically set a dynamic component’s behavior:
1. In the UI project that contains the dynamic component, create a Java class that extends the oracle.adf.view.rich.model.BaseAttributeDescriptor class.

Example 28–17 shows a sample class that adds a method to apply a custom style to the label for the Sal attribute.

Example 28–17 Custom Implementation of BaseAttributeDescriptor

```java
public class CustomizedDescriptor extends BaseAttributeDescriptor {
    public CustomizedDescriptor(BaseAttributeDescriptor base) {
        _base = base;
    }

    public Object getLabelStyle() {
        if (getName().equals("Sal"))
            return "color:red; font-weight:bold";
        else
            return null;
    }
}
```
2. Create a managed bean for the page. For more information, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

3. In the managed bean, create a method that returns an instance of the custom descriptor that you created in step 1. Example 28–18 shows such a method.

**Example 28–18 Managed Bean Method That Returns a Custom Attribute Descriptor**

```java
public CustomizedDescriptor getCustomizedAttributes(String attrName)
{
    // create value expression for "#{attrName}" and evaluate it to get object
    // of 'attr'
    BaseAttributeDescriptor attrMetadata = null;
    Class klass = null;

    try
    {
        klass =
        ClassLoaderUtils.loadClass("oracle.adf.view.rich.model.BaseAttributeDescriptor");
    }
    catch (ClassNotFoundException e)
    {
        throw new RuntimeException("Can not find class
        oracle.adf.view.rich.model.BaseAttributeDescriptor");
    }

    FacesContext facesContext = FacesContext.getCurrentInstance();
    ELContext elContext = facesContext.getELContext();
    ValueExpression valueExpression = createValueExpression(attrName, klass);

    if (valueExpression != null)
    {
        attrMetadata = (BaseAttributeDescriptor)valueExpression.getValue(elContext);
        return new CustomizedDescriptor(attrMetadata);
    }

    return null;
}
```

4. In the source editor for the page containing the dynamic component, bind the dynamic component's `attributeModel` property to the managed bean method that returns the customized attribute descriptor.

**Example 28–19 attributeModel Attribute Bound to a Managed Bean**

```xml
<af:panelFormLayout id="pfl1">
    <af:iterator id="i1" value="#{bindings.EmpVO1.attributesModel.attributes}" var="attr">
        <af:dynamicComponent value="#{bindings[attr.containerName][attr.name].inputValue}"
            attributeModel="#{attributeCustomBean.getCustomizedAttributes('attr')}"/>
    </af:iterator>
</af:panelFormLayout>
```
28.9.8 How to Access a Dynamic Component Programmatically

If you need to access a dynamic component instance programmatically to make changes based on a user action, you can do so by using a managed bean.

Before you begin:

It may be helpful to have an understanding of dynamic forms. For more information, see Section 28.9, "Creating a Form with Dynamic Components."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete this task:

Create a dynamic form as shown in Section 28.9.2, "How to Create a Dynamic Form" or a dynamic table as shown in Section 29.5.1, "How to Create a Dynamic Table."

To programmatically access a dynamic component's binding instance:

1. Create a managed bean method that identifies dynamic component, casts the component to RichDynamicComponent, and then applies any changes.
   For more information, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

2. In the page containing the dynamic component, add a command component to the page and bind its actionListener property to the managed bean method.

Example 28–20 shows a managed bean method that changes the label style for a dynamic component.

Example 28–20 Managed Bean Code to Access a Dynamic Component's Binding Instance

```java
public void changeLabelColor (ActionEvent event)
{
    UIComponent component = event.getComponent().getParent();
    component = component.findComponent("pfl1");

    while(component != null)
    {
        if(component.getId().equals("it1"))
        {
            RichDynamicComponent rdc = (RichDynamicComponent)component;
            rdc.setLabelStyle("color:red");
            break;
        } else
        {
            component = component.getChildren().get(0);
        }
    }
}
```

28.9.9 How to Access a Dynamic Component’s Binding Instance Programmatically

If you need to access a runtime binding instance of a dynamic component programmatically, you can do so using a managed bean.

Before you begin:

It may be helpful to have an understanding of dynamic forms. For more information, see Section 28.9, "Creating a Form with Dynamic Components."
You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete this task:

Create a dynamic form as shown in Section 28.9.2, "How to Create a Dynamic Form" or a dynamic table as shown in Section 29.5.1, "How to Create a Dynamic Table."

To access a dynamic component's binding instance programmatically:

1. Create a managed bean method that accesses the binding container through the FacesContext, gets the AttributesModel, and then applies the desired business logic.

   For more information, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

2. In the page containing the dynamic component, add a command component to the page and bind its actionListener property to the managed bean method.

Example 28–21 illustrates a managed bean method that will set the DeptNo value of the current row to 9999.

Example 28–21 Managed Bean Method That Accesses a Dynamic Component's Binding Context

```java
public void setValueThroughBinding(ActionEvent event) {
    // get binding container
    FacesContext facesContext = FacesContext.getCurrentInstance();
    ELContext elContext = facesContext.getELContext();
    ValueExpression valueExpression = createValueExpression("bindings",
                DCBindingContainer.class);
    DCBindingContainer binding = (DCBindingContainer)
        valueExpression.getValue(elContext);

    // get AttributesModel and attribute metadata list
    valueExpression = createValueExpression("bindings.EmpVO1.attributesModel",
                AttributesModel.class);
    AttributesModel attributesModel = (AttributesModel)
        valueExpression.getValue(elContext);
    List<BaseAttributeDescriptor> attrList = attributesModel.getAttributes();

    // get AttributeMetadata for "Empno"
    BaseAttributeDescriptor deptNoAttributeBase = null;
    FacesAttributeDescriptor deptNoAttribute = null;
    for (BaseAttributeDescriptor attrDescriptor: attrList) {
        if ("Comm".equals(attrDescriptor.getName())) {
            deptNoAttributeBase = attrDescriptor;
            break;
        }
    }
    deptNoAttribute = (FacesAttributeDescriptor)deptNoAttributeBase;
    if (deptNoAttribute == null || deptNoAttribute.getContainerName() == null) {
        System.out.println("AttributesModel of Empno or its model name");
        System.out.println("can not be found.");
        return;
    }

    // set DeptNo value to 9999
    deptNoAttribute.setValue(9999);
}
```
// get Deptno attribute value binding, set input value
JUFormBinding fb = (JUFormBinding) binding.findExecutableBinding((String)
    deptNoAttribute.getContainerName());
JUCtrlValueBinding valueBinding = (JUCtrlValueBinding)
    fb.getControlBinding(deptNoAttribute.getName());
valueBinding.setInputValue(Integer.valueOf(9999));
System.out.println("Found JUCtrlValueBinding "+ deptNoAttribute.getName()");
System.out.println("set its value to 9999.");
}

28.10 Modifying the UI Components and Bindings on a Form

Once you use the Data Controls panel to create any type of form (except a dynamic form), you can then delete attributes, change the order in which they are displayed, change the component used to display data, and change the attribute to which the components are bound.

---

**Note:** You cannot change how a dynamic form displays using the following procedures. You must change display information on the view object or entity object instead.

---

28.10.1 How to Modify the UI Components and Bindings

You can modify certain aspects of the default components dropped from the Data Controls panel. You can use the Structure window to change the order in which components are displayed, to add new components or change existing components, or to delete components. You can use the Properties window to change or delete bindings, or to change the label displayed for a component.

**Before you begin:**

It may be helpful to have a general understanding of working with UI components after they have been generated. For more information, see Section 28.10, "Modifying the UI Components and Bindings on a Form."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 28.1.2, "Additional Functionality for Databound Pages."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

**To modify default components and bindings:**

1. Use the Structure window to do the following:

   - Change the order of the UI components by dragging them up or down the tree. A black line with an arrowhead denotes where the UI component will be placed.
- Add a UI component. Right-click an existing UI component in the Structure window and choose to place the new component before, after, or inside the selected component. You then choose from a list of UI components.

- Bind a UI component. Right-click an existing UI component in the Structure window and choose **Bind to ADF Control**. You can then select the object to which you want your component bound.

- Rebind a UI component. Right-click an existing UI component in the Structure window and choose **Rebind to another ADF Control**. You can then select the new control object to which you want your component bound.

- Delete a UI component. Right-click the component and choose **Delete**. If you wish to keep the component, but delete the binding, you need to use the Properties window. See the second bullet point in Step 2.

2. With the UI component selected in the Structure window, you can then do the following in the Properties window:

- Add a non-ADF binding for the UI component. Enter an EL expression in the **Value** field, or use the dropdown menu and choose **Edit**.

- Delete a binding for the UI component by deleting the EL expression.

- Change the label for the UI component. By default, the label is bound to the binding’s **label** property of its hint. This property allows your page to use the UI control hints for labels that you have defined for your entity object attributes or view object attributes. The UI hints allow you to change the value once and have it appear the same on all pages that display the label.

  You can change the label just for the current page. To do so, select the **label** attribute. You can enter text or an EL expression to bind the label value to something else, for example, a key in a properties or resource file.

  For example, the **inputText** component used to display the name of a product might have the following for its **Label** attribute:

  ```elixir
  #{bindings.ProductName.hints.label}
  ```

  However, you could change the expression to instead bind to a key in a properties file, for example:

  ```elixir
  #{properties['productName']}
  ```

  In this example, `properties` is a variable defined in the JSF page used to load a properties file.

28.10.2 What Happens When You Modify Attributes and Bindings

When you modify how an attribute is displayed by moving or changing the UI component, JDeveloper changes the corresponding code on the JSF page. When you use the binding editors to add or change a binding, JDeveloper adds the code to the JSF page, and also adds the appropriate elements to the page definition file.
This chapter describes how to create tables with data modeled from ADF Business Components, using ADF data controls and ADF Faces components, including editable tables, input tables, and dynamic tables.

This chapter includes the following sections:

- Section 29.1, "About Creating ADF Databound Tables"
- Section 29.2, "Creating a Basic Table"
- Section 29.3, "Creating an Editable Table"
- Section 29.4, "Creating an Input Table"
- Section 29.5, "Creating a Table with Dynamic Components"
- Section 29.6, "Modifying the Attributes Displayed in the Table"

### 29.1 About Creating ADF Databound Tables

Unlike forms, tables allow you to display more than one data object from a collection at a time.

You can create tables that simply display data, or you can create tables that allow you to edit or create data. Once you drop a collection as a table, you can add command buttons bound to actions that execute some logic on a selected row. You can also modify the default components to suit your needs.

### 29.1.1 ADF Databound Tables Use Cases and Examples

Figure 29–1 shows the Products table on the Inventory Control tab of the Summit sample application for Oracle ADF. This table is used to display all of the products in the inventory and enables the user to select a product to see its inventory status in an adjoining graph.
Figure 29–1  Read-only Table

Products

<table>
<thead>
<tr>
<th>Id</th>
<th>Name</th>
<th>Description</th>
<th>Suggested Wholesale Price</th>
</tr>
</thead>
<tbody>
<tr>
<td>1001</td>
<td>Bunny Boot</td>
<td>Beginners ski boot</td>
<td>$150.00</td>
</tr>
<tr>
<td>1002</td>
<td>Ace Ski Boot</td>
<td>Intermediate ski boot</td>
<td>$200.00</td>
</tr>
<tr>
<td>1003</td>
<td>Pro Ski Boot</td>
<td>Advanced ski boot</td>
<td>$410.00</td>
</tr>
<tr>
<td>1004</td>
<td>Bunny Ski Pole</td>
<td>Beginner's ski pole</td>
<td>$16.25</td>
</tr>
<tr>
<td>1005</td>
<td>Ace Ski Pole</td>
<td>Intermediate ski pole</td>
<td>$21.95</td>
</tr>
<tr>
<td>1006</td>
<td>Pro Ski Pole</td>
<td>Advanced ski pole</td>
<td>$40.95</td>
</tr>
<tr>
<td>2010</td>
<td>Junior Soccer Ball</td>
<td>Junior soccer ball</td>
<td>$11.00</td>
</tr>
<tr>
<td>2018</td>
<td>World Cup Soccer ...</td>
<td>World cup soccer ball</td>
<td>$28.00</td>
</tr>
<tr>
<td>2020</td>
<td>World Cup Net</td>
<td>World cup net</td>
<td>$123.00</td>
</tr>
</tbody>
</table>

You can create a table that simply displays information, as shown in Figure 29–1, or you can allow the user to edit the information and create new records, as shown in Figure 29–2.

Figure 29–2  Edit Table

Product Id | Product Name         | Price | Quantity | Item Total
-----------|----------------------|-------|----------|-------------
10,023     | Pro Ski Pole         | $40.95| 91 ()    | $3,726.45   |
20,512     | Black Hawk Elbow Pads | $8.00| 13 ()    | $104.00     |
20,106     | Junior Soccer Ball   | $11.00| 74 ()    | $814.00     |
10,022     | Ace Ski Pole         | $21.95| 18 ()    | $395.10     |
50,530     | Cabrera Bat          | $45.00| 55 ()    | $2,475.00   |
20,201     | World Cup Net        | $123.00| 67 ()   | $8,241.00   |
20,106     | World Cup Soccer Ball| $28.00| 19 ()    | $532.00     |

29.1.2 Additional Functionality for Databound Tables

You may find it helpful to understand other ADF Faces features before you implement your table and tree components. Additionally, once you have added a tree or table component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that table and tree components can use.

- **ADF view objects**: Much of how the components display and function in the table is controlled by the corresponding view objects. For more information, see Chapter 5, "Defining SQL Queries Using View Objects."

- **ADF application modules**: The Data Controls panel, from which you drag databound components to your pages, is populated with representations of view objects that you have added to application modules. For more information, see Chapter 13, "Implementing Business Services with Application Modules."

- **Adapter-based data controls**: If you are using other types of business services, such as EJB components or web services, you can create data control for those business service as described in Developing Applications with Oracle ADF Data Controls.
- **ADF Model and data binding**: When you create databound tables in an ADF web application, you use ADF Model and data binding. For more information, see Chapter 17, "Using ADF Model in a Fusion Web Application."

- **ADF Faces**: For detailed information about developing with ADF Faces, see *Developing Web User Interfaces with Oracle ADF Faces*.

- **Command buttons**: You may want to add command button or links that invoke some functionality against the data set. For more advanced functionality than what is covered in this chapter, see Chapter 30, "Using Command Components to Invoke Functionality in the View Layer."

- **Filtered tables**: You can create tables that provide filtering, in effect executing a query-by-example search against the data in the table. For more information, see Section 33.5, "Creating Standalone Filtered Search Tables from Named View Criteria."

- **Task flows**: If your table takes part in a transaction, for example an input table, then you may need to use an ADF task flow to invoke certain operations before or after the table is rendered. For more information, see Part IV, "Creating ADF Task Flows".

- **Validation**: You may want certain fields to be validated before they are submitted to the data store. For more information, see Chapter 11, "Defining Validation and Business Rules Declaratively" and Chapter 18, "Using Validation in the ADF Model Layer."

- **Active data**: If your application uses active data, then you can have the data in your tables and trees update automatically, whenever the data in the data source changes. For more information, see Chapter 47, "Using the Active Data Service."

---

**Note:** If you wish to use active data, and your application uses ADF Business Components, then your tables must conform to the following:

- The binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
- The binding rule contains a single attribute.
- The table does not use filtering.
- The tree component's nodeStamp facet contains a single outputText tag and contains no other tags.

---

### 29.2 Creating a Basic Table

Unlike with forms where you bind the individual UI components that make up a form to the individual attributes on the collection, with a table you bind the ADF Faces table component to the complete collection or to a range of n data objects at a time from the collection. The individual components used to display the data in the columns are then bound to the attributes. The iterator binding handles displaying the correct data for each object, while the table component handles displaying each object in a row. JDeveloper allows you to do this declaratively, so that you don’t need to write any code.
29.2.1 How to Create a Basic Table

To create a table using a data control, you bind the `table` component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**Before you begin:**

It may be helpful to have an understanding of ADF Faces databound tables. For more information, see Section 29.2, "Creating a Basic Table."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 29.1.2, "Additional Functionality for Databound Tables."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

**To create a databound table:**

1. From the Data Controls panel, select a collection.

   For example, to create a simple table in the Summit ADF sample application that displays all of the customers, you would select the `Customers` collection.

2. Drag the collection onto a JSF page, and from the context menu, choose **Table/List View > ADF Table**.

3. The Create Table dialog shows each attribute in the collection, and allows you to determine how these attributes will behave and appear as columns in your table. Using this dialog, you can do the following:

   - Make the table read-only.

   - Allow the ADF Model layer to handle selection by selecting the **Single Row** or **Multiple Rows** radio button. Selecting either of these options means that the iterator binding will access the iterator to determine the selected row or rows. Select one of these options unless you do not want the table to allow selection.

   - Allow the ADF Model layer to handle column sorting by selecting the **Enabling Sorting** checkbox. Selecting this option means that the iterator binding will access the iterator, which will perform an order-by query to determine the order. Select this option unless you do not want to allow column sorting.

   - Allow the columns in the table to be filtered using entered criteria by selecting the **Enabling Filtering** checkbox. Selecting this option allows the user to enter criteria in text fields above each column. That criteria is then used to build a Query-by-Example (QBE) search on the collection, so that the table will display only the results returned by the query. For more information, see Section 33.5, "Creating Standalone Filtered Search Tables from Named View Criteria."
Group columns for selected attributes together under a parent column, by selecting the desired attributes (shown as rows in the dialog), and clicking the Group button. Figure 29–3 shows how five grouped columns appear in the visual editor after the table is created.

Figure 29–3 Grouped Columns in an ADF Faces Table

<table>
<thead>
<tr>
<th>Name</th>
<th>Mailing Address</th>
<th>City</th>
<th>State</th>
<th>Country</th>
<th>Zip code</th>
</tr>
</thead>
<tbody>
<tr>
<td>#{...Name.input}</td>
<td>#{...Address.inp}</td>
<td>#{...City.inputVs}</td>
<td>#{...State}</td>
<td>#{...Country}</td>
<td>#{...ZipCo}</td>
</tr>
</tbody>
</table>

Change the display label for a column. By default, the label is bound to the labels property for any control hint defined for the attribute on the table binding. This binding allows you to change the value of a label text once on the view object, and have the change appear the same on all pages that display the label.

Instead of using this default, you can enter text or an EL expression to bind the label value to something else, for example, a key in a resource file.

Change the value binding for a column. You can change the column to be bound to a different attribute. If you simply want to rearrange the columns, you should use the order buttons. If you do change the attribute binding for a column, the label for the column also changes.

Change the UI component used to display an attribute. The UI components are set based on the table you selected when you dropped the collection onto the page, on the type of the corresponding attribute (for example, inputDate components are used for attributes that are dates), and on whether or not default components were set as control hints on the corresponding view object. You can change to another component using the dropdown list.

Tip: If one of the attributes for your table is also a primary key, you may want to choose a UI component that will not allow a user to change the value.

Tip: If you want to use a component that is not listed in the dropdown menu, use this dialog to select the outputText component, and then manually add the other tag to the page.

Change the order of the columns using the order buttons.

Add a column using the Add icon. There’s no limit to the number of columns you can add. When you first click the icon, JDeveloper adds a new column line at the bottom of the dialog and populates it with the values from the first

Note: For JPA-based data controls, filtering does not work on tables that are created from nested collections in the data control. If you drop such a collection on a page, you should leave this checkbox unselected to avoid runtime errors. For more information on JPA-based data controls, see “About EJB Data Controls” in Developing Applications with Oracle ADF Data Controls.
attribute in the bound collection; subsequent new columns are populated with values from the next attribute in the sequence, and so on.

- Delete a column using the **Delete** icon.

- Make the table dynamic by selecting the **Generate columns dynamically at runtime** checkbox. For more information on dynamic tables, see Section 29.5, "Creating a Table with Dynamic Components."

4. Once the table is dropped on the page, you can use the Properties window to set other display properties of the table. For example, you may want to set the width of the table to a certain percentage or size. For more information about display properties, see the "Using Tables, Trees, and Other Collection-Based Components" chapter of *Developing Web User Interfaces with Oracle ADF Faces."

**Tip:** When you set the table width to 100%, the table will not include borders, so the actual width of the table will be larger. To have the table set to 100% of the container width, expand the **Style** section of the Properties window, select the **Box** tab, and set the **Border Width** attribute to 0 pixels.

5. If you want the user to be able to edit information in the table and save any changes, you need to provide a way to submit and persist those changes. For more information, see Section 29.3, "Creating an Editable Table." For procedures on creating tables that allow users to input data, see Section 29.4, "Creating an Input Table."

### 29.2.2 What Happens When You Create a Table

Dropping a table from the Data Controls panel has the same effect as dropping a text field or form. Briefly, JDeveloper does the following:

- Creates the bindings for the table and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

For more information, see Section 28.2.2, "What Happens When You Create a Text Field."

### 29.2.2.1 Iterator and Value Bindings for Tables

When you drop a table from the Data Controls panel, a **tree** value binding is created. A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher level node. In the case of a table, it is a flattened hierarchy, where each attribute (column) is a subnode off the table. Like an attribute binding used in forms, the tree value binding references the iterator binding, while the iterator binding references an iterator for the data collection, which facilitates iterating over the data objects in the collection. Instead of creating a separate binding for each attribute, only the tree binding to the table node is created. In the tree binding, the **AttrNames** element within the **nodeDefinition** element contains a child element for each attribute that you want to be available for display or reference in each row of the table.

The tree value binding is an instance of the **FacesCtrlHierBinding** class that extends the core **JUCtrlHierBinding** class to add two JSF specific properties:

- **collectionModel**: Returns the data wrapped by an object that extends the **javax.faces.model.DataModel** object that JSF and ADF Faces use for collection-valued components like tables.
Creating a Basic Table

Creating ADF Databound Tables

29-7

- `treeModel`: Extends `collectionModel` to return data that is hierarchical in nature. For more information, see Chapter 31, "Displaying Master-Detail Data."

Example 29–1 shows the value binding for the table created when you drop the Summit sample application for ADF task flows’s `ProductVO1` collection.

**Example 29–1  Value Binding Entries for a Table in the Page Definition File**

```xml
<bindings>
  <tree IterBinding="ProductVO1Iterator" id="ProductVO1">
    <nodeDefinition
      DefName="oracle.summit.model.views.ProductVO"
      Name="ProductVO10">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Name"/>
        <Item Value="ShortDesc"/>
        <Item Value="LongtextId"/>
        <Item Value="ImageId"/>
        <Item Value="SuggestedWhlslPrice"/>
        <Item Value="WhlslUnits"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

Only the table component needs to be bound to the model (as opposed to the columns or the text components within the individual cells), because only the table needs access to the data. The tree binding for the table drills down to the individual structure attributes in the table, and the table columns can then derive their information from the table component.

29.2.2.2 Code on the JSF Page for an ADF Faces Table

When you use the Data Controls panel to drop a table onto a JSF page, JDeveloper inserts an ADF Faces `table` component, which contains an ADF Faces `column` component for each attribute named in the table binding. Each column then contains another component (such as an `inputText` or `outputText` component) bound to the attribute’s value. Each column’s heading is bound to the `labels` property for the control hint of the attribute.

**Tip:** If an attribute is marked as hidden on the associated view or entity object, no corresponding UI is created for it.

Example 29–2 shows a code excerpt from a table created by dropping the `ProductsVO1` collection as a read-only table.

**Example 29–2  JSF Code for an ADF Faces Table**

```xml
<af:table value="#{bindings.ProductVO1.collectionModel}" var="row"
  rows="#{bindings.ProductVO1.rangeSize}"
  emptyText="#{bindings.ProductVO1.viewable ? 'No data to display.' : 'Access Denied.'}
  fetchSize="#{bindings.ProductVO1.rangeSize}" rowBandingInterval="0"
  selectedRowKeys="#{bindings.ProductVO1.collectionModel.selectedRow}"
  selectionListener="#{bindings.ProductVO1.collectionModel.makeCurrent}"
  rowSelection="single" id="t1">
  <af:column headerText="#{bindings.ProductVO1.hints.Id.label}" id="c1">
    <af:outputText value="#{row.Id}"
```
Creating a Basic Table

The tree binding iterates over the data exposed by the iterator binding. Note that the table’s value is bound to the `collectionModel` property, which accesses the `collectionModel` object. The table wraps the result set from the iterator binding in a `collectionModel` object. The `collectionModel` allows each item in the collection to be available within the table component using the `var` attribute.

In the example, the table iterates over the rows in the current range of the `ProductVO1` iterator binding. The iterator binding binds to a row set iterator that keeps track of the current row. When you set the `var` attribute on the table to `row`, each column then accesses the current data object for the current row presented to the table tag using the `row` variable, as shown for the value of the `af:outputText` tag:

```af:outputText value='#{row.Id}' />
```

When you drop an ADF Table and do not specify it as a read-only table, input components are generated instead of output components, as shown in Example 29–3. The value of the input component is implicitly bound to a specific row in the binding container through the `bindings` property, instead of being bound to the row variable. Additionally, JDeveloper adds validator components for each input component. By using the `bindings` property, any raised exception can be linked to the corresponding binding object or objects. The controller iterates through all exceptions in the binding container and retrieves the binding object to get the client ID when creating `FacesMessage` objects. This retrieval allows the table to display errors for specific cells. This strategy is used for all input components, including selection components such as lists.

**Example 29–3  Input Components Within a Table**

```af:table value='#{bindings.ProductVO1.collectionModel}' var='row'
rows='#{bindings.ProductVO1.rangeSize}'
emptyText='#{bindings.ProductVO1.viewable ? 'No data to display.' : 'Access Denied.'}'
fetchSize='#{bindings.ProductVO1.rangeSize}' rowBandingInterval='0'
id='t1'>
<af:column headerText='#{bindings.ProductVO1.hints.Id.label}' id='c1'>
<af:inputText value='#{row.bindings.Id.inputValue}'
label='#{bindings.ProductVO1.hints.Id.label}'
required='#{bindings.ProductVO1.hints.Id.mandatory}'>
columns="#{bindings.ProductVO1hints.Id.displayWidth}"
maximumLength="#{bindings.ProductVO1hints.Id.precision}"
shortDesc="#{bindings.ProductVO1hints.Id.tooltip}"
 id="it1">
  <f:validator binding="#{row.bindings.Id.validator}"/>
  <af:convertNumber groupingUsed="false"
   pattern="#{bindings.ProductVO1hints.Id.format}"/>
</af:inputText>
</af:column>

For more information about using ADF Faces validators and converters, see the "Validating and Converting Input" chapter of Developing Web User Interfaces with Oracle ADF Faces.

Table 29–1 shows the other attributes defined by default for ADF Faces tables created using the Data Controls panel.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>rows</td>
<td>Determines how many rows to display at one time.</td>
<td>An EL expression that, by default, evaluates to the rangeSize property of the associated iterator binding, which determines how many rows of data are fetched from a data control at one time. Note that the value of the rows attribute must be equal to or less than the corresponding iterator’s rangeSize value, as the table cannot display more rows than are returned.</td>
</tr>
<tr>
<td>first</td>
<td>Index of the first row in a range (based on 0).</td>
<td>An EL expression that evaluates to the rangeStart property of the associated iterator binding.</td>
</tr>
<tr>
<td>emptyText</td>
<td>Text to display when there are no rows to return.</td>
<td>An EL expression that evaluates to the viewable property on the iterator. If the table is viewable, the attribute displays No data to display when no objects are returned. If the table is not viewable (for example, if there are authorization restrictions set against the table), it displays Access Denied.</td>
</tr>
<tr>
<td>fetchSize</td>
<td>Number of rows of data fetched from the data source.</td>
<td>An EL expression that, by default, evaluates to the rangeSize property of the associated iterator binding. For more information about the rangeSize property, see Section 28.4.2.2, &quot;Iterator RangeSize Attribute Defined.&quot; This attribute can be set to a larger number than the rows attribute. Note that to improve scrolling behavior in a table, when the table’s iterator binding is expected to manage a data set consisting of over 200 items, and the view object is configured to use range paging, the iterator actually returns a set of ranges instead of just one range. For more information about using range paging for view objects, see Section 9.1.5, &quot;Efficiently Scrolling Through Large Result Sets Using Range Paging.&quot; For more information on range paging for JPA-based data controls, see &quot;Paginated Fetching of Data in EJB Data Controls&quot; in Developing Applications with Oracle ADF Data Controls.</td>
</tr>
</tbody>
</table>
29.2.3 What You May Need to Know About Setting the Current Row in a Table

When you use tables in an application and you allow the ADF Model layer to manage row selection, the current row is determined by the iterator. When a user selects a row in an ADF Faces table, the row in the table is shaded, and the component notifies the iterator of the selected row. To do this, the selectedRowKeys attribute of the table is bound to the collection model’s selected row, as shown in Example 29–4.

**Example 29–4 Selection Attributes on a Table**

```af:table value="#{bindings.ProductVO1.collectionModel}" var="row"
  .
  .
  .
  selectedRowKeys="#{bindings.ProductVO1.collectionModel.selectedRow}"
  selectionListener="#{bindings.ProductVO1.collectionModel.makeCurrent}"
  rowSelection="single">
```

This binding binds the selected keys in the table to the selected row of the collection model. The selectionListener attribute is then bound to the collection model’s makeCurrent property. This binding makes the selected row of the collection the current row of the iterator.

**Note:** If you create a custom selection listener, you must create a method binding to the makeCurrent property on the collection model (for example #{binding.Products.collectionModel.makeCurrent}) and invoke this method binding in the custom selection listener before any custom logic.

Although a table can handle selection automatically, there may be cases where you need to programmatically set the current row for an object on an iterator.

---

**Table 29–1 (Cont.) ADF Faces Table Attributes and Populated Values**

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>selectedRowKeys</td>
<td>The selection state for the table.</td>
<td>An EL expression that by default, evaluates to the selected row on the collection model.</td>
</tr>
<tr>
<td>selectionListener</td>
<td>Reference to a method that listens for a selection event.</td>
<td>An EL expression that by default, evaluates to the makeCurrent method on the collection model.</td>
</tr>
<tr>
<td>rowSelection</td>
<td>Determines whether rows are selectable.</td>
<td>Set to single to allow one row to be selected at a time. Set to multiple to allow more than one row to be selected.</td>
</tr>
</tbody>
</table>

**Column Attributes**

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
<th>Default Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>sortProperty</td>
<td>Determines the property on which to sort the column.</td>
<td>Set to the columns corresponding attribute binding value.</td>
</tr>
<tr>
<td>sortable</td>
<td>Determines whether a column can be sorted.</td>
<td>Set to false. When set to true, the iterator binding will access the iterator to determine the order.</td>
</tr>
<tr>
<td>headerText</td>
<td>Determines the text displayed at the top of the column.</td>
<td>An EL expression that, by default, evaluates to the label control hint set on the corresponding attribute.</td>
</tr>
</tbody>
</table>
Creating a Basic Table

You can call the `getKey()` method on any view row to get a `Key` object that encapsulates the one or more key attributes that identify the row. You can also use a `Key` object to find a view row in a row set using the `findByKey()` method. At runtime, when either the `setCurrentRowWithKey` or the `setCurrentRowWithKeyValue` built-in operation is invoked by name by the data binding layer, the `findByKey()` method is used to find the row based on the value passed in as a parameter before the found row is set as the current row.

The `setCurrentRowWithKey` and `setCurrentRowWithKeyValue` operations both expect a parameter named `rowKey`, but they differ precisely by what each expects that `rowKey` parameter value to be at runtime:

**setCurrentRowWithKey Operation**

`setCurrentRowWithKey` expects the `rowKey` parameter value to be the serialized string representation of a view row key. This is a hexadecimal-encoded string that looks similar to this:

```
000200000002C2020000002C102000000010000010A5AB7DAD9
```

The serialized string representation of a key encodes all of the key attributes that might comprise a view row’s key in a way that can be conveniently passed as a single value in a browser URL string or form parameter. At runtime, if you inadvertently pass a parameter value that is not a legal serialized string key, you may receive exceptions like `oracle.jbo.InvalidParamException` or `java.io.EOFException` as a result. In your web page, you can access the value of the serialized string key of a row by referencing the `rowKeyStr` property of an ADF control binding (for example, `{#(bindings.SomeAttrName.rowKeyStr)}`) or the `row` variable of an ADF Faces table (e.g. `{#(row.rowKeyStr)}`).

**setCurrentRowWithKeyValue Operation**

The `setCurrentRowWithKeyValue` operation expects the `rowKey` parameter value to be the literal value representing the key of the view row. For example, its value would be simply "201" to find product number 201.

---

**Note:** If you write custom code in an application module class and need to find a row based on a serialized string key passed from the client, you can use the `getRowFromKey()` method in the `JboUtil` class in the `oracle.jbo.client` package:

```
static public Row getRowFromKey(RowSetIterator rsi, String sKey)
```

The first parameter is the view object instance in which you’d like to find the row. The second parameter is the serialized string format of the key.

---

### 29.2.4 What You May Need to Know About Getting Row Data Programmatically

`CollectionModel` supports a version of the `getRowData` method that takes a row key parameter and thus allows you to get row data without changing currency.

For example, you can replace this code:

```
CollectionModelInstance.setRowKey(RowKeyInstance);
JUctrlHierNodeBinding rowData = (JUctrlHierNodeBinding)
    CollectionModelInstance.getRowData();
```

with this code:

```
```
This is particularly useful when your view object uses range paging, since it enables you to avoid having to use the setRowKey method. (If you use setRowKey, you might also need to provide custom code to ensure that the row that you specify with that method is within the current range of rows.)

### 29.3 Creating an Editable Table

You can create a table that allows the user to edit information within the table, and then commit those changes to the data source. You can use built-in data control operations to create command buttons for changing the data, and place those buttons in a toolbar in the table. For example, you might use the Delete operation to create a button that allows a user to delete a record from the current range.

It is important to note that the collection-specific operations are executed only against objects in the ADF cache. You need to use the Commit operation on the root data control to actually commit any changes to the data source. You use the data control’s Rollback operation to roll back any changes made to the cached object. If the page is part of a transaction within a bounded task flow, you would most likely use these operations to resolve the transaction in a task flow return activity. For more information, see Section 24.3, "Managing Transactions in Task Flows.”

---

**Note:** For data controls which do not have the Commit and Rollback operations available, such as data controls based on web services or stateless EJB session beans, you need to provide custom methods to save the data to the data source. For JPA-based data controls, you can use the mergeEntity or persistEntity methods to save changes, but these methods only work on a single row. For more information on working with JPA-based data controls, see "About Commit Models for EJB Session Beans" in Developing Applications with Oracle ADF Data Controls.

---

When you decide to use editable components to display your data, you have the option of the table displaying all rows as editable immediately, or displaying all rows as read-only until the user double-clicks within the row. Figure 29–4 shows a table whose rows all have editable fields. The page renders using the components that were added to the page (for example, inputText and inputDate, components).

**Figure 29–4 Table with Editable Fields**

<table>
<thead>
<tr>
<th>Id</th>
<th>Name</th>
<th>ShortDesc</th>
</tr>
</thead>
<tbody>
<tr>
<td>10011</td>
<td>Bunny Boot</td>
<td>Beginners ski boot</td>
</tr>
<tr>
<td>10012</td>
<td>Ace Ski Boot</td>
<td>Intermediate ski bc</td>
</tr>
<tr>
<td>10013</td>
<td>Pro Ski Boot</td>
<td>Advanced ski boot</td>
</tr>
<tr>
<td>10021</td>
<td>Bunny Ski Pole</td>
<td>Beginner’s ski pole</td>
</tr>
<tr>
<td>10022</td>
<td>Ace Ski Pole</td>
<td>Intermediate ski pc</td>
</tr>
</tbody>
</table>

**Figure 29–5** shows the same table, but configured so that the user must double-click (or single-click if the row is already selected) a row in order to edit or enter data. Note that outputText components are used to display the data in the nonselected rows,
even though the same input components as in Figure 29–4 were used to build the page. The only row that actually renders those components is the row selected for editing.

**Figure 29–5  Click to Edit a Row**

<table>
<thead>
<tr>
<th>Name</th>
<th>Id</th>
<th>ShortDesc</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bunny Boot</td>
<td>10011</td>
<td>Beginners ski boot</td>

<td>Intermediate ski pole</td>
</tr>
</tbody>
</table>

For more information about how ADF Faces table components handle editing, see the "Editing Data in Tables, Trees, and Tree Tables" section of *Developing Web User Interfaces with Oracle ADF Faces*.

### 29.3.1 How to Create an Editable Table

To create an editable table, you follow similar procedures to creating a basic table, then you add command buttons bound to operations. However, in order for the table to contain a toolbar, you need to add an ADF Faces component that associates the toolbar with the items in the collection used to build the table.

**Before you begin:**

It may be helpful to have an understanding of editable databound tables. For more information, see Section 29.3, "Creating an Editable Table."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 29.1.2, "Additional Functionality for Databound Tables."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in *Developing Applications with Oracle ADF Data Controls*.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

**To create an editable table:**

1. From the Data Controls panel, select a collection.
   
   For example, to create a simple table in the Summit ADF task flow sample application that will allow you to edit products in the system, you would select the ProductVO1 collection.

2. Drag the collection onto a JSF page, and from the context menu, choose **Table /List View > ADF Table**.
   
   This creates an editable table using input components.

3. Use the ensuing Create Table dialog to determine how the attributes should behave and appear as columns in your table. Be sure to select the **Single Row** or **Multiple Rows** radio button in order to allow the user to select a row to edit.
For more information about using this dialog to configure the table, see Section 29.2.1, "How to Create a Basic Table."

4. With the table selected in the Structure window, expand the Behavior section of the Properties window and set the EditingMode attribute. If you want all the rows to be editable select editAll. If you want the user to click into a row to make it editable, select clickToEdit.

5. From the Structure window, right-click the table component and choose Surround With.

6. In the Surround With dialog, ensure that ADF Faces is selected in the dropdown list, select the Panel Collection component, and click OK.

   The panelCollection component’s toolbar facet will hold the toolbar which, in turn, will hold the command components used to update the data.

7. In the Structure window, right-click the panelCollection's f:facet - toolbar facet node and choose Insert inside f:facet - toolbar > Toolbar.

   This creates a toolbar that already contains a default menu that allows users to change how the table is displayed and a Detach link that detaches the entire table and displays it such that it occupies the majority of the space in the browser window. For more information about the panelCollection component, see the "Displaying Table Menus, Toolbars, and Status Bars" section of Developing Web User Interfaces with Oracle ADF Faces.

8. From the Data Controls panel, select the operation associated with the collection of objects on which you wish the operation to execute, drag it onto the toolbar component in the Structure window, and choose Create > ADF Button from the context menu. This will place the databound command component inside the toolbar.

   For example, if you want to be able to delete a product record, you would drag the Delete operation associated with the ProductVO1 collection. Figure 29–6 shows the operations associated with the ProductVO1 collection.
Figure 29–6  Operations Associated with a Collection

9. If you need a button for submitting changes to the cache, right-click the `af:toolbar` component in the Structure window and choose Insert Inside Toolbar > Button.

Note: You can use other means to submit changes to the cache, such as setting the `autoSubmit` property to `true` for the input components in the table. For more information, see "Using Partial Triggers" in Developing Web User Interfaces with Oracle ADF Faces.

10. If the page is not part of a transaction within a bounded task flow, then you need to create buttons that allow the user to either commit or rollback the changes. From the Data Controls panel, drag the Commit and Rollback operations associated with the root-level data control, and drop them as either a button or link into the toolbar.

Figure 29–7 shows the commit and roll back operations for the `BackOfficeAppModuleDataControl` data control.
Creating an Input Table

Figure 29–7  Commit and Rollback Operations for a Data Control

If the page is part of a transaction within a bounded task flow, then you can simply enter Commit and Rollback as the values for the transaction resolution when creating the task flow return activity. For more information, see Section 24.3, "Managing Transactions in Task Flows."

Tip: To create a table that allows you to insert a new record into the data store, see Section 29.4, "Creating an Input Table."

29.3.2 What Happens When You Create an Editable Table

Creating an editable table is similar to creating a form used to edit records. Action bindings are created for the operations dropped from the Data Controls panel. For details, see Section 28.4.2, "What Happens When You Create Command Components Using Operations."

29.4 Creating an Input Table

You can create a table that allows users to insert a new blank row into a table and then add values for each column (any default values set on the corresponding entity or view object will be automatically populated).

29.4.1 How to Create an Input Table

When you create an input table, you want the user to see the new blank row in the context of the other rows within the current row set. To allow this insertion, you use the CreateInsert operation. As opposed to the Create operation, the CreateInsert operation actually creates the new row within the row set instead of only in the cache. In addition, you need to configure the table to respond to that user action. ADF Faces components can be set so that one component refreshes based on an interaction with another component, without the whole page needing to be refreshed. This is known as partial page rendering.

Note: The CreateInsert operation is not available for adapter-based data controls, such as those based web services or Java classes. However, for JPA-based data controls, the Create operation adds the new row to the row set like CreateInsert does for data controls based on application modules. For more information, see "Data Control Built-in Operations" in Developing Applications with Oracle ADF Data Controls.

Before you begin:

It may be helpful to have an understanding of ADF Faces input tables. For more information, see Section 29.4, "Creating an Input Table."
You may also find it helpful to understand other ADF functionality and features. For more information, see Section 29.1.2, "Additional Functionality for Databound Tables."

You will need to complete these tasks:

- Create an editable table, as described in Section 29, "Creating an Editable Table."
- If your table is not part of a bounded task flow, include buttons bound to the Commit and Rollback operations.

To create an input table:

1. From the Data Controls panel, drag the CreateInsert operation associated with the dropped collection and drop it as a toolbar button into the toolbar. You may want to change the ID to something more recognizable, such as CreateNewRow. This will make it easier to identify when you need to select it as the partial trigger.

   **Note:** If the collection is a child to another collection (for example, in the Summit ADF sample application the OrdersForCustomer collection is a child to the Customers collection), then instead of using the CreateInsert operation, you need to use the Create with Parameters operation so that the record to create for the child collection is associated with the parent collection.

2. In the Structure window, select the table component. In the Properties window, expand the Behavior section.
3. In the Properties window, mouse over the PartialTriggers attribute, click the dropdown menu, and choose Edit.
4. In the Edit Property dialog, expand the toolbar facet for the panelCollection component and then expand the toolbar that contains the CreateInsert command component. Select that component and shuttle it to the Selected panel. Click OK. This sets that component to be the trigger that will cause the table to refresh.

### 29.4.2 What Happens When You Create an Input Table

When you use the CreateInsert operation to create an input table, JDeveloper:

- Creates an iterator binding for the collection, an action binding for the CreateInsert operation, and attribute bindings for the table. The CreateInsert operation is responsible for creating the new row in the row set. If you created command buttons or links using the Commit and Rollback operations, JDeveloper also creates an action bindings for those operations.

- Inserts code in the JSF page for the table using ADF Faces table, column, and inputText components, and in the case of the operations, button components.

**Example 29–5** shows the page definition file for an input table created from the ProductVO1 collection (some attributes were deleted in the Create Table dialog when the collection was dropped).

**Example 29–5  Page Definition Code for an Input Table**

```xml
<executables>
  <iterator Binds="ProductVO1" RangeSize="25"
    DataControl="BackOfficeAppModuleDataControl" id="ProductVO1Iterator"/>
</executables>
<tree IterBinding="ProductVO1Iterator" id="ProductVO1">
  <nodeDefinition
```

Creating ADF Databound Tables  29-17
Example 29–6 shows the code added to the JSF page that provides partial page rendering, using the CreateInsert command toolbar button as the trigger to refresh the table.

Example 29–6  Partial Page Trigger Set on a Command Button for a Table

```xml
<af:form>
<af:panelCollection id="pc1">
<f:facet name="menus"/>
<f:facet name="toolbar">
<af:toolbar id="tb1">
<af:button actionListener="#{bindings.CreateInsert.execute}"
    text="CreateInsert"
    disabled="#{!bindings.CreateInsert.enabled}" id="CreateInsert"/>
<af:button actionListener="#{bindings.Commit.execute}"
    text="Commit"
    disabled="false" id="b2"/>
<af:button actionListener="#{bindings.Rollback.execute}"
    text="Rollback"
    disabled="#{!bindings.Rollback.enabled}" immediate="true" id="b3">
    <af:resetActionListener/>
</af:button>
</af:toolbar>
</f:facet>
<f:facet name="statusbar"/>
<af:table value="#{bindings.ProductVO1.collectionModel}" var="row"
    rows="#{bindings.ProductVO1.rangeSize}"
    emptyText="#{bindings.ProductVO1.viewable ? 'No data to display.' : 'Access Denied.'}"
    fetchSize="#{bindings.ProductVO1.rangeSize}"
    rowSelection='single' partialTriggers="CreateInsert" id="t1">
    <af:column sortProperty="Id" sortTable="false"
        headerText="#{bindings.ProductVO1.hints.Id.label}" id="c1">
        <af:inputText value="#{row.ProductId}" simple="true"/>
    </af:column>
</af:table>
</af:panelCollection>
</af:form>
```
29.4.3 What Happens at Runtime: How CreateInsert and Partial Page Refresh Work

When the button bound to the CreateInsert operation is invoked, the action executes, and a new instance for the collection is created and inserted as the page is rerendered. Because the button was configured to be a trigger that causes the table to refresh, the table redraws with the new empty row shown at the top. When the user clicks the button bound to the Commit action, the newly created rows in the row set are inserted into the database. For more information about partial page refresh, see the "Rerendering Partial Page Content" chapter in Developing Web User Interfaces with Oracle ADF Faces.

29.4.4 What You May Need to Know About Creating a Row and Sorting Columns

If your table columns allow sorting, and the user has sorted on a column before inserting a new row, then that new row will not be sorted. To have the column sort with the new row, the user must first sort the column opposite to the desired sort, and then resort. This is because the table assumes the column is already sorted, so clicking on the desired sort order first will have no effect on the column.

For example, say a user had sorted a column in ascending order, and then added a new row. Initially, that row appears at the top. If the user first clicks to sort the column again in ascending order, the table will not resort, as it assumes the column is already in ascending order. The user must first sort on descending order and then ascending order.

If you want the data to automatically sort on a specific column in a specific order after inserting a row, then programmatically queue a SortEvent after the commit, and implement a handler to execute the sort.

If you want to allow sorting on a column for which the view object attribute is defined by a custom domain data type, you must implement the compareTo() method for the table's sort button click event:

```java
public int compareTo(Object theObject)
```

The method will return 0 for values that are equal, less than 0 if the current object is less than theObject, and greater than 0 if the current object is greater. The object comparison for attributes behaves just like String comparisons.

29.4.5 What You May Need to Know About Create and CreateInsert

When you use the Create or CreateInsert operation to declaratively create a new row, it performs the following lines of code:

```java
// create a new row for the view object
Row newRow = yourViewObject.createRow();
// mark the row as being "initialized", but not yet new
```
newRow.setNewRowState(Row.STATUS_INITIALIZED);

However, if you are using the CreateInsert operation, it performs the additional line of code to insert the row into the row set:

```java
// insert the new row into the view object's default rowset
yourViewObject.insertRow(newRow);
```

When you create a row in an entity-based view object, the Transaction object associated with the current application module immediately takes note of the fact. The new entity row that gets created behind the view row is already part of the Transaction's list of pending changes. When a newly created row is marked as having the initialized state, it is removed from the Transaction's pending changes list and is considered a blank row in which the end user has not yet entered any data values. The term initialized is appropriate since the end user will see the new row initialized with any default values that the underlying entity object has defined. If the user never enters any data into any attribute of that initialized row, then it is as if the row never existed. At transaction commit time, since that row is not part of the Transaction's pending changes list, no INSERT statement will be attempted for it.

As soon as at least one attribute in an initialized row is set, it automatically transitions from the initialized status to the new status (Row.STATUS_NEW). At that time, the underlying entity row is enrolled in the Transaction's list of pending changes, and the new row will be permanently saved the next time you commit the transaction.

---

**Note:** If the end user performs steps that result in creating many initialized rows but never populating them, it might seem likely to cause a slow memory leak. However, the memory used by an initialized row that never transitions to the new state will eventually be reclaimed by the Java virtual machine's garbage collector.

---

### 29.4.6 What You May Need to Know About Saving Multiple Rows in a JPA-Based Data Control

EJB data controls and JPA-based bean data controls do not have the built-in CreateInsert operation available. However, it is possible to replicate the behavior of CreateInsert with the Create operation in these data controls by setting the data control's EagerPersist property to true. This property is set to true by default for data controls based on stateful session beans that use container-managed transactions and an explicit commit model. For more information, see “About Commit Models for EJB Session Beans” in *Developing Applications with Oracle ADF Data Controls*.

### 29.5 Creating a Table with Dynamic Components

Instead of creating static databound tables where you provide tags for each component directly in the page, you can use a dynamic component to create tables where the binding metadata, columns, and the components used to display the bound content are determined at runtime.

Figure 29–8 shows a dynamic table at runtime that was created by setting UI hints for attributes on the CustomerVO view object and then dropping the Customers data control collection as a dynamic table. Among the UI hints set were LABEL and DISPLAYHINT (the latter of which can be set to Hide in order to not include the given attribute in the dynamic form).
29.5.1 How to Create a Dynamic Table

To create a dynamic table, you drop a collection from the data controls panel as an ADF Table and specify that the fields be generated dynamically.

Before you begin:

It may be helpful to have an understanding of the dynamic component feature and dynamic databound tables. For more information, see Section 28.9.1, "About Dynamic Components" and Section 29.5, "Creating a Table with Dynamic Components."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 29.1.2, "Additional Functionality for Databound Tables."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

To create a dynamic table:

1. Set UI hints on the view object or data control structure definition file that corresponds to the collection for which you are creating the dynamic form.

   UI hints determine things such as the type of UI component to use to display the attribute, the label, the tooltip, whether the field should be automatically submitted, etc. You can also determine whether a given attribute is displayed or hidden. For procedures on creating UI hints, see Section 5.13, "Defining UI Hints for View Objects."

2. Optionally, for the Category hint on each view object attribute, specify a category or click the New Category icon to create a new category.

   Any attributes that have the same category can be grouped together in dynamic tables that you create based on that view object.

3. Optionally, for any categories that you have created in step 2, set the UI hints for the category’s label and tooltip. These can be set in the UI Categories tab of the view object’s overview editor.
4. From the Data Controls panel, select the collection that represents the view object.
5. Drag the collection onto the page, and from the context menu, choose **Table/List View > ADF Table**.
6. In the Create Table dialog, select the **Generate columns dynamically at runtime** checkbox.
7. If you have specified any categories for attributes in step 2, select the **Include Column Groups** checkbox in order for the form to organize the display of columns into any checkbox in order for the table to group the columns according to those categories.

### 29.5.2 What Happens When You Use Dynamic Components

When you drop a collection as a dynamic table on a page, the following things happen:

- The page definition is populated with a variableIterator binding, an iterator binding to the iterator, and a tree value binding. For more information, see Section 28.9.3.1, "Bindings Created for the Dynamic Form."
- The JSF page is populated with a table tag and one or more iterator, column and dynamicComponent tags. In addition, if the **Include Column Groups** option is selected, switcher and group tags are added.

#### 29.5.2.1 Tags Created for a Dynamic Table without Grouping

In the JSF page, JDeveloper inserts a table tag, within which it nests an iterator tag that iterates over the attributes of the collection. Within that iterator tag is nested a column tag, which contains a dynamicComponent tag. The dynamicComponent in turn displays the appropriate component for each column as determined at runtime.

Example 29–7 shows the code that is generated when you drop the Countries data control object as a dynamic table (but do not select the **Include Column Groups** option).

**Example 29–7  JSF Page Code for a Dynamic Table**

```xml
<af:table value="#{bindings.Countries.collectionModel}" var="row"
   rows="#{bindings.Countries.rangeSize}"
   emptyText="#{bindings.Countries.viewable ? 'No data to display.' : 'Access Denied.'}"
   rowBandingInterval="0" fetchSize="#{bindings.Countries.rangeSize}"
   id="t1">
  <af:iterator id="i1"
    value="#{bindings.Countries.attributesModel.attributes}"
    var="column">
    <af:column headerText="#{column.label}" id="c1">
      <af:dynamicComponent id="d2" attributeModel="#{column}"
        value="#{row.bindings[column.name].inputValue}"/>
    </af:column>
  </af:iterator>
</af:table>
```

The value attribute of the iterator tag uses an EL expression that evaluates to the attributesModel.attributes property of the collection’s tree binding. The attributesModel property is used to retrieve the data object’s attributes and their metadata, such as component type, label, tooltip, and other properties of the real
component to be rendered. The attributes property of attributesModel signifies that a flat (unhierarchical) list of displayable attributes and their metadata is provided.

The attributeModel attribute of the dynamicComponent tag is bound to the EL expression #{column}, which references the variable that is defined in the iterator’s var attribute and that serves as a pointer to the current attribute of the data control collection and its corresponding metadata. The EL expression for the dynamicComponent’s value attribute also references the variable column.

### 29.5.2.2 Tags Created for a Dynamic Table with Grouping

If you have selected the Include Column Groups checkbox in the Create Table dialog, the generated JSF page includes the switcher and group tags in addition to the tags described in Section 29.5.2.1, "Tags Created for a Dynamic Table without Grouping."

The switcher tag is nested directly within a column tag. Within the switcher tag are nested facet tags named GROUP and ATTRIBUTE. The GROUP facet contains a group tag, within which is an outputText tag to display the group name and an iterator tag, which contains a column tag that in turn contains a dynamicComponent tag. The ATTRIBUTE facet only contains a dynamicComponent tag.

For each attribute that the high-level iterator iterates over, the switcher dynamically determines whether to render a group or a column. If it renders a group, the iterator within the group then is used to render the columns within that group.

Example 29–8 shows the code that is generated if you create a dynamic form based on the Countries collection and choose to include column groups.

#### Example 29–8  JSF Page Code for a Dynamic Table with Groups

```xml
<af:table value="#{bindings.Countries.collectionModel}" var="row"
    rows="#{bindings.Countries.rangeSize}"
    emptyText="#{bindings.Countries.viewable ? 'No data to display.' : 'Access Denied.'}"
    rowBandingInterval="0" fetchSize="#{bindings.Countries.rangeSize}"
    id="t1">
    <af:iterator id="i1" value="#{bindings.Countries.attributesModel.hierarchicalAttributes}"
        var="column">
        <af:column headerText="#{column.label}" id="c1">
            <af:switcher id="sw1" facetName="#{column.descriptorType}"
                defaultFacet="ATTRIBUTE">
                <f:facet name="GROUP">
                    <af:iterator id="gi1" value="#{column.descriptors}"
                        var="nestedCol">
                        <af:column headerText="#{nestedCol.label}" id="c2">
                            <af:dynamicComponent id="gd1" attributeModel="#{nestedCol}"
                                value="#{row.bindings[nestedCol.name].inputValue}"/>
                        </af:column>
                    </af:iterator>
                </f:facet>
                <f:facet name="ATTRIBUTE">
                    <af:dynamicComponent id="ad1" attributeModel="#{column}"
                        value="#{row.bindings[column.name].inputValue}"/>
                </f:facet>
            </af:switcher>
        </af:column>
    </af:iterator>
</af:table>
```
The `value` attribute of the `iterator` tag uses an EL expression that evaluates to the `attributesModel.hierarchicalAttributes` property of the collection’s tree binding. The `attributesModel` property is used to retrieve the data object’s attributes and their metadata, such as component type, label, tooltip, and other properties of the real component to be rendered. The `hierarchicalAttributes` property signifies that a hierarchical list of displayable attributes and their metadata is provided, including any categories that have been set for any attributes in the UI hints.

The `attributeModel` attribute of the `dynamicComponent` tag is set to the EL expression `#{column}`, which references the variable that is defined in the iterator’s `var` attribute and that serves as a pointer to the current column (or category) of the data control collection and its corresponding metadata.

### 29.5.3 What Happens at Runtime: How Attribute Values Are Dynamically Determined

When a page with dynamic components is rendered, the bindings are created just as they are when items are dropped from the Data Controls panel at design time, except that they are created at runtime. For more information, see Section 28.9.4, "What Happens at Runtime: How Attribute Values Are Dynamically Determined."

### 29.5.4 How to Create a Dynamic Table with a detailStamp Facet

You can create a dynamic table that displays master content and includes `detailStamp` facet that enables a user to display detail for a given record. The detail content is obtained through the dynamic component’s bindings to a view link accessor on the master view object. Figure 29–9 shows a part of a dynamic table that contains such a detail facet. For more information on using `detailStamp` facets in tables, see "Adding Hidden Capabilities to a Table" in Developing Web User Interfaces with Oracle ADF Faces.

#### Figure 29–9 Dynamic Table with detailStamp Facet

<table>
<thead>
<tr>
<th>Employee Number</th>
<th>Employee Name</th>
<th>Job</th>
<th>Mgr</th>
</tr>
</thead>
<tbody>
<tr>
<td>5576</td>
<td>Test</td>
<td>Manager</td>
<td>7902</td>
</tr>
<tr>
<td>7839</td>
<td>KING</td>
<td>PRESIDENT</td>
<td></td>
</tr>
<tr>
<td>7566</td>
<td>JONES</td>
<td>MANAGER</td>
<td>7839</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Deptno</th>
<th>20</th>
</tr>
</thead>
<tbody>
<tr>
<td>Dname</td>
<td>RESEARCH</td>
</tr>
<tr>
<td>Loc</td>
<td>DALLAS</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>7902</th>
<th>FORD</th>
<th>ANALYST</th>
<th>7566</th>
</tr>
</thead>
<tbody>
<tr>
<td>7369</td>
<td>SMITH</td>
<td>CLERK</td>
<td>7902</td>
</tr>
<tr>
<td>7698</td>
<td>BLAKE</td>
<td>MANAGER</td>
<td>7839</td>
</tr>
</tbody>
</table>

### Before you begin:

It may be helpful to have an understanding of dynamic tables. For more information, see Section 29.5, "Creating a Table with Dynamic Components."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 29.1.2, "Additional Functionality for Databound Tables."
You will need to complete these tasks:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in Section 6.2.2, "How to Create a Master-Detail Hierarchy Based on View Objects Alone."

- Create a dynamic table as shown in Section 29.5.1, "How to Create a Dynamic Table."

**To create a dynamic table with a detailStamp facet:**

1. In the source editor for the JSF page, insert a `facet` tag within the dynamic table’s `table` tag.
2. Within the `facet` tag, insert a `panelFormLayout` tag.
3. Within the `panelFormLayout` tag, insert an `iterator` tag.
4. Bind the iterator’s `value` attribute to the `attributesModel.getLinkedViewAttributes('LinkedViewName')` property of your data object, where `LinkedViewName` is the name of a view link accessor that accesses the detail content.
5. Within the `iterator` tag, insert a `dynamicComponent` tag.
6. Bind the `dynamicComponent` tag’s `attributeModel` attribute to the value of the `iterator` tag’s `var` attribute.
7. Bind the `dynamicComponent` tag’s `value` attribute to an expression that returns the detail data for the selected row.

Example 29–9 shows the JSF page code for a dynamic table that uses a detailStamp facet to display data retrieved through a view link accessor.

**Example 29–9  Tags for Dynamic Table With Context-Sensitive Content**

```xml
<af:table value="#{bindings.EmpVO3.collectionModel}" var="row" id="t1" ...
<f:facet name="detailStamp">
<af:panelForm id="pgl1" layout="vertical">
<af:iterator id="iter3" var="detail" value="#{bindings.EmpVO3.attributesModel.getLinkedViewAttributes('DeptView')}">
<af:dynamicComponent value="#{row['DeptView'].bindings[detail.name].inputValue}" attributeModel="#{detail}" id="dc1"/>
</af:iterator>
</af:panelForm>
</f:facet>
<af:iterator id="itr1" var="column" values="#{bindings.EmpVO3.attributesModel.attributes}"
<af:column headerText="#{column.label}" id="dcc1">
<af:dynamicComponent values="#{row.bindings[column.name].inputValue}"
attributeModel="#{column}" id="dc1"/>
</af:column>
</af:iterator>
</af:table>
```

### 29.6 Modifying the Attributes Displayed in the Table

Once you use the Data Controls panel to create a table, you can then delete attributes, change the order in which they are displayed, change the component used to display...
them, and change the attribute binding for the component. You can also add new attributes, or rebind the table to a new data control.

29.6.1 How to Modify the Displayed Attributes

You can modify the following aspects of a table that was created using the Data Controls panel:

- Change the binding for the label of a column
- Change the UI component bound to an attribute
- Add or delete columns that represent the attributes
- Reorder the columns in the table
- Enable selection and sorting

Before you begin:

It may be helpful to have an understanding of modifying databound tables. For more information, see Section 29.6, "Modifying the Attributes Displayed in the Table."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 29.1.2, "Additional Functionality for Databound Tables."

You will need to complete this task:

Create a databound table as described in Section 29.2, "Creating a Basic Table."

To change the attributes for a table:

1. In the Structure window, select the table component.
2. In the Properties window, expand the Columns section to change, add, or delete the attributes that are displayed as columns. You can also change the UI component used within the column to display the data.
3. Expand other sections of the Properties window to change the display and behavior of the table, such as filtering and sorting.

29.6.2 How to Change the Binding for a Table

Instead of modifying a binding, you can completely change the object to which the table is bound.

Before you begin:

It may be helpful to have an understanding of modifying databound tables. For more information, see Section 29.6, "Modifying the Attributes Displayed in the Table."

You may also find it helpful to understand other ADF functionality and features. For more information, see Section 29.1.2, "Additional Functionality for Databound Tables."

You will need to complete this task:

- Create a databound table as described in Section 29.2, "Creating a Basic Table."

To rebind a table:

1. Right-click the table in the Structure window and choose Rebind to Another ADF Control.
2. In the Bind to ADF Control dialog, select the new collection to which you want to bind the table.
Note that changing the binding for the table will also change the binding for all the columns. You can then use the procedures in Section 29.6.1, "How to Modify the Displayed Attributes" to modify those bindings.

**Tip:** You can also rebind a table by dragging a different view object on top of the existing table.

### 29.6.3 What Happens When You Modify Bindings or Displayed Attributes

When you simply modify how an attribute is displayed by moving the UI component or changing the UI component, JDeveloper changes the corresponding code on the JSF page. When you use the binding editors to add or change a binding, JDeveloper adds the code to the JSF page, and also adds the appropriate elements to the page definition file.
This chapter describes how to invoke custom methods on ADF Business Components using ADF Faces command components and ADF Model data bindings in the Fusion web application. Specifically, it describes how you can use ADF Faces components to invoke ADF Business Components client interface methods, including how to pass parameters to a method and how to override the declarative method created when you drag and drop a method from the Data Controls panel.

This chapter includes the following sections:

- Section 30.1, "About Command Components"
- Section 30.2, "Creating Command Components to Execute Methods"
- Section 30.3, "Setting Parameter Values Using a Command Component"
- Section 30.4, "Overriding Declarative Methods"

### 30.1 About Command Components

Once you create a basic page and add navigation capabilities, you may want to add more complex features, such as passing parameters between pages or providing the ability to override declarative actions. Oracle ADF provides many features that allow you to add this complex functionality using very little actual code.

Some of the implementation methods in this chapter are intended for page-level designs. You may be able to perform many of the same functions by using task flows. For more information, see Chapter 20, "Getting Started with ADF Task Flows."

### 30.1.1 Command Component Use Cases and Examples

You can use command components to perform an action, such as passing parameters, overriding declarative actions, or performing some logic. You can bind a command component to a custom method in the Data Controls panel. For example, if you have a custom method called `deleteOrderItem()`, you can create a button bound to this method so that when the user presses this button, the order item will be deleted.

You can also use the `setPropertyListener` tag within a command component to assign values when an event fires. For example, assume you have a button that initiates a search and displays the results on another page depending on a parameter value stored in a managed bean. You can use the `setPropertyListener` property to pass this parameter value to the method that checks this value.
You can add code to a declarative method that is bound to a command component. For example, after you have created a declarative Commit button, you can add code to a managed bean and then override the Commit operation for additional processing.

### 30.1.2 Additional Functionality for Command Components

You may find it helpful to understand other Oracle ADF features before you work with command components. Following are links to other functionality that may be of interest.

- For information about creating custom methods that can be added to the page as a command component, see Section 13.7, "Customizing an Application Module with Service Methods" and Section 13.9, "Publishing Custom Service Methods to UI Clients."
- For information about creating command components from operations, see Section 28.4.2, "What Happens When You Create Command Components Using Operations."
- If you want to use EL expressions in your methods, see Section 28.4.2.3, "EL Expressions Created to Bind to Operations."
- For more information about the command button’s actionListener attribute, see Section 28.4.3, "What Happens at Runtime: How Action Events and Action Listeners Work."
- For more information about ADF bindings, see Section 17, "Using ADF Model in a Fusion Web Application."
- If you are using task flows, you can use the task flow parameter passing mechanism. For more information, see Chapter 22, "Using Parameters in Task Flows."
- If you are using managed beans, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

### 30.2 Creating Command Components to Execute Methods

When your application contains custom methods, these methods appear in the Data Controls panel. You can then drag these methods and drop them as command buttons. When a user clicks the button, the method is executed.

For more information about creating custom methods, see Section 13.7, "Customizing an Application Module with Service Methods," and Section 13.9, "Publishing Custom Service Methods to UI Clients."

**Note:** If you are using task flows, you can call methods directly from the task flow definition. For more information, see Section 21.5, "Using Method Call Activities."

For example, the ItemsForOrder view object in the Summit sample application for Oracle ADF contains the deleteOrderItem() method. This method updates the items in the shopping cart. To allow the user to execute this method, you drag the deleteOrderItem() method from the Data Controls panel, as shown in Figure 30–1.
In order to perform the required business logic, many methods require a value for their parameter or parameters. This means that when you create a button bound to the method, you need to create an EL expression to specify where the value for the parameter(s) is to be retrieved from. For example, if you use the `populateInventoryForProduct(String productId)` method, you need to configure the method action binding to retrieve a product ID so that the method can display the inventory for the product with that ID.

### 30.2.1 How to Create a Command Component Bound to a Custom Method

You create a command component bound to custom method by dragging the custom method from the Data Controls panel to a form.

**Before you begin:**

It may be helpful to have an understanding of custom methods. For more information, see Section 30.2, "Creating Command Components to Execute Methods."

You may also find it helpful to understand functionality that can be added using other command components. For more information, see Section 30.1.2, "Additional Functionality for Command Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and any custom methods that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

**To create a command component bound to a custom method:**

1. From the Data Controls panel, drag the method onto the page.

   **Tip:** If you are dropping a button for a method that needs to work with data in a table or form, that button must be dropped inside the table or form.

2. From the context menu, choose Create > Methods > ADF Button.

   If the method takes parameters, the Edit Action Binding dialog opens. In the Edit Action Binding dialog, enter values for each parameter or click the **Show EL**
Expression Builder menu selection in the Value column of Parameters to launch the EL Expression Builder.

30.2.2 What Happens When You Create Command Components Using a Method

When you drop a method as a command button, JDeveloper:

- Defines a method action binding for the method.
- If the method takes any parameters, JDeveloper creates NamedData elements that hold the parameter values.
- Inserts code in the JSF page for the ADF Faces command component.
- Binds the button to the method using actionListener.
- Uses the return value from the method call.

30.2.2.1 Action Bindings

JDeveloper adds an action binding for the method. Action bindings use the RequiresUpdateModel property, which determines whether or not the model needs to be updated before the action is executed. For command operations, this property is set to true by default, which means that any changes made at the view layer must be moved to the model before the operation is executed.

30.2.2.2 Method Parameters

When you drop a method that takes parameters onto a JSF page, JDeveloper creates a method action binding. This binding is what causes the method to be executed when a user clicks the command component. When the method requires parameters to run, JDeveloper also creates NamedData elements for each parameter. These elements represent the parameters of the method.

For example, in the Summit sample application for ADF task flows, the populateInventoryForProduct(String) method action binding contains a NamedData element for the String parameter. This element is bound to the value specified when you created the action binding. Example 30–1 shows the method action binding created when you drop the populateInventoryForProduct(String) method, and bind the String parameter (named productId) to the appropriate variable.

Example 30–1  Method Action Binding for a Parameter Method

```<methodAction id="populateInventoryForProduct" RequiresUpdateModel="true" Action="invokeMethod"
    MethodName="populateInventoryForProduct" IsViewObjectMethod="true"
    DataControl="BackOfficeAppModuleDataControl"
    InstanceName="data.BackOfficeAppModuleDataControl.InventoryVO1">
    <NamedData NDName="productId" NDType="java.lang.String"/>
</methodAction>
```

30.2.2.3 ADF Faces Component Code

JDeveloper adds code for the ADF Faces component to the JSF page. This code is similar to the code for any other command button, as described in Section 28.4.2.3, "EL Expressions Created to Bind to Operations." However, instead of being bound to the execute method of the action binding for a built-in operation, the button is bound to the execute method of the method action binding for the method that was dropped.
30.2.2.4 EL Expressions Used to Bind to Methods

Like creating command buttons using operations, when you create a command button using a method, JDeveloper binds the button to the method using the actionListener attribute. The button is bound to the execute property of the action binding for the given method using an EL expression. This EL expression causes the binding’s method to be invoked on the application module. For more information about the command button’s actionListener attribute, see Section 28.4.3, "What Happens at Runtime: How Action Events and Action Listeners Work."

Tip: Instead of binding a button to the execute method on the action binding, you can bind the button to the method in a backing bean that overrides the execute method. Doing so allows you to add logic before or after the original method runs. For more information, see Section 30.4, "Overriding Declarative Methods."

Like navigation operations, the disabled property on the button uses an EL expression to determine whether or not to display the button. Example 30–2 shows the EL expression used to bind the command button to the populateInventoryForProduct(String) method.

Example 30–2 JSF Code to Bind a Command Button to a Method

```xml
<af:button actionListener="#{bindings.populateInventoryForProduct.execute}"
    text="populateInventoryForProduct"
    disabled="#{bindings.populateInventoryForProduct.enabled}"
    id="b1"/>
```

Tip: When you drop a command button component onto the page, JDeveloper automatically gives it an ID based on the number of the same type of component that was previously dropped. For example, b1 and b2 for the first two buttons dropped. If you change the ID to something more descriptive, you must manually update any references to it in any EL expressions in the page.

30.2.2.5 Using the Return Value from a Method Call

You can also use the return value from a method call. Example 30–3 shows a custom method that returns a string value.

Example 30–3 Custom Method That Returns a Value

```java
/**
 * Custom method.
 */

public String getHelloString() {
    return "Hello World";
}
```

Example 30–4 shows the code in the JSF page for the command button and an outputText component.

Example 30–4 Command Button to Call the Custom Method

```xml
<af:button actionListener="#{bindings.getHelloString.execute}"
    text="getHelloString"
    disabled="#{bindings.getHelloString.enabled}"
When the user clicks the command button, it calls the custom method. The method returns the string "Hello World" to be shown as the value of the outputText component.

### 30.2.3 What Happens at Runtime: Command Button Method Bindings

When the user clicks the button, the method binding causes the associated method to be invoked, passing in the value bound to the NamedData element as the parameter. For example, if a user clicks a button bound to the `populateInventoryForProduct(String productId)` method, the method takes the value of the `productId` parameter and displays the inventory for that product.

### 30.3 Setting Parameter Values Using a Command Component

There may be cases where an action on one page needs to set parameters that will be used to determine application functionality. For example, you can create a search button on one page that will navigate to a results table on another page. But the results table will display only if a parameter value is false.

You can use a managed bean to pass this parameter between the pages, and to contain the method that is used to check the value of this parameter. The managed bean is instantiated as the search page is rendered, and a method on the bean checks that parameter. If it is null (which it will be the first time the page is rendered), the bean sets the value to true.

For more information about creating custom methods, see Section 13.7, "Customizing an Application Module with Service Methods," and Section 13.9, "Publishing Custom Service Methods to UI Clients."

#### Note
If you are using task flows, you can use the task flow parameter passing mechanism. For more information, see Chapter 22, "Using Parameters in Task Flows."

A `setPropertyListener` component with type property set to action, which is nested in the command button that executed this search, is then used to set this flag to false, thus causing the results table to display once the search is executed. For information about using managed beans, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

### 30.3.1 How to Set Parameters Using `setPropertyListener` Within a Command Component

You can use the `setPropertyListener` component to set values on other objects. This component must be a child of a command component.

#### Before you begin:
It may be helpful to have an understanding of how `setPropertyListener` and managed bean can be used to set a value. For more information, see Section 30.3, "Setting Parameter Values Using a Command Component."
You may also find it helpful to understand functionality that can be added using other command components. For more information, see Section 30.1.2, "Additional Functionality for Command Components."

You will need to complete this task:

- Create an application module that contains instances of the view objects and any custom methods that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

**To use the setPropertyListener component:**

1. In the Applications window, double-click the web page that contains the command component to which you want to add the listener.
2. In the design editor for the page, right-click the command component and choose Insert Inside Button > ADF Faces.
3. In the Insert ADF Faces Item dialog, select Set Property Listener and click OK.
4. In the Insert Set Property Listener dialog, enter the parameter value in the From field.
   
   You can bring up an expression builder for this field by hovering to the right of the field, clicking the icon that appears, and choosing Expression Builder.

5. Enter the parameter target in the To field.
   
   You can bring up an expression builder for this field by hovering to the right of the field, clicking the icon that appears, and choosing Expression Builder.

   **Tip:** Consider storing the parameter value on a managed bean or in scope instead of setting it directly on the resulting page’s page definition file. By setting it directly on the next page, you lose the ability to easily change navigation in the future. For more information, see Section 26.4, "Using a Managed Bean in a Fusion Web Application." Additionally, the data in a binding container is valid only during the request in which the container was prepared. The data may change between the time you set it and the time the next page is rendered.

6. From the Type dropdown menu, select Action.
7. Click OK.

**30.3.2 What Happens When You Set Parameters Using a setPropertyListener**

The setPropertyListener component lets the command component set a value before it navigates to the next page. When you set the from attribute either to the source of the value you need to pass or to the actual value, the component will be able to access that value. When you set the to attribute to a target, the command component is able to set the value on the target. Example 30–5 shows the code on the JSF page for a command component that takes the value false and sets it as the value of the initialSearch flag on the searchResults managed bean.
Overriding Declarative Methods

### Example 30–5  JSF Page Code for a Command Button Using a `setPropertyListener` Component

```xml
<af:button actionListener="#{bindings.Execute.execute}"
    text=Search>
    <af:setPropertyListener from="#{false}"
        to="#{searchResults.initialSearch}"/>
        type="action"/>
</af:button>
```

### 30.3.3 What Happens at Runtime: `setPropertyListener` for a Command Component

When a user clicks the command component, before navigation occurs, the `setPropertyListener` component sets the parameter value. In Example 30–5, the `setPropertyListener` takes the value `false` and sets it as the value for the `initialSearch` attribute on the `searchResults` managed bean. Now, any component that needs to know this value in determining whether or not to render can access it using the EL expression `#{searchResults.initialSearch}`.

### 30.4 Overriding Declarative Methods

When you drop an operation or method as a command button, JDeveloper binds the button to the `execute` method for the operation or method. However, there may be occasions when you need to add logic before or after the existing logic.

---

**Note:** If you are using task flows, you can call custom methods from the task flow. For more information, see Section 20, "Getting Started with ADF Task Flows."

---

JDeveloper allows you to add logic to a declarative operation by creating a new method and property on a managed bean that provides access to the binding container. By default, this generated code executes the operation or method. You can then add logic before or after this code. JDeveloper automatically binds the command component to this new method, instead of to the `execute` property on the original operation or method. Now when the user clicks the button, the new method is executed.

For example, in the `Customers.jsff` fragment of the Summit ADF task flow sample application, you can click the New icon to create a new order. However, the declarative `CreateInsert` operation requires additional processing. When the button is clicked, a new tab needs to be displayed showing the order details. To provide this processing, logic is added to the `createNewOrder` method in the `CustomersBackingBean` managed bean.

In order to override a declarative method, you must have a managed bean to hold the new method to which the command component will be bound. If your page has a backing bean associated with it, JDeveloper adds the code needed to access the binding object to this backing bean. If your page does not have a backing bean, JDeveloper asks you to create one.

### 30.4.1 How to Override a Declarative Method

You can add a command component and override its declarative methods using a managed bean.
Before you begin:

It may be helpful to have an understanding of how to override declarative methods. For more information, see Section 30.4, "Overriding Declarative Methods."

You may also find it helpful to understand functionality that can be added using other command components. For more information, see Section 30.1.2, "Additional Functionality for Command Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and any custom methods that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

---

**Note:** You cannot override the declarative method if the command component currently has an EL expression as its value for the Action attribute, because JDeveloper will not overwrite an EL expression. You must remove this value before continuing.

---

To override a declarative method:

1. Drag the operation or method to be overridden onto the JSF page and drop it as a UI command component.

   The component is created and bound to the associated binding object in the ADF Model layer with the ActionListener attribute.

   For more information about creating command components using methods on the Data Controls panel, see Section 30.2, "Creating Command Components to Execute Methods."

   For more information about creating command components from operations, see Section 28.4.2, "What Happens When You Create Command Components Using Operations."

2. On the JSF page, double-click the component.

3. In the Bind Action Property dialog, identify the backing bean and the method to which you want to bind the component, using one of the following techniques:

   - If auto-binding has been enabled on the page (by selecting the Automatically Expose UI Components in a New Managed Bean option that is available on the Managed Bean tab of the Create JSF Page wizard), the backing bean is already selected for you.
     
     - To create a new method, enter a name for the method in the Method field, which initially displays a default name.
     
     or
     
     - To use an existing method, select a method from the dropdown list in the Method field.
     
     - Select Use ADF Binding for Generation.

   - If the page is not using auto-binding, you can select from an existing backing bean or create a new one.
Overriding Declarative Methods

- Click **New** to create a new backing bean. In the Create Managed Bean dialog, name the bean and the class, and set the bean’s scope.

  or

- Select an existing backing bean and method from the dropdown lists. **Figure 30–2** shows the Bind Action Property dialog with a method from a managed bean specified for the method binding.

  **Figure 30–2  Bind Action Property Dialog**

  ![Bind Action Property Dialog](image)

  Note: Whenever there is a value for the **ActionListener** attribute on the command component, JDeveloper understands that the button is bound to the **execute** property of a binding. If you have removed that binding, you will not be given the choice to generate the ADF binding code. You will need to insert the code manually, or to set a dummy value for the **ActionListener** before double-clicking the command component.

  4. After identifying the backing bean and method, click **OK** in the Bind Action Property dialog.

  The managed bean opens in the source editor. **Example 30–6** shows the code inserted into the bean in the Summit ADF task flow sample application. In this example, a command button is bound to the **CreateInsert** operation.

  **Example 30–6  Generated Code in a Backing Bean to Access the Binding Object**

  ```java
  public void createNewOrder() {
      BindingContainer bindings = getBindings();
      OperationBinding operationBinding = bindings.getOperationBinding("CreateInsert");
      Object result = operationBinding.execute();
      if (!operationBinding.getErrors().isEmpty()) {
          return null;
      }
  }
  ```

  5. You can now add logic either before or after the binding object is accessed, as shown by the code in bold in **Example 30–7**.
Example 30–7  Code Added to the Overridden Method

```java
public void createNewOrder() {
    //This method is called when creating a new order
    //to create the record and switch the tab
    getSdi3().setDisclosed(false);
    getSdi4().setDisclosed(true);
    BindingContainer bindings = getBindings();
    OperationBinding operationBinding =
        bindings.getOperationBinding("CreateInsert");
    operationBinding.execute();
    AdfFacesContext adfFacesContext = AdfFacesContext.getCurrentInstance();
    adfFacesContext.addPartialTarget(getSdi4());
}
```

In addition to any processing logic, you may also want to write conditional logic to return one of multiple outcomes. For example, you might want to return null if there is an error in the processing, or another outcome value if the processing was successful. A return value of null causes the navigation handler to forgo evaluating navigation cases and to immediately redisplay the current page.

**Tip:** To trigger a specific navigation case, the outcome value returned by the method must exactly match the outcome value in the navigation rule, including case.

The command button is now bound to this new method using the Action attribute instead of the ActionListener attribute. If a value had previously existed for the Action attribute (such as an outcome string), that value is added as the return for the new method. If there was no value, the return is kept as null.

### 30.4.2 What Happens When You Override a Declarative Method

When you override a declarative method, JDeveloper adds a managed property to your backing bean with the managed property value of `#{bindings}` (the reference to the binding container), and it adds a strongly typed bean property to your class of the `BindingContainer` type, which the JSF runtime will then set with the value of the managed property expression `#{bindings}`. JDeveloper also adds logic to the UI command action method. This logic includes the strongly typed `getBindings()` method used to access the current binding container.

The code does the following:

- Accesses the binding container.
- Finds the binding for the associated method, and executes it.
- Adds a return for the method that can be used for navigation. By default, the return is null. If an outcome string had previously existed for the button's Action attribute, that attribute is used as the return value. You can change this code as needed.

JDeveloper automatically rebinds the UI command component to the new method using the Action attribute, instead of the ActionListener attribute. Example 30–8 shows the code when a CreateInsert operation is declaratively added to a page.

**Example 30–8 JSF Page Code for a Command Button Bound to a Declarative Method**

```xml
<af:button actionListener="#{bindings.CreateInsert.execute}"
    text="CreateInsert"
    disabled="#{!bindings.CreateInsert.enabled}"/>
```
Example 30–9 shows the code for the button tag after the method on the page’s backing bean is overridden. Note that the action attribute is now bound to the backing bean’s method.

**Example 30–9  JSF Page Code for a Command Button Bound to an Overridden Method**

```xml
<af:button text="New"
    action="#{backingBeanScope.CustomersBackingBean.createNewOrder}"/>
```

**Tip:** If when you click the button that uses the overridden method you receive this error:

```
SEVERE: Managed bean main_bean could not be created
The scope of the referenced object: '#{bindings}' is shorter than the referring object
```

it is because the managed bean that contains the overriding method has a scope that is greater than request (that is, either session or application). Because the data in the binding container referenced in the method has a scope of request, the scope of this managed bean must be set to the same or a lesser scope.
This chapter describes how to create master-detail objects with data modeled from ADF Business Components, using ADF data controls and ADF Faces components. It describes how to display master-detail data by using prebuilt master-detail widgets, tables, trees and tree tables and how to work with selection events.

This chapter includes the following sections:

- Section 31.1, "About Displaying Master-Detail Data"
- Section 31.2, "Prerequisites for Master-Detail Tables, Forms, and Trees"
- Section 31.3, "Using Tables and Forms to Display Master-Detail Objects"
- Section 31.4, "Using Trees to Display Master-Detail Objects"
- Section 31.5, "Using Tree Tables to Display Master-Detail Objects"
- Section 31.6, "About Selection Events in Trees and Tree Tables"

For information about using a selection list to populate a collection with a key value from a related master or detail collection, see Chapter 32, "Creating Databound Selection Lists and Shuttles".

### 31.1 About Displaying Master-Detail Data

There are many instances where data needs to be presented in a hierarchical manner. In a master-detail relationship, when the user changes the selected item in the master data object, the data set displayed in the detail data object changes with it. For example, selecting the television categories in the master object would display all the models of televisions in the detail object.

When using ADF Model in combination with ADF Faces UI components, you can declaratively create master-detail pages that display the data from multiple objects simultaneously when those objects have a master-detail relationship defined. ADF iterator bindings automatically manage the synchronization of the detail data objects displayed for a selected master data object.

In ADF Business Components, a master-detail relationship is established when a view link is created to associate two view object instances. As described in Section 5.1, "About View Objects", a view link represents the relationship between two view objects, which is usually, but not necessarily, based on a foreign-key relationship between the underlying data tables. The view link associates a row of one view object instance (the master object) with one or more rows of another view object instance (the detail object).
31.1.1 Master-Detail Tables, Forms, and Trees Use Cases and Examples

When objects have a master-detail relationship, you can declaratively create pages that display the data from both objects simultaneously. For example, the page shown in Figure 31–1 displays an entry for a customer in a form at the top of the page and a table of the customer’s orders at the bottom of the page. This is possible because the objects have a master-detail relationship. In this example, the Customers view object is the master object and OrdersForCustomer is the detail object. ADF iterators automatically manage the synchronization of the detail data objects displayed for a selected master data object. Iterator bindings simplify building user interfaces that allow scrolling and paging through collections of data and drilling-down from summary to detail information.

You display master and detail objects in forms, tables, trees, and tree tables. You can display these objects on the same page or on separate pages. For example, you can display the master object in a table on one page and detail objects in a read-only form on another page.

A master object can have many detail objects, and each detail object can in turn have its own detail objects, down to many levels of depth. If one of the detail objects in this hierarchy is dropped from the Applications window as a master-detail form on a page, only its immediate parent master object displays on the page. The hierarchy will not display all the way up to the topmost parent object.

If you display the detail object as a tree or tree table object, it is possible to display the entire hierarchy with multiple levels of depth, starting with the topmost master object, and traversing detail children objects at each node.

Figure 31–1 shows an example of a master form with detail table. When the user navigates through the customers using the command buttons, the table lists the orders that the customer has made.

Figure 31–2 shows a tree that has two levels of nodes. You can use trees to display hierarchical information. In this example, a tree is used to display customers grouped
by countries. The user can expand nodes to traverse down a branch of the tree to access the leaf items.

**Figure 31–2  Multi-level Tree**

- **Customers**
  - Brazil
    - 201 Unisports
  - Japan
    - 202 Simms Athletics
  - India
    - 203 Delhi Sports
  - USA
  - Hong Kong
  - France

**Figure 31–3** shows the same grouping of customers by country, but using a tree table instead of a tree. In addition to the hierarchical node levels of a tree, a tree table can also display column information for each node. You can also focus on subtrees as well as collapsing and expanding the elements.

**Figure 31–3  Tree Table**

<table>

### 31.1.2 Additional Functionality for Master-Detail Tables, Forms, and Trees

You may find it helpful to understand other Oracle ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- **ADF view objects and view links**: Much of how the components display and function in the form is controlled by the corresponding view objects. For more information about creating view objects and establishing a master-detail hierarchy in your data model with view links, see Section 6.2, "Working with Multiple Tables in a Master-Detail Hierarchy."

- **ADF application modules**: The Data Controls panel, from which you drag databound components to your pages, is populated with representations of view objects that you have added to application modules. For more information, see Chapter 13, "Implementing Business Services with Application Modules."

- **Adapter-based data controls**: If you are using other types of business services, such as EJB components or web services, you can create data control for those business service as described in Developing Applications with Oracle ADF Data Controls.
ADF Model and data binding: When you create forms in an ADF web application, you use ADF Model and data binding. For more information, see Chapter 17, "Using ADF Model in a Fusion Web Application."

ADF Faces: You also use ADF Faces UI components. For detailed information about developing with ADF Faces, see Developing Web User Interfaces with Oracle ADF Faces.

ADF forms and tables: If you want to modify the default forms or tables, see Section 28.3, "Creating Basic Forms Using Data Control Collections" or Section 29.2, "Creating a Basic Table."

Task flows: If your form takes part in a transaction, then you may need to use an ADF task flow to invoke certain operations before or after the form is rendered. For more information, see Part IV, "Creating ADF Task Flows".

Event handling: You may need to write listener methods to process client-side events. For more information, see the "Handling Events" chapter of Developing Web User Interfaces with Oracle ADF Faces.

Managed beans: You may need to create managed beans for event handling and other front-end processing. For more information about creating and using managed beans, see Section 26.4, "Using a Managed Bean in a Fusion Web Application."

### 31.2 Prerequisites for Master-Detail Tables, Forms, and Trees

Master-detail tables, forms, trees, and tree tables require a master-detail relationship to be established in the data model. That master-detail relationship is then reflected in the Data Controls panel, from where you can drag and drop objects to declaratively create pages that display master-detail data.

In an ADF Business Components application, you indicate a master-detail relationship by creating a view link between two view objects. Then you add the master view object and the detail view object instances to the application module data model. For more information, see Section 6.2.4, "How to Enable Active Master-Detail Coordination in the Data Model."

---

**Note:** For data controls based on other business services, such as web services or EJB session beans, the master-detail relationship is typically inferred from standard mechanisms within those services, such as definition files for web services orJoinColumn annotations in JPA-based beans.

For example, in the Summit sample application for Oracle ADF, there is a view link from the CustomerVO view object to the OrdVO view object based on the CustomerId attribute, both contained in the application module data model, as shown in Figure 31–4. A change in the current row of the master view object instance causes the row set of the detail view object instance to refresh to include the details for the current master.
31.2.1 How to Identify Master-Detail Objects on the Data Controls Panel

You can identify master-detail objects by looking at the hierarchy in the Data Controls panel.

Before you begin:

It may help to understand the basics of master-detail relationships. For more information, see Section 31.2, "Prerequisites for Master-Detail Tables, Forms, and Trees."

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Section 31.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."

You will need to complete this task:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as

Note: In the Summit ADF sample application, the view link between the CustomerVO view object and OrdVO view object is a one-way relationship. If the view link were bidirectional and both sets of master and detail view objects were added to the application module data model, then the Data Controls panel would also display the OrdersForCustomer collection at the same node level as the Customers collection, and the detail instance of the OrdersForCustomer collection as a child of the Customers collection.
described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

**To identify master-detail objects:**
- In the Applications window, open the Data Controls panel, expand any collection nodes, and look for collection child nodes of those collections.

Any child collection node of a collection node represents the detail part of a master-detail relationship with the parent node. A parent collection can be part of a master-detail relationship with multiple child collections. And collections can be nested in multiple layers, meaning that a collection can be the detail part of one master-detail relationship and the master part of another master-detail relationship.

Figure 31–5 shows two master-detail related collections in the Data Controls panel of the Summit ADF sample application. The *Customers* collection is an instance of the *CustomerVO* view object, and the *OrdersForCustomer* collection, which appears as a child of the *Customers* collection, is an instance of the *OrdVO* view object.

**Note:** The master-detail hierarchy displayed in the Data Controls panel does not reflect the cardinality of the relationship (that is, one-to-many, one-to-one, many-to-many). The hierarchy simply shows which collection (the master) is being use to retrieve one or more objects from another collection (the detail).

*Figure 31–5  Master-Detail Objects in the Data Controls Panel*

The master-detail hierarchy on the Data Controls panel reflects the hierarchy defined in the application module data model, as shown in Figure 31–4. For more information about the icons displayed on the Data Controls panel, see Section 17.4.1, "How to Use the Data Controls Panel."
31.3 Using Tables and Forms to Display Master-Detail Objects

You can create master-detail functionality on a page with form and table components. You can do so either by creating individual form and table components or by using pre-built widgets that encompass both the master and detail components.

The pre-built widgets enable you to create a read-only master-detail browse page in a single declarative action using the Data Controls panel. All you have to do is drop the detail collection on the page and choose the type of widget you want to use. The generated components include range navigation that enables the end user to scroll through the data objects in collections. You can delete unwanted attributes by removing the text field or column from the page.

Figure 31–6 shows an example of prebuilt master-detail widget, which displays general order information in a form at the top of the page and order details in a table at the bottom of the page. When the user clicks the **Next** button to scroll through the records in the master data at the top of the page, the page automatically updates to display the detail data for the currently displayed master record.

There are some cases when the pre-built master-detail UI components that JDeveloper provides cannot provide the functionality you require. For example, you may need to make a component editable or bind components programatically instead of using the master-detail UI components. In these cases, you can create master-detail pages by creating forms and tables separately. When components are created from a collection and nested collection, the nested collection’s iterator binding manages coordination between the master and detail component automatically. For more information, see Section 31.3.2, "How to Create Master-Detail Forms from Separate Components" and Section 31.3.5, "How to Display Master-Detail Components on Separate Pages."
31.3.1 How to Display Master-Detail Objects in Tables and Forms Using Master-Detail Widgets

The Data Controls panel enables you to create both the master and detail widgets on one page with a single declarative action using prebuilt master-detail forms and tables. These prebuilt master-detail widgets are read-only. For information about displaying master and detail data on separate pages, see Section 31.3.2, "How to Create Master-Detail Forms from Separate Components." For information about displaying master and detail data on separate pages, see Section 31.3.5, "How to Display Master-Detail Components on Separate Pages."

Before you begin:
It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see Section 31.3, "Using Tables and Forms to Display Master-Detail Objects."

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Section 31.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in Section 13.2, "Creating and Modifying an Application Module." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

To create a master-detail page using the prebuilt ADF master-detail forms and tables:

1. From the Data Controls panel, locate the detail object, as described in Section 31.2.1, "How to Identify Master-Detail Objects on the Data Controls Panel."

2. Drag and drop the detail object onto the JSF page.

3. From the Master-Detail submenu of the context menu, choose one of the following components:

   - **ADF Master Table, Detail Form**: Displays the master objects in a read-only table and the detail objects in a read-only form under the table.

     When a specific data object is selected in the master table, the first related detail data object is displayed in the form below it. The user must use the form navigation to scroll through each subsequent detail data object.

   - **ADF Master Form, Detail Table**: Displays the master objects in a read-only form and the detail objects in a read-only table under the form.

     When a specific master data object is displayed in the form, the related detail data objects are displayed in a table below it.

Note: You can also use the `detailStamp` facet of a master table to display the detail for selected rows. See Section 29.5.4, "How to Create a Dynamic Table with a detailStamp Facet" for information on doing so with a dynamic component.
Using Tables and Forms to Display Master-Detail Objects

31.3.2 How to Create Master-Detail Forms from Separate Components

Instead of using the pre-built master-detail widgets to create master-detail forms, you can create table and form components separately from data control objects that have a master-detail relationship and take advantage of the detail object’s iterator bindings to provide the master-detail coordination. Creating master-detail forms from separate components enables you more flexibility in how the components and their bindings are generated.

Before you begin:

Before you begin:
It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see Section 31.3, "Using Tables and Forms to Display Master-Detail Objects."

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Section 31.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in Section 6.2.2, "How to Create a Master-Detail Hierarchy Based on View Objects Alone." Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

To create a master-detail form with individual components:

1. Create the detail widget by dragging a child collection from the Data Controls panel and dropping it as a table or a form on the JSF page or fragment that corresponds to the detail view activity. For more information, see Section 31.2.1, "How to Identify Master-Detail Objects on the Data Controls Panel."

   For more information on creation of the individual components, see Section 28.3, "Creating Basic Forms Using Data Control Collections" and Section 29.2, "Creating a Basic Table."

2. Create the master widget by dragging the collection that is the parent of the collection in step 1 and dropping it as a table or a form on the JSF page or fragment that corresponds to the master view activity.
31.3.3 What Happens When You Create Master-Detail Tables and Forms

When you drag and drop a collection from the Data Controls panel, JDeveloper does many things for you, including adding code to the JSF page and the corresponding entries in the page definition file. For a general description of what happens and what is created when you use the Data Controls panel, see Section 17.4.2, "What Happens When You Use the Data Controls Panel."

31.3.3.1 Code Generated in a Master-Detail JSF Page

The JSF code generated for a prebuilt master-detail widget is similar to the JSF code generated when you use the Data Controls panel to create a read-only form or table. If you are building your own master-detail widgets, you might want to consider including similar components that are automatically included in the prebuilt master-detail tables and forms.

The tables and forms in the prebuilt master-detail widgets include a `panelHeader` tag that contains the name of the data control populating the master form or table. You can change this label as needed using a string or an EL expression that binds to a resource bundle.

If there is more than one object in a collection, a form in a prebuilt master-detail widget includes four `button` tags for range navigation: First, Previous, Next, and Last. These range navigation buttons enable the user to scroll through the objects in the collection. The `actionListener` attribute of each button is bound to a data control operation, which performs the navigation. The `execute` property used in the `actionListener` binding, invokes the operation when the button is clicked. (If the form displays a single object, JDeveloper automatically omits the range navigation components.) For more information about range navigation, see Section 28.5, "Incorporating Range Navigation into Forms."

**Tip:** If you drop an ADF Master Table, Detail Form or ADF Master Table, Detail Table widget on the page, the parent tag of the detail component (for example, `panelHeader` tag or `table` tag) automatically has the `partialTriggers` attribute set to the `id` of the master component (see Section 29.4.1, "How to Create an Input Table" for more information about partial triggers). At runtime, the `partialTriggers` attribute causes only the detail component to be rerendered when the user makes a selection in the master component, which is called partial page rendering. Partial page rendering is used because only the detail component needs to be rerendered to display the new data. The table does not need to be rerendered when the user simply makes a selection in the facet.

31.3.3.2 Binding Objects Defined in a Master-Detail Page Definition File

Example 31–1 shows the page definition file created for a master-detail page that was created by dropping the `OrdersFromCustomer` collection, which is a detail object under the `Customers` object, on the page as an ADF Master Form, Detail Table.

The `executables` element defines two iterators: one for the master object and one for the detail object. At runtime, the data model and the row set iterator for the detail view object instance keep the row set of the detail view object refreshed to the correct set of rows for the current master row as that current row changes. For more information, see Section 31.3.4, "What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms".

The `bindings` element defines the value bindings for the form and the table. The attribute bindings that populate the text fields in the form are defined in the
attributeValues elements. The id attribute of the attributeValues element contains the name of each data attribute, and the IterBinding attribute references an iterator binding to display data from the master object in the text fields.

The range navigation buttons in the form are bound to the action bindings defined in the action elements. As in the attribute bindings, the IterBinding attribute of the action binding references the iterator binding for the master object.

The table, which displays the detail data, is bound to the table binding object defined in the table element. The IterBinding attribute references the iterator binding for the detail object.

For more information about the elements and attributes of the page definition file, see Section A.8, "pageNamePageDef.xml."

**Example 31–1 Binding Objects Defined in the Page Definition for a Master-Detail Page**

```xml
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="Customers" RangeSize="25"
    DataControl="BackOfficeAppModuleDataControl" id="CustomersIterator"
    ChangeEventPolicy="ppr"/>
  <iterator Binds="OrdersForCustomer" RangeSize="25"
    DataControl="BackOfficeAppModuleDataControl"
    id="OrdersForCustomerIterator" ChangeEventPolicy="ppr"/>
</executables>

<bindings>
  <action IterBinding="CustomersIterator" id="First" RequiresUpdateModel="true"
    Action="first"/>
  <action IterBinding="CustomersIterator" id="Previous" RequiresUpdateModel="true"
    Action="previous"/>
  <action IterBinding="CustomersIterator" id="Next" RequiresUpdateModel="true"
    Action="next"/>
  <action IterBinding="CustomersIterator" id="Last" RequiresUpdateModel="true"
    Action="last"/>
  <attributeValues IterBinding="CustomersIterator" id="Id">
    <AttrNames>
      <Item Value="Id"/>
    </AttrNames>
  </attributeValues>
  <attributeValues IterBinding="CustomersIterator" id="Name">
    <AttrNames>
      <Item Value="Name"/>
    </AttrNames>
  </attributeValues>
  <attributeValues IterBinding="CustomersIterator" id="Phone">
    <AttrNames>
      <Item Value="Phone"/>
    </AttrNames>
  </attributeValues>
  <attributeValues IterBinding="OrdersForCustomerIterator" id="OrdersForCustomer">
    <nodeDefinition DefName="oracle.summit.model.views.OrdVO"
      Name="OrdersForCustomer0">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="CustomerId"/>
        <Item Value="DateOrdered"/>
      </AttrNames>
    </nodeDefinition>
  </attributeValues>
</bindings>
```
31.3.4 What Happens at Runtime: ADF Iterator for Master-Detail Tables and Forms

At runtime, an ADF iterator determines which row from the master table object to display in the master-detail form. When the form first displays, the first master table object row appears highlighted in the master section of the form. Detail table rows that are associated with the master row display in the detail section of the form.

As described in Section 31.3.3.2, “Binding Objects Defined in a Master-Detail Page Definition File,” ADF iterators are associated with underlying rowsetIterator objects. These iterators manage which data objects, or rows, currently display on a page. At runtime, the row set iterators manage the data displayed in the master and detail components.

Both the master and detail row set iterators listen to row set navigation events, such as the user clicking the range navigation buttons, and display the appropriate row in the UI. In the case of the default master-detail components, the row set navigation events are the command buttons on a form (First, Previous, Next, Last).

The row set iterator for the detail collection manages the synchronization of the detail data with the master data. Because of the underlying view link from the master view object to the detail view object, the detail row set iterator listens for row navigation events in both the master and detail collections. If a row set navigation event occurs in the master collection, the detail row set iterator automatically executes and returns the detail rows related to the current master row.

31.3.5 How to Display Master-Detail Components on Separate Pages

The default master-detail components display the master-detail data on a single page. However, using the master and detail objects on the Data Controls panel, you can also display the collections on separate pages (or on separate fragments on the same page), and still have the binding iterators manage the synchronization of the master and detail objects.

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see Section 31.3, “Using Tables and Forms to Display Master-Detail Objects.”

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Section 31.1.2, “Additional Functionality for Master-Detail Tables, Forms, and Trees.”

You will need to complete this task:

- Create an application module that contains instances of the view objects and view links that establish the desired master-detail hierarchy, as described in Section 6.2.2, “How to Create a Master-Detail Hierarchy Based on View Objects Alone.” Alternatively, if you are using another type of business service, create a
data control for that business service as described in "Exposing Business Services with Data Controls" in *Developing Applications with Oracle ADF Data Controls*.

**To create master and detail objects on separate pages:**

1. Create an ADF task flow as described in Section 20.2.1, "How to Create a Task Flow."
   
   If you plan to use page fragments to hold the master and detail components, select the Create with Page Fragments checkbox in this step.

2. Add two view activities to the task flow, one for the master view and one for the detail view, as described in Section 20.3.1, "How to Add an Activity to a Task Flow."

3. In the task flow definition file, add a control flow case from the master view to the detail view, and a control flow case to return from the detail view to the master view. For more information, see Section 20.4.1, "How to Add a Control Flow Rule to a Task Flow."

4. Create two JSF pages or two JSF fragments to hold the master and detail components.
   
   You can create a page or fragment for a view activity by clicking on the view activity in the overview editor for task flow.
   
   If you already have pages or fragments that you want to map to the view activities, you can do so by selecting the view activity in the overview editor for the task flow, navigating to the Properties window, and specifying the JSF page or fragment in the Page property.

5. Create the detail component by dragging a child collection from the Data Controls panel and dropping it as a table or a form on the JSF page or fragment that corresponds to the detail view activity. For more information, see Section 31.2.1, "How to Identify Master-Detail Objects on the Data Controls Panel."
   
   For more information on creating forms and tables, see Section 28.3, "Creating Basic Forms Using Data Control Collections" and Section 29.2, "Creating a Basic Table."

6. Create the master component by dragging the collection that is the parent of the collection in step 5 and dropping it as a table or a form on the JSF page or fragment that corresponds to the master view activity.

7. Add command buttons or links to each page.

8. In the action attribute of each button, specify the control flow case that is used to navigate to the other page. You can get this value from the from-outcome property of the corresponding control flow case.

   For example, in the Summit ADF sample application, the Customers.jsff fragment contains a table created from the OrdersFromCustomer collection. That table serves as both a detail view of customer orders and a master view for the Order Items table that is created from the ItemsFromOrder collection and is located in Orders.jsff (and appears on the Order tab). Figure 31–7 shows the Orders table as a detail view for a customer, and Figure 31–8 shows the order that is selected in that table and displays that order’s detail. Though the OrdersFromCustomer collection is used in both the Customers.jsff and Orders.jsff fragments, it does not have to be used in both places to maintain master-detail coordination. The iterator binding for the ItemsFromOrder maintains the master-detail coordination, even across the page fragments.
31.4 Using Trees to Display Master-Detail Objects

In addition to tables and forms, you can also display master-detail data in hierarchical trees. The ADF Faces tree component is used to display hierarchical data. It can display multiple root nodes that are populated by a binding on a master object. Each root node in the tree may have any number of branches, which are populated by bindings on detail objects. A tree can have multiple levels of nodes, each representing a detail object of the parent node. Each node in the tree is indented to show its level in the hierarchy.

The tree component includes mechanisms for expanding and collapsing the tree nodes; however, it does not have focusing capability. If you need to use focusing, consider using the ADF Faces treeTable component (for more information, see Section 31.5, "Using Tree Tables to Display Master-Detail Objects"). By default, the icon
for each node in the tree is a folder; however, you can use your own icons for each level of nodes in the hierarchy.

Figure 31–9 shows an example of a tree located in the Customers.jsff fragment of the Summit ADF sample application. The tree displays two levels of nodes: root and branch. The root nodes display countries. The branch nodes display customers.

Figure 31–9  Databound ADF Faces Tree

```
Customers
  Brazil
    201 Unisports
  Japan
    202 Simms Athletics
  India
    203 Delhi Sports
  USA
  Hong Kong
  France
```

31.4.1 How to Display Master-Detail Objects in Trees

A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher level node. Each node level in a databound ADF Faces tree component is populated by a different data collection. In JDeveloper, you define a databound tree using the Edit Tree Binding dialog, which enables you to define the rules for populating each node level in the tree. There must be one rule for each node level in the hierarchy. Each rule defines the following node-level properties:

- The data collection that populates that node level
- The attributes from the data collection that are displayed at that node level

To enable creation of the Customers tree in the Summit ADF sample application as shown in Figure 31–9, a view object, CountryVO was first created to return a list of countries. Another view object, CustomerVO was then created to return customers. And a view link was created from CountryVO to CustomerVO in order to establish a master-detail relationship.

In this case, it is also possible to add a third-level and fourth-level nodes, since CustomerVO has a view link to the view object OrdVO, and OrdVO has a view link to ItemVO.

In the case where a branch of the tree is recursive, a single view object accompanied by a self-referential view link must be defined in the data model project. For example, take a collection defined by EmployeesView, where the root node of each branch is specified by the ManagerId attribute and the child nodes of the same branch are the employees (also known as "direct reports") who are related to the ManagerId. The source and destination view object named by the self-referential view link are both defined as EmployeesView, but the destination can be renamed to DirectReports for clarify. For more information about creating self-referential view links, see Section 6.3.1, "How to Create a Recursive Master-Detail Hierarchy for an Entity-Based View Object."
Note: When your business services are based on ADF Business Components, you can programmatically access a master view object’s view link accessor attribute to return a detail object to be displayed as a branch of the current node level. For information about view link accessors, see Section 6.2.6, "How to Access the Detail Collection Using the View Link Accessor."

Before you begin:

It may help to understand the options that are available to you when you create a master-detail table and form. For more information, see Section 31.4, "Using Trees to Display Master-Detail Objects."

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Section 31.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."

You will need to complete these tasks:

- Create the master-detail view objects and view links in the data model project, optimize the performance of row set access for tree components, and add the master view object (and optionally the detail view object) to the application module. For details about setting the optimization flag Retain Row Set, see Section 6.2.6.3, "Optimizing View Link Accessor Access to Display Master-Detail Data." For information on creating the master-detail hierarchy and adding it to the application module, see Section 6.2.2, "How to Create a Master-Detail Hierarchy Based on View Objects Alone."

  Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

- Create a JSF page as described in Section 26.3, "Creating a Web Page."

To display master-detail objects in a tree:

1. Drag the master object from the Data Controls panel, and drop it onto the page. This should be the master data that will represent the root level of the tree.

2. From the context menu, choose Tree > ADF Tree.

  JDeveloper displays the Edit Tree Binding dialog, as shown in Figure 31–10. You use the binding editor to define a rule for each level that you want to appear in the tree.

  When the dialog first appears, the collection that you dragged is displayed in the Root Data Source dropdown list and the corresponding view object is displayed in the Tree Level Rules list. This will represent the master data collection.

  Tip: If you don’t see the data collection you want in the Root Data Source list, click the Add button. In the Add Data Source dialog, select a data control and an iterator name to create a new data source. Then click the Add Rule icon and select Add Rule to add the master rule.
Using Trees to Display Master-Detail Objects

Displaying Master-Detail Data

3. Click the **Add Rule** icon and then select a detail collection to add to the **Tree Level Rules** list. A detail data source should appear under the master data source, as shown in Figure 31–11.

**Figure 31–11  Master-Detail Tree Level Rules**
If you are creating a tree with a recursive master-detail hierarchy, then you only need to define a rule that specifies a data source with a self accessor. A recursive tree displays root nodes based on a single collection and displays the child nodes from the attributes of a self accessor that recursively fetches data from that collection. The recursive tree differs from a typical master-detail tree because it requires only a single rule to define the branches of the tree. A recursive data source should display the data source followed by the name of the self accessor in brackets, as shown in Figure 31–12.

Repeat this step for any additional nodes (or further levels of hierarchy) that you want to add to the tree.

Figure 31–12 Recursive Tree Level Rule

4. In the Tree Level Rules list, select one of the rules.
5. In the bottom part of the dialog, set the attribute or attributes that you want to be used for the node’s display by shuffling those attributes to the to the Display Attributes list.
6. Repeat steps 4 and 5 for each of the rest of the rules.
7. Click OK.

31.4.2 What Happens When You Create an ADF Databound Tree

When you drag and drop from the Data Controls panel, JDeveloper does many things for you. For a general description of what happens and what is created when you use the Data Controls panel, see Section 17.4.1, "How to Use the Data Controls Panel.”

When you create a databound tree using the Data Controls panel, JDeveloper adds binding objects to the page definition file, and it also adds the tree tag to the JSF Page. The resulting UI component is fully functional and does not require any further modification.

31.4.2.1 Code Generated in the JSF Page

Example 31–2 shows the code generated in a JSF page when you use the Data Controls panel to create a tree. This sample tree displays two levels of nodes: countries and customers. The Countries collection was used to populate the root node.

Example 31–2 Code in a JSF Page for a Databound Tree

```xml
<af:tree value="#{bindings.Countries.treeModel}"
  var="node"
  selectionListener="#{bindings.Countries.treeModel.makeCurrent}"
  rowSelection="single" id='t1'
  <f:facet name='nodeStamp'>
    <af:outputText value="#{node}" id='ot1'/>
  </f:facet>
</af:tree>
```
By default, the `<af:tree>` tag is created inside a form. The `value` attribute of the `<tree>` tag contains an EL expression that binds the `<tree>` component to the `Countries` tree binding object in the page definition file. The `treeModel` property in the binding expression refers to an ADF class that defines how the `<tree>` hierarchy is displayed, based on the underlying data model. The `var` attribute provides access to the current node.

In the `<f:facet>` tag, the `nodeStamp` facet is used to display the data for each node. Instead of having a component for each node, the `<tree>` repeatedly renders the `nodeStamp` facet, similar to the way rows are rendered for the ADF Faces table component.

The ADF Faces `<tree>` component uses an instance of the `oracle.adf.view.faces.model.PathSet` class to display expanded nodes. This instance is stored as the `treeState` attribute on the component. You may use this instance to programmatically control the expanded or collapsed state of an element in the hierarchy. Any element contained by the `PathSet` instance is deemed expanded. All other elements are collapsed. For more information, see "What You May Need to Know About Programmatically Expanding and Collapsing Nodes" in Developing Web User Interfaces with Oracle ADF Faces.

### 31.4.2.2 Binding Objects Defined in the Page Definition File

Example 31–3 shows the binding objects defined in the page definition file that pertain to the `Countries` ADF databound tree in the Summit ADF sample application.

**Example 31–3 Binding Objects Defined in the Page Definition File for a Databound Tree**

```xml
<executables>
  ...
  <iterator Binds="Countries" RangeSize="25"
    DataControl="BackOfficeAppModuleDataControl"
    id="CountriesIterator"/>
</executables>
<bindings>
  ...
  <tree IterBinding="CountriesIterator" id="Countries">
    <nodeDefinition DefName="oracle.summit.model.views.CountryVO"
      Name="Countries0">
      <AttrNames>
        <Item Value="Country"/>
      </AttrNames>
      <Accessors>
        <Item Value="CustomerVO"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="oracle.summit.model.views.CustomerVO"
      Name="Countries1"
      TargetIterator="${bindings.CustomersIterator}">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Name"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

The page definition file contains the rule information defined in the Tree Binding Editor. In the `executables` element, notice that although the tree displays two levels...
of nodes, only one iterator binding object is needed. This iterator iterates over the
master collection, which populates the root nodes of the tree. The accessor you
specified in the node rules returns the detail data for each branch node.

The tree element is the value binding for all the attributes displayed in the tree. The
iterBinding attribute of the tree element references the iterator binding that
populates the data in the tree. The AttrNames element within the tree element
defines binding objects for all the attributes in the master collection. However, the
attributes that you select to appear in the tree are defined in the AttrNames elements
within the nodeDefinition elements.

The nodeDefinition elements define the rules for populating the nodes of the tree.
There is one nodeDefinition element for each node, and each one contains the
following attributes and subelements:

- DefName: An attribute that contains the fully qualified name of the data collection
  that will be used to populate the node.
- id: An attribute that defines the name of the node.
- AttrNames: A subelement that defines the attributes that will be displayed in the
  node at runtime.
- Accessors: A subelement that defines the accessor attribute that returns the next
  branch of the tree.

The order of the nodeDefinition elements within the page definition file defines the
order or level of the nodes in the tree, where the first nodeDefinition element
defines the root node. Each subsequent nodeDefinition element defines a subnode
of the one before it.

For more information about the elements and attributes of the page definition file, see
Appendix A.8, "pageNamePageDef.xml."

### 31.4.3 What Happens at Runtime: How an ADF Databound Tree Is Displayed

Tree components use org.apache.myfaces.trinidad.model.TreeModel to
access data. This class extends CollectionModel, which is used by the ADF Faces
table component to access data. For more information about the TreeModel class,
refer to the ADF Faces Javadoc.

When a page with a tree is displayed, the iterator binding on the tree populates the
root nodes. When a user collapses or expands a node to display or hide its branches, a
DisclosureEvent event is sent. The isExpanded method on this event determines
whether the user is expanding or collapsing the node. The DisclosureEvent event
has an associated listener.

The DisclosureListener attribute on the tree is bound to the accessor attribute
specified in the node rule defined in the page definition file. This accessor attribute is
invoked in response to the DisclosureEvent event; in other words, whenever a user
expands the node the accessor attribute populates the branch nodes.

### 31.4.4 How to Synchronize Other Parts of a Page With a Tree Selection

In addition to synchronizing a detail view with a master view, you can synchronize
other parts of a page with a tree selection. For each node definition (rule), you can
specify an optional TargetIterator property and set it to an EL expression for an
iterator binding in the current binding container. The expression is evaluated at
runtime when the user selects a row in the tree. The iterator binding’s view row key
attributes match (in order, number, and data type) the view row key of the iterator.
from which the `nodeDefinition` type’s rows are retrieved for the tree. At runtime, when the tree control receives a `selectionChanged` event, it passes in the list of keys for each level of the tree. These keys uniquely identify the selected node.

**Note:** You can view a page’s `nodeDefinition` elements by expanding a node binding in the page definition editor. These are the same tree binding rules that you can configure in the tree binding dialog.

The tree binding starts at the top of the tree. For each tree level whose key is present in the `Currently Selected Tree Node Keys` list, if there is a `TargetIterator` property configured for that `nodeDefinition`, the tree binding performs a `setCurrentRowWithKey()` operation on the selected target iterator. It uses the key from the appropriate level of the `Currently Selected Tree Node Keys` list.

For example, the Summit ADF sample application contains a tree that displays countries at the top node and customers at the second level. When a user selects a customer in the tree, a form displaying the customer information is displayed in the Summit Customer Management panel of the page as shown in Figure 31–13. This functionality consists of a tree that was created from the `Countries` data control object, a form created from the `Customers` object, and a detail table created from the `OrdersFromCustomer` object (which is nested under `Customers` in the Data Controls panel).

**Before you begin:**

It may help to understand the options that are available to you when you create a tree. For more information, see Section 31.4, "Using Trees to Display Master-Detail Objects."

You may also find it useful to understand additional functionality that can be used with master-detail tables and trees. For more information, see Section 31.1.2, "Additional Functionality for Master-Detail Tables, Forms, and Trees."

You will need to complete these tasks:

- Create the master-detail view objects and view links in the data model project, optimize the performance of row set access for tree components, and add the
master view object (and optionally the detail view object) to the application module. For details about setting the optimization flag Retain Row Set, see Section 6.2.6.3, "Optimizing View Link Accessor Access to Display Master-Detail Data." For information on creating the master-detail hierarchy and adding it to the application module, see Section 6.2.2, "How to Create a Master-Detail Hierarchy Based on View Objects Alone."

Alternatively, if you are using another type of business service, create a data control for that business service as described in "Exposing Business Services with Data Controls" in Developing Applications with Oracle ADF Data Controls.

■ Create a JSF page as described in Section 26.3, "Creating a Web Page."

To synchronize another part of the page with the tree selection:

1. From the Data Controls panel, drag the detail collection from which a record will be displayed based on the user selection in a tree, and drop it as a form or another databound component.

2. From the Data Controls panel, drag the parent collection of the detail collection that you just dropped and choose Create > Tree > ADF Tree (or ADF Tree Table).

3. In the Edit Tree Binding dialog, configure tree binding rules for all of the levels of the tree hierarchy as described in Section 31.4.1, "How to Display Master-Detail Objects in Trees," and leave the dialog open.

4. Select the detail tree-level rule that corresponds to the same collection that is used in step 1.

5. Expand the Target Data Source node and click the EL Picker button.

6. In the Variables dialog, expand ADF Bindings, expand bindings, and select the iterator binding for the component that you created in step 1.

   The expression will display in the Expression text area. The expression should look something like ${bindings.CustomersIterator}. This expression will then be used to set the target iterator when a user clicks a detail node.

7. Click OK to exit the Variables dialog, and click OK to exit the Edit Tree Binding dialog.

31.5 Using Tree Tables to Display Master-Detail Objects

Use the ADF Faces treeTable component to display a hierarchy of master-detail collections in a table. The advantage of using a treeTable component rather than a tree component is that the treeTable component provides a mechanism that enables users to focus the view on a particular node in the tree.

For example, you can create a tree table that displays levels of nodes for countries and customers where each root node represents an individual country. The branches off the root nodes display the customers for that country. As with trees, to create such a tree table, it is necessary to have master-detail relationships between the collections in the hierarchy.

A databound ADF Faces treeTable displays one root node at a time, but provides navigation for scrolling through the different root nodes. Each root node can display any number of branch nodes. Every node is displayed in a separate row of the table, and each row provides a focusing mechanism in the leftmost column.

You can edit the following treeTable component properties in the Properties window:
Range navigation: The user can click the Previous and Next navigation buttons to scroll through the root nodes.

List navigation: The list navigation, which is located between the Previous and Next buttons, enables the user to navigate to a specific root node in the data collection using a selection list.

Node expanding and collapsing mechanism: The user can open or close each node individually or use the Expand All or Collapse All command links. By default, the icon for opening and closing the individual nodes is an arrowhead with a plus or minus sign. You can also use a custom icon of your choosing.

Focusing mechanism: When the user clicks on the focusing icon (which is displayed in the leftmost column) next to a node, the page is redisplayed showing only that node and its branches. A navigation link is provided to enable the user to return to the parent node.

### 31.5.1 How to Display Master-Detail Objects in Tree Tables

The steps for creating an ADF Faces databound tree table are exactly the same as those for creating an ADF Faces databound tree, except that you drop the data collection as an ADF Tree Table instead of an ADF Tree. For more information, see Section 31.4.1, "How to Display Master-Detail Objects in Trees.”

### 31.5.2 What Happens When You Create a Databound Tree Table

When you drag and drop from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see Section 17.4.1, "How to Use the Data Controls Panel.”

When you create a databound tree table using the Data Controls panel, JDeveloper adds binding objects to the page definition file, and it also adds the treeTable tag to the JSF Page. The resulting UI component is fully functional and does not require any further modification.

#### 31.5.2.1 Code Generated in the JSF Page

Example 31–4 shows the code generated in a JSF page when you use the Data Controls panel to create a tree table. This sample tree table displays two levels of nodes: countries and customers.

By default, the treeTable tag is created inside a form. The value attribute of the treeTable tag contains an EL expression that binds the tree component to the binding object that will populate it with data. The treeModel property refers to an ADF class that defines how the tree hierarchy is displayed, based on the underlying data model. The var attribute provides access to the current node.

**Example 31–4  Code Generated in the JSF Page for a Databound ADF Faces Tree Table**

```xml
<af:treeTable value="#{bindings.Countries.treeModel}" var="node"
    selectionListener="#{bindings.Countries.treeModel.makeCurrent}"
    rowSelection="single"
    id="tt1">
  <f:facet name="nodeStamp">
    <af:column id="c1">
      <af:outputText value="#{node}" id="ot1"/>
    </af:column>
  </f:facet>
  <f:facet name="pathStamp">
    <af:outputText value="#{node}" id="ot2"/>
  </f:facet>
</af:treeTable>
```
The nodeStamp facet is used to display the data for each node. Instead of having a component for each node, the tree repeatedly renders the nodeStamp facet, similar to the way rows are rendered for the ADF Faces table component. The pathStamp facet renders the column and the path links above the table that enable the user to return to the parent node after focusing on a detail node.

### 31.5.2.2 Binding Objects Defined in the Page Definition File

The binding objects created in the page definition file for a tree table are exactly the same as those created for a tree. For more information, see Section 31.4.2.2, "Binding Objects Defined in the Page Definition File."

### 31.5.3 What Happens at Runtime: Events for Tree Tables

Tree components use oracle.adf.view.faces.model.TreeModel to access data. This class extends CollectionModel, which is used by the ADF Faces table component to access data. For more information about the TreeModel class, refer to the ADF Faces Javadoc.

When a page with a tree table is displayed, the iterator binding on the treeTable component populates the root node and listens for a row navigation event (such as the user clicking the **Next** or **Previous** buttons or selecting a row from the range navigator). When the user initiates a row navigation event, the iterator displays the appropriate row.

If the user changes the view focus (by clicking on the component’s focus icon), the treeTable component generates a focus event (FocusEvent). The node to which the user wants to change focus is made the current node before the event is delivered. The treeTable component then modifies the focusPath property accordingly. You can bind the FocusListener attribute on the tree to a method on a managed bean. This method will then be invoked in response to the focus event.

When a user collapses or expands a node, a disclosure event (DisclosureEvent) is sent. The isExpanded method on the disclosure event determines whether the user is expanding or collapsing the node. The disclosure event has an associated listener, DisclosureListener. The DisclosureListener attribute on the tree table is bound to the accessor attribute specified in the node rule defined in the page definition file. This accessor attribute is invoked in response to a disclosure event (for example, the user expands a node) and returns the collection that populates that node.

The treeTable component includes **Expand All** and **Collapse All** links. When a user clicks one of these links, the treeTable sends a DisclosureAllEvent event. The isExpandAll method on this event determines whether the user is expanding or collapsing all the nodes. The table then expands or collapses the nodes that are children of the root node currently in focus. In large trees, the expand all command will not expand nodes beyond the immediate children. The ADF Faces treeTable component uses an instance of the oracle.adf.view.faces.model.PathSet class to determine expanded nodes. This instance is stored as the treeState attribute on the component. You can use this instance to programmatically control the expanded or collapsed state of a node in the hierarchy. Any node contained by the PathSet instance is deemed expanded. All other nodes are collapsed. This class also supports operations like addAll() and removeAll().
For more information about the ADF Faces treeTable component, refer to the oracle.adf.view.faces.component.core.data.CoreTreeTable class in the ADF Faces Javadoc.

31.6 About Selection Events in Trees and Tree Tables

There may be cases when you need to determine which node in a tree or tree table has been selected in order to handle some processing in your application. For example, an application might require processing to determine the products that match a product category node that is selected by the user.

Whenever a user selects a node in a tree (or a row in a table), the component triggers selection events. A selectionEvent event reports which rows were just deselected and which rows were just selected. The current selection, that is, the selected row or rows, is managed by the RowKeySet object, which keeps track of all currently selected nodes by adding and deleting the associated key for the row into or out of the key set. When a user selects a new node, and the tree or table is configured for single selection, then the previously selected key is discarded and the newly selected key is added. If the tree or table is configured for multiple selection, then the newly selected keys are added to the set, and the previously selected keys may or may not be discarded, based on how the nodes were selected. For example, if the user pressed the CTRL key, then the newly selected nodes would be added to the current set.

For more information on selection events, see “What You May Need to Know About Performing an Action on Selected Rows in Tables” in Developing Web User Interfaces with Oracle ADF Faces.

Note: In cases where you merely need to synchronize the row currency between the selected node and other UI components on the page, you can do so declaratively using the TargetIterator property for each node definition. For more information, see Section 31.4.4, “How to Synchronize Other Parts of a Page With a Tree Selection.”

Selection changes in a tree or table will also trigger contextual events for communicating between regions within a page. For more information, see Chapter 40, "Using Contextual Events."
This chapter describes how to create lists and shuttle components from data modeled with ADF Business Components, using ADF data binding and ADF Faces components. It describes how to create the List of Value (LOV) components that utilize a query to populate the selection list. It includes instructions for creating standard selection components that use a model-driven, fixed-value, or dynamically generated list. It describes how to add navigation list bindings to let users navigate through a list of objects in a collection. It also describes how to use the shuttle component to allow the user to quickly move items between two lists.

This chapter includes the following sections:

- **Section 32.1, "About Selection Lists and Shuttles"
- **Section 32.2, "Creating List of Values (LOV) Components"
- **Section 32.3, "Creating a Selection List"
- **Section 32.4, "Creating a List with Navigation List Binding"
- **Section 32.5, "Creating a Databound Shuttle"

### 32.1 About Selection Lists and Shuttles

Selection list components present the user with a list of choices as input values. The selection list may be model-driven, obtained from a fixed list, or dynamically created at runtime. Selection list components can be rendered as lists, radio buttons, checkboxes, and list boxes. Some selection types can also be singular (select one) or multiple (select many).

Selection lists and shuttles work the same way as do standard JSF list components. ADF Faces list components, however, provide extra functionality such as support for label and message display, automatic form submission, and partial page rendering. When you present users with a list, they can readily see the available choices and make a selection. Picking from a list also eliminates typing errors that may occur.

List of values (LOV) components are UI components that allow the user to enter values by picking from a list that is generated by a query. The LOV displays inside a modal popup dialog that typically includes search capabilities. The `af:inputListOfValues` and `af:inputComboboxListOfValues` components, for example, offer additional features that are not available in selection lists, such as search fields inside the LOV modal dialog and queries based on multiple table columns. For more information, see **Section G.3.6, "How to Create a Popup List of Values"** and *Developing Web User Interfaces with Oracle ADF Faces*. 
List of values components offer more complex search and input capabilities by using the query component to create a popup search panel with a results table. The query component also has features such as auto-suggestion, smart list filtering, and custom facets for additional functionality.

When the user selects an item from a navigation list, a corresponding component bound to the list also changes its value in response to the selection. For example, when the user selects a product from a shopping list, the table that is bound to the products list updates to display the details of the selected product.

A shuttle allows the user to easily see the available items on an available list and the selected items in the selected list and to quickly move those items back and forth between the lists.

Shuttles provide a visual way to select items from an available list and at the same time see those selected items. ADF Faces provides the selectManyShuttle component and the selectOrderShuttle component, which allow reordering of the selected list. Both components can be implemented by adding code in a managed bean to populate the lists.

### 32.1.1 Selection Lists and Shuttles Use Cases and Examples

You can use a selection list component such as selectOneChoice for a single value input selection situation in which the list is relatively small. For example, you can use a selectOneChoice to select from a list of product colors or the type of credit card being used.

For larger lists and with more complex filtering, use an af:inputListOfValues or af:inputComboboxListOfValues component. These components use the query component to perform a transactional search to populate the list. For instance, you can use the af:inputComboboxListOfValues to select from a list of countries in an address input page.

Use the selectShuttle components when you want the user to be able to assemble a list of items and be able to select and unselect them. You should use the shuttle components when the number of items is large but not overwhelming to display. The user can review the selection and be able to iteratively select and unselect the items until the user is satisfied with the final selection. For instance, the available list could be the options available for a particular automobile and the user can shuttle the options the user likes to the selected list.

### 32.1.2 Additional Functionality for Selection Lists and Shuttles

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- For more information about using LOV components with search forms and the af:query component, see Section 33.1.2, "List of Values (LOV) Input Fields."

- You can use the LOV in a task flow that uses an isolated data control. For more information about shared and isolated data controls, see Section 24.2, "Sharing Data Controls Between Task Flows."

- LOVs are associated with a named view criteria. For more information about setting view criteria options, see Section 5.9.1, "How to Create Named View Criteria Declaratively."
LOV components uses the `af:query` component to populate the selection list. For more information about the `af:query` component, see Chapter 33, "Creating ADF Databound Search Forms."

### 32.2 Creating List of Values (LOV) Components

List of values (LOV) components are input components that allow the user to enter values by picking from a list that is generated by a query. ADF Faces provides the `af:inputListOfValues` and `af:inputComboboxListOfValues` components. If you are creating a fully featured LOV component, you must define the LOV in the view object as described in Section 5.12, "Working with List of Values (LOV) in View Object Attributes."

If you are using dependent LOVs as part of your search form, you must use them with the `af:query` component. For more information about using LOV components with search forms, see Section 33.1.2, "List of Values (LOV) Input Fields."

The `af:inputListOfValues` component has a search icon next to the search criteria field, as shown in Figure 32–1.

![Figure 32–1 Search Criteria Input Field Defined as an inputListOfValues](image)

The `af:inputComboboxListOfValues` component has a dropdown icon next to the field, as shown in Figure 32–2 for the State attribute.

![Figure 32–2 Search Criteria Input Field Defined as an inputComboboxListofValues](image)

For `af:inputComboboxListOfValues`, clicking the dropdown icon displays the LOV dropdown list and either a More or a Search link, as shown in Figure 32–3. A Search link appears when the LOV Search and Select popup dialog contains a search panel to refine the search. A More link appears when the popup dialog contains only the list-of-values table or when a smart list is used.

![Figure 32–3 LOV Dropdown List with Search Link for inputComboboxListofValues](image)

The user can select any of the items in the dropdown list to populate the input field. The dropdown list includes a filtered list of values and an optional list of most recently used items. The width of each attribute in the dropdown list can be configured using the DisplayWidth UI hint for that attribute in the view object definition. The width of
the dropdown list will be the sum of the widths of all the attributes in the dropdown list.

The user can also enter the value into the field. If the user enters data that is of a different data type than what is defined for the inputcomboboxListOfValues, a conversion error will be thrown. For example, if the inputcomboboxListOfValues is of NUMBER datatype and the user enters an alphanumeric string, a conversion error will result.

You can create custom content to be rendered in the Search and Select dialog using the searchContent facet. You can add components such as input text, tables, and trees to display the custom content. You will need to define the returnPopupDataValue attribute and implement a returnPopupListener. When you want to add the auto-complete feature with your custom popup, you can disable the popup by adding launchPopupEvent.setLaunchPopup(false) to your LaunchPopupListener() code. However, clicking on the Search link will still launch the Search and Select dialog. For more information about adding custom content, see the "Using List-of-Values Components" chapter of Developing Web User Interfaces with Oracle ADF Faces.

The resultsTable facet is used to display a custom message when the results table of the Search and Select dialog is empty.

If the component’s readOnly attribute is set to true, then the input field will not be rendered and the value cannot be changed. By default, the readOnly attribute is set to false, which also enables the editMode attribute to determine whether the user is permitted only to select a value from the list (editMode set to select) or whether the user can also enter a value into the input field (editMode set to input).

You can also set up the LOV component to display a list of selectable suggested items when the user types in a partial value. For example, when the user types in CA, then a suggested list which partially matches CA is displayed as a suggested items list. The user can select an item from the list to be entered into the input field. If there are no matches, a "No results found" message will be displayed. You add the af: autoSuggestBehavior tag from the Components window into the LOV and set the selectedItem attribute to the suggestedItems method implemented in ADF Model.

Note that auto suggest behavior occurs in the Apply Request Values phase. If the immediate property is set to true, validation will be performed in the same phase. If there is a validation error, the suggestion list will not be displayed. If you want to add auto suggest behavior, do not set immediate to true.

When the user clicks the Search or More link (or for af:inputListOfValues, the search icon), the LOV Search and Select dialog appears with the full list of values in a table format. The LOV Search and Select dialog launched from a More link is shown in Figure 32–4.
Figure 32–4  LOV Search and Select Dialog

If a user enters a partial string in the LOV and click Search or tab out, a Search and Select dialog will appear with the partial string displayed in the search field and the resulting list of matching values in a table. The user can then select an entry from the list to be the LOV value.

The Search and Select popup dialog also presents a create function that allows the user to add a new row. Be aware that if you are creating a new record using the LOV Search and Select dialog, the new row will appear as an empty row in the table if the LOV has the Query Automatically control hint set to false. The content of the row will appear when you perform a query using the Search button. Example 32–1 shows a code sample that uses a link to invoke the create function.

Example 32–1  Create Function Sample Code

```xml
<f:facet name="customActions">
    <af:link id="createLink" text="Create...
        partialSubmit="true">
        <af:showPopupBehavior popupId="createSLPopup"
            alignId="createLink"/>
    </af:link>
</f:facet>
```

If the LOV is part of a task flow that is using an isolated data control, and you use the create function to add a new record, the newly added record will not be displayed in the parent page. This is because the search region is also using an isolated data control scope, so the underlying view object updates are not displayed. For more information about shared and isolated data controls, see Section 24.2, “Sharing Data Controls Between Task Flows.”

To programmatically refresh the LOV and display the view object updates, add a returnListener to the Create link with code similar to that shown in Example 32–2.

Example 32–2  Code to Refresh the LOV

```java
public void refreshLOV() {
    BindingContainer bindings = this.getBindings();
    oracle.jbo.uicli.binding.JUCtrlListBinding lovBinding =
        (oracle.jbo.uicli.binding.JUCtrlListBinding)
An LOV is associated with a data source via the view accessor. You can apply one or more view criteria to the view accessor associated with the LOV. The view accessor provides permanent filtering to the LOV data source. In addition to this permanent filtering, you may be able to apply other filters.

The LOV dialog may include a query panel to allow the user to enter criteria to search for the list of values, or it may contain only a table of results. When you define the LOV in the view object, you can use the UI hints to specify whether a search region should be displayed, which view criteria should be used as the search to populate the list of values, and which LOV component to use. Figure 32–5 shows the Create List of Values dialog and some of its options. In this example, the search region will be made available with the All Queryable Attributes named view criteria used for the query, and af:inputComboboxListOfValues as the component. Another useful option for the af:inputComboboxListOfValues is the Show in Combo Box option, which allows you to select the number of attributes to display in the dropdown list and in the Search and Select dialog. For more information on LOV UI hints, see Section 5.12.5, “How to Set User Interface Hints on a View Object LOV-Enabled Attribute.”

For both af:inputListOfValues and af:inputComboboxListOfValues, if the user enters a partial match in the input search field and presses the Tab or Enter key, the LOV automatically launches the LOV Search and Select dialog and executes the query after applying an auto-generated view criteria with a single item representing the partial match value entered by the user. If there are matches, the Search and Select dialog displays all the entries matching the partially entered criteria. If there are no entries that match the entered partial match, then the dialog displays all the entries.

By default, in the af:inputComboboxListOfValues component auto-complete feature, the search is case-sensitive. If you want the search to be case-insensitive, create a view criteria to be associated with that LOV attribute. In the Create View Criteria dialog, deselect the Ignore Case checkbox for that view criteria item before you apply that view criteria to the LOV definition. For more information about setting view criteria options, see Section 5.9.1, "How to Create Named View Criteria Declaratively.”
You can also set up the LOV component to display a list of selectable suggested items when the user types in a partial value. For example, when the user types in Ca, then a suggested list which partially matches CA is displayed as a suggested items list. The user can select an item from the list to be entered into the input field. You add this auto-suggest behavior feature by including an `af:autoSuggestBehavior` tag from the Components window in the LOV and set the `selectedItem` attribute to the `suggestItems` method implemented in ADF Model.

If the LOV is an `af:inputComboboxListOfValues`, you can apply an additional view criteria to further filter the values in the dropdown list to create a smart list. If the Filter Combo Box Using UI hint is not applied, the dropdown list is filtered by the view criteria applied to the view accessor. Note that this smart list filter applies only to the dropdown list. The full list is still used for validation and for searching from the LOV Search and Select popup dialog. When smart list is enabled, the LOV’s Search and Select dialog will display a More link instead of the Search link.

If both the auto-suggest behavior and smart list filter are enabled for an LOV, auto-suggest will search from the smart list first. If the user waits for two seconds without clicking, then auto-suggest will also search from the full list and append the results. You can also specify the number of suggested items returned by setting the `maxSuggestedItems` attribute (-1 indicates a complete list). If `maxSuggestedItems > 0`, a More link is rendered for the user to click on to launch the LOV’s Search and Select dialog. Example 32–3 shows the code from an LOV with both auto-suggest behavior and a smart list.

Example 32–3  Auto-Suggest Behavior and Smart List

```
af:autoSuggestBehavior
    suggestItems="#{bindings.CountryName.suggestItems}"
    smartList="#{bindings.CountryName.smartList}" />
```
You can define an attribute in the view object to be one or more LOVs. If multiple LOVs are defined on an attribute, each LOV has its own name, view accessor, data mappings, validator, and UI hints (except for the Default List Type hint, which is defined once for the attribute). To switch between LOVs to be used at runtime, an LOV switcher is used. The LOV switcher can be based on an existing attribute of type String, or created as a new String attribute solely for switching between LOVs. The LOV switcher returns the name of the LOV to use at runtime. For instance, you can create three LOVs for the price attribute, and designate the CountryName attribute as the LOV switcher. At runtime, the value of CountryName will switch the price attribute to use the LOV that reflects the country’s price and currency.

If an attribute is defined as an LOV, you can set the Support Multiple Value Selection control hint in its view criteria to enable users to make multiple selections in the search criteria field. If multiple selection is enabled on an LOV attribute, and the Equal to or Not equal to operator is chosen, a selectManyChoice component will render in the query panel. The user can select multiple items as the search criteria.

If the value of an LOV depends on the value of another LOV, then the two LOVs are called cascading LOVs. For instance, the list of values for the City LOV depends on the value of the CountryName LOV that was selected. If the LOV is defined as a named bind variable, or if validation is enabled, the LOV query may behave differently depending on such conditions as whether null values for the named bind variable are acceptable. If the bind variable is null, you may want the LOV query to return an empty list. The view criteria’s Ignore Null Values and Validation options can be used to define LOV query behavior.

If the view object has an LOV with a bind variable, you should set that view object bind variable’s control hint to Hide. Otherwise, the bind variable will be displayed in the LOV Search and Select popup dialog. In the view object overview editor’s Query tab, double-click the bind variable, click the Control Hints tab and select Hide from the Display Hint dropdown list.

---

**Note:** List of values are designed to return valid values only. As a result, validation rules defined on data source view object attributes will be suppressed. You should ensure that the list of values returned only contains valid values. For more information, see Section 11.3.5, "What You May Need to Know About List of Values and Attribute Validation Rules."

**Best Practice:** An attribute that has been enabled as an LOV should not be used as search criteria in a manually created search form using the "Find Mode" iterator. Creating a search form in this way could result in SQL exception: java.sql.SQLException: Attempt to set a parameter name that does not occur in the SQL. It is best practice to use the query and quick query components for creating search forms. For more information, see Chapter 33, "Creating ADF Databound Search Forms."

Displaying an LOV list for a name attribute when the view object’s key attribute is a numerical value requires mapping supplemental attributes on the LOV-enabled attribute. For example, to display a list of credit cards by name instead of by their payment option ID value, you can create an LOV on the name reference attribute and define the primary key attribute as a supplemental attribute to the LOV. For details
about creating an LOV-enabled reference attribute, see Section 5.12.4, "How to Define an LOV to Display a Reference Attribute."

---

**Note:** af:inputListOfValues and af:inputComboboxListofValues assume the list of values returned from the Search and Select dialog to be valid. Any ADF Business Components validation errors will not be displayed.

---

For more information about different usage scenarios and other view criteria options, see Section 5.9.1, "How to Create Named View Criteria Declaratively," and Section 5.9.3, "What You May Need to Know About Bind Variables in View Criteria."

### 32.2.1 How to Create an LOV

You can create the LOV using either the af:inputListOfValues or the af:inputComboboxListofValues component. You can add auto-suggest behavior to the component to display a list of possible matches from user input.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create an LOV. For more information, see Section 32.2, "Creating List of Values (LOV) Components."

You may also find it helpful to understand functionality that can be used with LOVs. For more information, see Section 32.1.2, "Additional Functionality for Selection Lists and Shuttles."

You will need to complete this task:

Define the attribute to be an LOV in the view object by following the procedure described in Section 5.12, "Working with List of Values (LOV) in View Object Attributes."

**To create an LOV:**

1. In the Application window, double-click the web page that will display the component.

2. From the Data Controls panel, drag and drop the attribute onto the JSF page and choose Create > List of Values > ADF LOV Input or Create > List of Values > ADF LOV Choice List.

3. In the ADF Faces page of the Components window, from the Operations panel drag and drop Auto Suggest Behavior as a child to the LOV component.

4. In the Property Inspector, enter values for Auto Suggest Behavior:
   - **SuggestItems**: EL expression that resolves to the suggestItems method.
   - **SmartList**: EL expression that resolves to the smartList method.
   - **MaxSuggestedItems**: Number of items to be displayed in the auto-suggest list. Enter -1 to display the complete list.

**Example 32–4** shows an inputListOfValues component with the auto-suggest behavior and smart list features.
Example 32–4  LOV Component with Auto-Suggest Behavior

```xml
<af:inputListOfValues id="salesRepIdId"
    popupTitle="Search and Select: #{bindings.SalesRepId.hints.label}"
    value="#{bindings.SalesRepId.inputValue}"
    label="#{bindings.SalesRepId.hints.label}"
    model="#{bindings.SalesRepId.listOfValuesModel}"
    required="#{bindings.SalesRepId.hints.mandatory}"
    columns="#{bindings.SalesRepId.hints.displayWidth}"
    shortDesc="#{bindings.SalesRepId.hints.tooltip}"
>
    <f:validator binding="#{bindings.SalesRepId.validator}"/>
    <af:autoSuggestBehavior suggestItems="#{bindings.SalesRepId.suggestedItems}"
        smartList="#{bindings.SalesRepId.smartList}"
        maxSuggestedItems="5"/>
</af:inputListOfValues>
```

5. If you added the auto-suggest behavior, you must not set the component’s immediate property to true.

32.2.2 What Happens When You Create an LOV

When you drag and drop an attribute from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see Section 28.2.2, "What Happens When You Create a Text Field."

When you drag and drop an attribute defined as an LOV from the Data Controls panel onto a JSF page as an inputListOfValues or inputComboboxListOfValues component, JDeveloper adds code to the page similar to that shown in Example 32–5. The State attribute in the CustomerVO view object has been defined as an LOV and its default component is set to be an inputComboboxListOfValues. The component gets its properties from the control hints defined declaratively in the view object. If you want to include the auto-suggest behavior, you must manually add that tag from the Components window.

Example 32–5  inputComboboxListOfValues Component Code in a JSF Page

```xml
<af:inputComboboxListOfValues id="stateId"
    popupTitle="Search and Select: #{bindings.State.hints.label}"
    value="#{bindings.State.inputValue}"
    label="#{bindings.State.hints.label}"
    model="#{bindings.State.listOfValuesModel}"
    required="#{bindings.State.hints.mandatory}"
    columns="#{bindings.State.hints.displayWidth}"
    shortDesc="#{bindings.State.hints.tooltip}"
>
    <f:validator binding="#{bindings.State.validator}"/>
</af:inputComboboxListOfValues>
```

In the page definition file, JDeveloper adds code as shown in Example 32–6. The bindings section of the page definition specifies that the LOV is for the State attribute and the name of the LOV is LOV_State. JDeveloper adds the definitions for the iterator binding objects into the executables element, and the list of values binding object into the bindings element.

Example 32–6  inputComboboxListOfValues Component Code in Page Definition

```xml
<executables>
    <variableIterator id="variables"/>
    <iterator Binds="Customers" RangeSize="25"
```
Creating a Selection List

ADF Faces Core includes components for selecting a single value and multiple values from a list. For example, `selectOneChoice` allows the user to select an item from a dropdown list, and `selectManyChoice` allows the user to select several items from a list of checkboxes. Selection lists are described in Table 32–1.

Table 32–1  ADF Faces Single and Multiple List Components

<table>
<thead>
<tr>
<th>ADF Faces component</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>SelectOneChoice</td>
<td>Select a single value from a list of items.</td>
<td><img src="image" alt="SelectOneChoice Example" /></td>
</tr>
<tr>
<td>SelectOneRadio</td>
<td>Select a single value from a set of radio buttons.</td>
<td><img src="image" alt="SelectOneRadio Example" /></td>
</tr>
<tr>
<td>SelectOneListbox</td>
<td>Select a single value from a scrollable list of items.</td>
<td><img src="image" alt="SelectOneListbox Example" /></td>
</tr>
</tbody>
</table>

For more information about the page definition file and ADF data binding expressions, see Section 17.7, "Working with Page Definition Files," and Section 17.8, "Creating ADF Data Binding EL Expressions."

32.2.3 What You May Need to Know About List Validators and LOV

If you are defining an attribute in the view object to be a list of values attribute, you can define an equivalent list validation rule in the underlying entity object as long as the list validation rule is based on the same list. You should not define other types of validation rules in the entity object for an attribute already defined as a list of values in the view object. Doing so may result in unexpected behavior and validation errors. For more information about defining validation rules, see Section 11–3, "List Validator Using a View Object Attribute," and Section 11.4, "Using the Built-in Declarative Validation Rules."

32.3 Creating a Selection List

ADF Faces Core includes components for selecting a single value and multiple values from a list. For example, `selectOneChoice` allows the user to select an item from a dropdown list, and `selectManyChoice` allows the user to select several items from a list of checkboxes. Selection lists are described in Table 32–1.

Table 32–1  ADF Faces Single and Multiple List Components

<table>
<thead>
<tr>
<th>ADF Faces component</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>SelectOneChoice</td>
<td>Select a single value from a list of items.</td>
<td><img src="image" alt="SelectOneChoice Example" /></td>
</tr>
<tr>
<td>SelectOneRadio</td>
<td>Select a single value from a set of radio buttons.</td>
<td><img src="image" alt="SelectOneRadio Example" /></td>
</tr>
<tr>
<td>SelectOneListbox</td>
<td>Select a single value from a scrollable list of items.</td>
<td><img src="image" alt="SelectOneListbox Example" /></td>
</tr>
</tbody>
</table>
Creating a Selection List

You can create selection lists using the SelectOneChoice ADF Faces component. The steps are similar for creating other single-value selection lists, such as SelectOneRadio and SelectOneListbox.

A databound selection list displays values from a data control collection or a static list and updates an attribute in another collection or a method parameter based on the user’s selection. When adding a binding to a list, you use an attribute from the data control that will be populated by the selected value in the list.

### Table 32–1  (Cont.) ADF Faces Single and Multiple List Components

<table>
<thead>
<tr>
<th>ADF Faces component</th>
<th>Description</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>SelectManyChoice</td>
<td>Select multiple values from a scrollable list of checkboxes.</td>
<td><img src="image1" alt="SelectManyChoice Example" /></td>
</tr>
<tr>
<td>SelectManyCheckbox</td>
<td>Select multiple values from a group of checkboxes.</td>
<td><img src="image2" alt="SelectManyCheckbox Example" /></td>
</tr>
<tr>
<td>SelectManyListbox</td>
<td>Select multiple values from a scrollable list of checkboxes.</td>
<td><img src="image3" alt="SelectManyListbox Example" /></td>
</tr>
</tbody>
</table>

You can create selection lists using the SelectOneChoice ADF Faces component. The steps are similar for creating other single-value selection lists, such as SelectOneRadio and SelectOneListbox.

To create a selection list, you choose a base data source and a list data source in the Edit List Binding dialog:

- **Base data source**: Select the data collection that you want to bind to your control and that contains the attributes to be updated from user selections.
- **List data source**: Select the data collection that contains the attributes to display.

The data collection is based on the view object. For more information about creating a view object, see Section 5.2.1, "How to Create an Entity-Based View Object.”

You can create three types of selection lists in the Edit List Binding dialog:
Creating a Selection List

- Model-driven list: List selections are based on a list of values bound to a data collection. This type of selection list offers significant advantages over the other two, as described in Section 32.3.1, "How to Create a Model-Driven List."

- Static list: List selections are based on a fixed list that you create manually by entering values one at a time into the editor. For more information, see Section 32.3.3, "How to Create a Selection List Containing Fixed Values."

- Dynamic list: List selections are generated dynamically based on one or more databound attribute values. For more information, see Section 32.3.5, "How to Create a Selection List Containing Dynamically Generated Values."

### 32.3.1 How to Create a Model-Driven List

A model-driven list is based on a list of values that is bound to a view data object. Lists of Values are typically used in forms to enable an end user to select an attribute value from a dropdown list instead of having to enter it manually. When the user submits the form with the selected values, ADF data bindings in the ADF Model layer update the value on the view object attributes corresponding to the databound fields.

**Note:** One way to create a model-driven list is to drag a collection from the Data Controls panel onto a JSF page, choose one of the ADF Forms in the context menu, and accept the defaults. The advantage is that if there are LOVs defined on the underlying view object attributes, all the LOVs on the entire form will be configured automatically. For more information, see Section 5.12.1, "How to Define a Single LOV-Enabled View Object Attribute."

You can also use the list of values as the basis for creating a selection list. The advantages of creating a model-driven list based on a list of values are:

- Reuse: The list of values is bound to a view data collection. Any selection list that you create based on the data collection can use the same list of values. Because you define the LOV on the individual attributes of view objects in a data model project with ADF Business Components, you can customize the LOV usage for an attribute once and expect to see the changes anywhere that the business component is used in the user interface.

- Translation: Values in the list of values can be included in resource bundles used for translation.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create an selection list component. For more information, see Section 32.3, "Creating a Selection List."

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see Section 32.1.2, "Additional Functionality for Selection Lists and Shuttles."

You will need to complete these tasks:

1. Create a view object.
2. Create a view accessor on the object.
Creating a Selection List

3. Create a list of values that is bound to an attribute on the base data source for the selection list. For example, you can create a list of values bound to the CountryId attribute of the Addresses view data object.

For more information, see Section 5.12.1, "How to Define a Single LOV-Enabled View Object Attribute."

To create a model-driven selection list:
1. From the Data Controls panel, drag and drop the attribute onto the JSF page and, from the context menu, choose Create > Single Selections > ADF Select One Choice.
2. In the Edit List Binding dialog, click the Model Driven List radio button.
3. In the Base Data Source Attribute dropdown list, select an attribute on which you want to display a list of values.

The Base Data Source should be the collection you dragged from the Data Controls panel. If the collection does not appear in the dropdown list, click the Add button to select the collection you want.
4. In the Server List Binding Name dropdown list, select the name of the list-of-values definition that was created for the base attribute.

If a list-of-values definition was created for the attribute you have selected, the definition will appear in the dropdown list. For example, if you have defined LOV_State as the list-of-value definition for the State attribute, then LOV_State should appear in the Server List Binding Name dropdown list.
5. Click OK.

32.3.2 What Happens When You Create a Model-Driven Selection List

When you drag and drop an attribute from the Data Controls panel, JDeveloper does many things for you. For a full description of what happens and what is created when you use the Data Controls panel, see Section 28.2.2, "What Happens When You Create a Text Field."

Example 32–7 shows the page source code after you add a model-driven SelectOneChoice component to it.

Example 32–7 Model-Driven SelectOneChoice List in JSF Page Source Code

```xml
<af:selectOneChoice value="#{bindings.State.inputValue}"
   label="#{bindings.State.label}" 
   required="#{bindings.State.hints.mandatory}"
   shortDesc="#{bindings.State.hints.tooltip}"
   id="soc1">
   <f:selectItems value="#{bindings.State.items}" id="si1"/>
</af:selectOneChoice>
```

The f:selectItems tag, which provides the list of items for selection, is bound to the items property on the State list binding object in the binding container. For more information about ADF data binding expressions, see Section 17.6, "Configuring the ADF Binding Filter."

In the page definition file, JDeveloper adds the list binding object definitions in the bindings element, as shown in Example 32–8.
Creating a Selection List

Creating Databound Selection Lists and Shuttles

Example 32–8 List Binding Object for the Model-Driven List in the Page Definition File

```xml
<executables>
    <variableIterator id="variables"/>
    <iterator Binds="Customers" RangeSize="25"
             DataControl="BackOfficeAppModuleDataControl"
             id="CustomersIterator"/>
</executables>

<bindings>
    <list IterBinding="CustomersIterator"
          StaticList="false" Uses="LOV_State"
          id='State' DTSupportsMRU="true"
          SelectItemValueMode="ListObject"/>
</bindings>
```

In the `list` element, the `id` attribute specifies the name of the list binding object. The `IterBinding` attribute references the variable iterator, whose current row is a row of attributes representing each variable in the binding container. The variable iterator exposes the variable values to the bindings in the same way as do other collections of data.

For more information about the page definition file and ADF data binding expressions, see Section 17.7, "Working with Page Definition Files," and Section 17.8, "Creating ADF Data Binding EL Expressions."

32.3.3 How to Create a Selection List Containing Fixed Values

You can create a selection list containing selections that you code yourself, rather than retrieving the values from another data source. See Section 32.3.5, "How to Create a Selection List Containing Dynamically Generated Values," for information about populating selection lists with values that are dynamically generated from another data source.

Figure 32–6 Selection List Bound to a Fixed List of Values

`Figure 32–6 Selection List Bound to a Fixed List of Values`

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a selection list component. For more information, see Section 32.3, "Creating a Selection List."

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see Section 32.1.2, "Additional Functionality for Selection Lists and Shuttles."

You will need to complete this task:

Prepare a list of values that you will enter into the component as a fixed list.

To create a list bound to a fixed list of values:

1. From the Data Controls panel, drag and drop the attribute onto the JSF page and, from the context menu, choose Create > Single Selections > ADF Select One Choice.
2. In the Edit List Binding dialog, click the **Fixed List** radio button.

3. In the **Base Data Source Attribute** dropdown list, select an attribute on which you want to display a list of values.

   The **Base Data Source** should be the collection you dragged from the Data Controls panel. If the collection does not appear in the dropdown list, click the **Add** button to select the collection you want.

4. In the **Set of Values** box, enter each value you want to appear in the list. Press the Enter key to set a value before typing the next value. For example, if your attribute is Country, you could add the country codes India, Japan, and Russia.

   The order in which you enter the values is the order in which the list items are displayed in the **SelectOneRadio** control at runtime.

   The **SelectOneRadio** component supports a null value. If the user has not selected an item, the label of the item is shown as blank, and the value of the component defaults to an empty string. Instead of using blank or an empty string, you can specify a string to represent the null value. By default, the new string appears at the top of the list.

5. Click **OK**.

### 32.3.4 What Happens When You Create a Fixed Selection List

When you add a fixed selection list, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

**Example 32–9** shows the page source code after you add a fixed **SelectOneChoice** component to it.

**Example 32–9  Fixed SelectOneChoice List in JSF Page Source Code**

```xml
<af:selectOneChoice value="#{bindings.CountryIdStatic.inputValue}" label="#{bindings.CountryIdStatic.label}"
   
   <f:selectItems value="#{bindings.CountryIdStatic.items}"/>
</af:selectOneChoice>
```

The **f:selectItems** tag, which provides the list of items for selection, is bound to the **items** property on the **CountryId** list binding object in the binding container. For more information about ADF data binding expressions, see Section 17.8, "Creating ADF Data Binding EL Expressions."

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the **executables** element, and the list binding object into the **bindings** element, as shown in **Example 32–10**.

**Example 32–10  List Binding Object for the Fixed Selection List in the Page Definition File**

```xml
<executables>
   
   <iterator Binds='Addresses1' RangeSize='10'
   DataControl='BackOfficeAppModuleDataControl'
   id='Addresses1Iterator'/>
</executables>

<bindings>
   
   <list IterBinding='Addresses1Iterator' id='CountryIdStatic' ListOperMode='0'
   StaticList='true'>
   
   <AttrNames>
   
   <Item Value='CountryIdStatic'/>
```

32-16  Developing Fusion Web Applications with Oracle Application Development Framework
Creating Selection Lists

Creating Databound Selection Lists and Shuttles

32.3.5 How to Create a Selection List Containing Dynamically Generated Values

You can populate a selection list component with values dynamically at runtime.

Tip: Another option is to create a static view object or a database view object within a shared application module. Then use a model-driven LOV to create the list. This provides caching and translatability.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create a selection list component. For more information, see Section 32.3, "Creating a Selection List."

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see Section 32.1.2, "Additional Functionality for Selection Lists and Shuttles."

You will need to complete these tasks:
1. Define a data source for the list data source that provides the dynamic list of values.
2. Define a data source for the base data source that is to be updated based on the user’s selection.

To create a selection list bound containing dynamically generated values:
1. From the Data Controls panel, drag and drop the attribute onto the JSF page and, from the context menu, choose Create > Single Selections > ADF Select One Choice.
2. In the Edit List Binding dialog, click the Dynamic List radio button.
3. Select the Base Data Source from the dropdown list or click Add.
4. In the Add Data Source dialog, select the data collection that contains the attribute to be updated and click OK.
5. Select the List Data Source from the dropdown list or click Add.
6. In the Add Data Source dialog, select the data collection that contains the attribute that will be displayed and click OK.

Note: The list and base collections do not have to form a master-detail relationship, but the attribute in the list collection must have the same type as the base collection attributes.

For complete information about page definition files, see Section 17.7, "Working with Page Definition Files."
Creating a Selection List

7. In the Data Mapping section, you can accept the default mapping or select different attributes items from the Data Value and List Attribute lists to update the mapping.

The Data Value control contains the attribute on the data collection that is updated when the user selects an item in the selection list. The List Attribute control contains the attribute that populates the values in the selection list.

To add a second mapping, click Add.

8. In the List Items section, select values for:
   - Display Attribute: Select the attribute you want to be displayed.
   - "No Selection" Item: Specify whether or not the list displays a NULL value selection and how it is displayed.
   - MRU: Select to show a list of most recently used items. Specify the number of items to display in the MRU list and the separator to be used.

9. Click OK.

32.3.6 What Happens When You Create a Dynamic Selection List

When you add a dynamic selection list to a page, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

Example 32–11 shows the page source code after you add a dynamic SelectOneChoice component to it.

Example 32–11 Dynamic SelectOneChoice List in JSF Page Source Code

```xml
<af:selectOneChoice value="#{bindings.SalesRepId.inputValue}" label="#{bindings.SalesRepId.label}" required="#{bindings.SalesRepId.hints.mandatory}"
shortDesc="#{bindings.SalesRepId.hints.tooltip}" id="soc2">
  <f:selectItems value="#{bindings.SalesRepId.items}" id="si4"/>
  <f:validator binding="#{bindings.SalesRepId.validator}"/>
</af:selectOneChoice>
```

The f:selectItems tag, which provides the list of items for selection, is bound to the items property on the SalesRepId list binding object in the binding container. For more information about ADF data binding expressions, see Section 17.8, "Creating ADF Data Binding EL Expressions."

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the executables element, and the list binding object into the bindings element, as shown in Figure 32–12.

Example 32–12 List Binding Object for the Dynamic Selection List in the Page Definition File

```xml
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="SummitAppModuleDataControl.dataProvider.
BackOfficeAM.Customers" DataControl="SummitAppModuleDataControl" RangeSize="25"
  id="CustomersIterator"/>
  <iterator Binds="Countries" RangeSize="10"
  DataControl="BackOfficeAppModuleDataControl"
  id="CountriesIterator"/>
  <iterator Binds="Customers" RangeSize="-1"
```

32-18   Developing Fusion Web Applications with Oracle Application Development Framework
Creating a Selection List

Creating Databound Selection Lists and Shuttles

DataControl="BackOfficeAppModuleDataControl"
id="CustomersIterator1"/>
</executables>

bindings>
<list IterBindings="CountriesIterator" StaticList="false" id="SalesRepId"
DTSupportsMRU="true" SelectItemValueMode="ListObject"
ListIter="CustomersIterator1">
<AttrNames>
<Item Value="Id"/>
</AttrNames>
<ListAttrNames>
<Item Value="Id"/>
</ListAttrNames>
<ListDisplayAttrNames>
<Item Value="Id"/>
</ListDisplayAttrNames>
</list>
</bindings>

By default, JDeveloper sets the RangeSize attribute on the iterator element for the Customers iterator binding to a value of -1 thus allowing the iterator to furnish the full list of valid products for selection. In the list element, the id attribute specifies the name of the list binding object. The IterBinding attribute references the iterator that iterates over the Countries collection. The ListIter attribute references the iterator that iterates over the Customers collection. The AttrNames element specifies the base data source attributes returned by the base iterator. The ListAttrNames element defines the list data source attributes that are mapped to the base data source attributes. The ListDisplayAttrNames element specifies the list data source attribute that populates the values users see in the list at runtime.

For complete information about page definition files, see Section 17.7, "Working with Page Definition Files."

32.3.7 What You May Need to Know About Values in a Selection List

Once you have created a list binding, you may want to access a value in the list. You can set the component’s valuePassThru attribute to true either in the visual editor or in the Property Inspector. Example 32–13 shows the code for a selectOneChoice component.

Example 32–13  valuePassThru Attribute Set to true in selectOneChoice

<af:selectOneChoice value="#{bindings.Language.inputValue}"
label="#{bindings.Language.label}"
required="#{bindings.Language.hints.mandatory}"
shortDesc="#{bindings.Language.hints.tooltip}"
valueChangeListener="#{myBean.valueChanged}"
valuePassThru="true"
id="soc1">
<f:selectItems value="#{bindings.Language.items}" id="si1"/>
</af:selectOneChoice>

Only when the valuePassThru attribute is set to true and the Mode attribute in the corresponding page definition file is set to Object can the value passed to the valueChangeListener be of type Object (which is the actual value). By default, Mode is set to Index. Example 32–14 shows the Mode attribute in the page definition file.
Creating a List with Navigation List Binding

Navigation list binding lets users navigate through the objects in a collection. As the user changes the current object selection using the navigation list component, any other component that is also bound to the same collection through its attributes will display from the newly selected object. In addition, if the collection whose current row you change is the master view object instance in a data model master-detail relationship, the row set in the detail view object instance is automatically updated to show the appropriate data for the new current master row.

How to Create a List with Navigation List Binding

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create a navigation list. For more information, see Section 32.4, "Creating a List with Navigation List Binding."

You may also find it helpful to understand functionality that can be used with navigation lists. For more information, see Section 32.1.2, "Additional Functionality for Selection Lists and Shuttles."

To create a list that uses navigation list binding:
1. From the Data Controls panel, drag and drop the master collection to the page and choose Create > Navigation > ADF Navigation List.
   The master collection is where the user selects from.

2. In the Edit List Binding dialog, from the Base Data Source dropdown list, select the collection whose members will be used to create the list.
   This should be the collection you dragged from the Data Controls panel. If the collection does not appear in the dropdown list, click the Add button to select the collection you want.

3. From the Display Attribute dropdown list, select the attribute that will display in the list. You can choose the selection that includes all the attributes, and you can choose Select Multiple to launch a selection dialog.

4. In the Select Multiple Display Attributes dialog, shuttle the attributes you want to display from the Available Attributes list to the Attributes to Display list. Click OK to close the dialog.

5. Click OK.

6. From the Data Controls panel, drag and drop the detail collection inside the Details section of the page as an output component.
   The output component can be any component that is used to display the data. If you decide to use a table, you can choose Create > Table > ADF Table.
   The Detail section is an af:panelHeader component that was added by JDeveloper when you created the navigation list in Step 1.
32.4.2 What Happens When You Create a Navigational List Binding

When you add a navigation list to a page, JDeveloper adds source code to the JSF page and list and iterator binding objects to the page definition file.

On the page, JDeveloper adds a selectOneChoice component with a f:selectItems tag. The selectOneChoice component allows the user to select from a list of values based on the selected attribute in the source data collection. JDeveloper also adds an af:panelHeader component that will contain the component you chose to display the data based on the selection. In this example, a table component is added to display the data. Note that the af:panelHeader component has partialTriggers set to the selectOneChoice component id so that when the selection changes, new data will be displayed. Example 32–15 shows the page source code after you add a navigation list.

Example 32–15  Navigation List in JSF Page Source Code

```xml
<af:selectOneChoice id="nl1" autoSubmit="true" value="#{bindings.Customers.inputValue}" label="#{bindings.Customers.label}"
  f:selectItems value="#{bindings.Customers.items}" id="si1" />
<af:panelHeader text="Details" partialTriggers="nl1" id="ph1">
  <af:table value="#{bindings.OrdersForCustomer.collectionModel}" var="row" row="#{bindings.OrdersForCustomer.rangeSize}"
    emptyText="#{bindings.OrdersForCustomer.viewable ? 'No data to display.' : 'Access Denied.'}" fetchSize="#{bindings.OrdersForCustomer.rangeSize}" rowBandingInterval="0" id="t1">
    <af:column headerText="#{bindings.OrdersForCustomer.hints.Id.label}" id="c1">
      <af:inputText value="#{row.bindings.Id.inputValue}"
```

In the page definition file, JDeveloper adds the definitions for the iterator binding objects into the executables element. Example 32–16 shows the iterator bindings and navigation list bindings in the page definition file.

Example 32–16  List Binding for Navigation List in the Page Definition File

```xml
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="Customers" RangeSize="25" DataControl="BackOfficeAppModuleDataControl" id="CustomersIterator"/>
  <iterator Binds="OrdersForCustomer" RangeSize="25" DataControl="BackOfficeAppModuleDataControl" id="OrdersForCustomerIterator"/>
</executables>
<bindings>
  <navigationlist IterBinding="CustomersIterator" ListOperMode="navigation"
    ListIter="CustomersIterator"
    id="Customers" DTSupportsMRU="false">
    <AttrNames>
      <Item Value="Name"/>
    </AttrNames>
  </navigationlist>
  <tree IterBinding="OrdersForCustomerIterator" id="OrdersForCustomer">
    <nodeDefinition DefName="oracle.summit.model.views.OrdVO"
      Name="OrdersForCustomer0">
      <AttrNames>
```
32.5 Creating a Databound Shuttle

The `selectManyShuttle` and `selectOrderShuttle` components render two list boxes and buttons that allow the user to select multiple items from the leading (or available) list box and to move or shuttle those items over to the trailing (or selected) list box, and vice versa. You can also double-click an item to move it to the other list box. Figure 32–7 shows an example of a rendered `selectManyShuttle` component that is implemented in the Summit ADF sample application. You can specify any text you want for the headers that display above the list boxes.

![SelectManyShuttle Component](image)

The only difference between `selectManyShuttle` and `selectOrderShuttle` is that in the `selectOrderShuttle` component, the user can reorder the items in the trailing list box by using the up and down arrow buttons on the side.

The Summit ADF sample application uses a `selectManyShuttle` component to allow the user to select the products to order from a All available products list box to an Selected Products list box. The leading list box on the left displays all the available products. The trailing list box on the right displays the products the customer has selected.

Like other ADF Faces selection list components, the `selectManyShuttle` and `selectOrderShuttle` components can use the `f:selectItems` tag to provide the list of items available for display and selection in the leading list.

Before you can bind the `f:selectItems` tag, create a generic class that can be used by any page that requires a shuttle. In the class, declare and include getter and setter methods for the properties that describe the view object instance names that should be used for the list of all available choices (leading list or available product categories) and the list of selected choices (trailing list or assigned product categories). In the Summit ADF sample application, `f:selectItems` uses the binding container to retrieve the list of available products. Example 32–17 shows the `ShuttleBean` class.
that is created to manage the population and selection state of the shuttle component on the showshuttle.jsf page.

**Example 32–17 ShuttleBean Class**

```java
public class ShuttleBean {

    private List<oracle.jbo.domain.Number> _selectedProducts =
        new ArrayList<oracle.jbo.domain.Number>();

    public ShuttleBean()
    {
    }

    public void setSelectedProducts(List<oracle.jbo.domain.Number> _allocatedRoles) {
        this._selectedProducts = _allocatedRoles;
    }

    public List<oracle.jbo.domain.Number> getSelectedProducts() {
        return _selectedProducts;
    }

    public void onAddMultipleProducts(ActionEvent actionEvent) {
        DCBindingContainer dcBindings =
            (DCBindingContainer)BindingContext.getCurrent().getCurrentBindingsEntry();
        OperationBinding createMethod =
            dcBindings.getOperationBinding("CreateInsert");
        if ( createMethod != null && _selectedProducts.size() > 0 ) {
            DCIteratorBinding iterator =
                dcBindings.findIteratorBinding("ItemsForOrderIterator");
            for ( oracle.jbo.domain.Number productId : _selectedProducts )
            {
                createMethod.execute();
                iterator.getCurrentRow().setAttribute("ProductId", productId );
            }
        }
    }
}
```

The `getSelectedProducts()` method returns a List that defines the items in the shuttle's trailing list. The values returned by `getSelectedProducts()` are a subset of the values in the leading list. Values that are in the leading list but not in `getSelectedProducts()` will be ignored (and will generate an error in the server log). Note that the ShuttleBean class can call utility methods in the ADFUtils class if required. Also note that this class uses values for several properties of the base bean.

**Example 32–18** shows the managed bean and managed properties configured in order-select-many-item.xml task flow for working with the shuttle component.

**Example 32–18 Managed Bean for the Shuttle Component in the order-select-many-items Task Flow**

```xml
<?xml version="1.0" encoding="UTF-8"?>
<managed-bean id="__3">
    <managed-bean-name>ShuttleBean</managed-bean-name>
    <managed-bean-class>oracle.summit.backing.ShuttleBean</managed-bean-class>
    <managed-bean-scope>backingBean</managed-bean-scope>
</managed-bean>
<view id="showshuttle">
    <page>/orders/showshuttle.jsf</page>
</view>
```
32.5.1 How to Create a Databound Shuttle

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you create a shuttle. For more information, see Section 32.5, "Creating a Databound Shuttle."

You may also find it helpful to understand functionality that can be used with selection lists. For more information, see Section 32.1.2, "Additional Functionality for Selection Lists and Shuttles."

You will need to complete these tasks:

1. Create the relevant iterator bindings in the page definition file. Use Example 32–19 as a guide.
   
   In the Summit ADF sample application, a list binding for ProductId with ItemsForOrderIterator is added to the showshuttlePageDef.xml file to provide the list of products for populating the leading list.

2. Create a class similar to the ShuttleBean class and provide methods to process the values as required. Use Example 32–17 as a guide.

3. Configure the required managed bean and managed properties in the task flow definition or, in the case of an unbounded task flow, the adfc-config.xml file. Use Example 32–18 as a guide.

**To create a shuttle component:**

1. In the Applications window, double-click the web page that will display the component.

2. In the ADF Faces page of the Components window, from the Text and Selection panel, drag and drop SelectManyShuttle or SelectOrderShuttle onto the page. JDeveloper displays the Insert Shuttle wizard, as illustrated in Figure 32–8.
3. Select **Bind to list (select items)** and click **Bind**.

4. In the Expression Builder, expand tree structure to create an expression that will populate the values for the leading list and click **OK**.

   In the Summit ADF sample application, select **ADF Bindings > bindings > ProductId > items** to build the expression #{bindings.ProductId.items} and click **Finish**. This binds the f:selectedItem tag of the selectManyShuttle component to the data collection that populates the shuttle’s leading list with a list of products.

   If you decide to retrieve the values for the leading list using a method, for example, `getAllProducts()`, you should create this method in the managed bean. You would then bind to this method in the expression builder.

5. Click **Next**.

6. In the Common Properties page, click **Bind** next to the **Value** field.

7. In the Expression Builder, expand the tree to create an expression that will populate the values for the trailing list and click **OK**.

   In the Summit ADF sample application, select **ADF Managed Beans > BackingBeanScope > ShuttleBean > selectedProducts** to build the expression #{backingBeanScope.ShuttleBean.selectedProducts} and click **Finish**. This binds the value attribute to the selectedProducts() method that populates the shuttle’s trailing list.

8. You may want to add additional controls to process the selected values.

   In the Summit ADF sample application, an `af:button` component labeled **Done** is added to the page to process the selected products by calling the `onAddMultipleProducts` method defined in the ShuttleBean.
32.5.2 What Happens When You Create a Databound Shuttle

All the bindings of the showshuttle.jsf page are defined in the file showshuttlePageDef.xml. Example 32–19 shows part of the page definition file for the showshuttle.jsf page.

Example 32–19 Page Definition File for the showshuttle Page

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel" version="12.1.2.61.86" id="showshuttlePageDef" Packages="orders">
<parameters/>
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="ItemsForOrder" RangeSize="25"
    DataControl="BackOfficeAppModuleDataControl"
    id="ItemsForOrderIterator"/>
</executables>
<bindings>
  <list IterBinding="ItemsForOrderIterator" StaticList="false"
    Uses="LOV_ProductId" id="ProductId"
    DTSupportsMRU="true" SelectItemValueMode="ListObject"/>
  <action IterBinding="ItemsForOrderIterator" id="CreateInsert"
    RequiresUpdateModel="true" Action="createInsertRow"/>
</action>
</bindings>
</pageDefinition>
```

Example 32–20 shows the code for the selectManyShuttle component after you complete the Insert SelectManyShuttle dialog.

Example 32–20 SelectManyShuttle Component in showshuttle.jsff File

```xml
<af:selectManyShuttle id="sms1"
  value="#{backingBeanScope.ShuttleBean.selectedProducts}"
  leadingHeader="All available products" trailingHeader="Selected products">
  <f:selectItems value="#{bindings.ProductId.items}" id="si1"/>
</af:selectManyShuttle>
```
Creating ADF Databound Search Forms

This chapter describes how to create search forms from data modeled from ADF Business Components, using ADF data binding and ADF Faces components to perform complex searches on multiple attributes and search forms to search on a single attribute. For complex query search forms, it describes how to set up the query search form mode, results table, saved searches list, and personalization. For single attribute search forms, it describes how to configure the form layout. In addition, it includes information on using named bind variables and Query-by-Example (QBE) filtered table searches.

This chapter includes the following sections:

- Section 33.1, "About Creating Search Forms"
- Section 33.2, "Creating Query Search Forms"
- Section 33.3, "Setting Up Search Form Properties"
- Section 33.4, "Creating Quick Query Search Forms"
- Section 33.5, "Creating Standalone Filtered Search Tables from Named View Criteria"

33.1 About Creating Search Forms

You can create search forms that allow users to enter search criteria into input fields for known attributes of an object. The search criteria can be entered via input text fields or selected from a list of values in a popup list picker or dropdown list box. The entered criteria is constructed into a query to be executed. Named bind variables can be used to supply attribute values during runtime for the query. The results of the query can be displayed as a table, a form, or another UI component.

Oracle ADF supports two types of search forms: query and quick query. The query search form is a full-featured search form. The quick query search form is a simplified form with only one search criteria. Each of these search forms can be combined with a filtered table to display the results, thereby enabling additional search capabilities. You can also create a standalone filtered table to perform searches without the query or quick query search panel.

Search forms are based either on view criteria defined in view objects or on implicit view criteria defined by JDeveloper. Search forms are region-based components that are reusable and personalizable. They encapsulate and automate many of the actions and iterator management operations required to perform a query. You can create several search forms on the same page without any need to change or create new iterators.
A filtered table is a table that has additional Query-by-Example (QBE) search criteria fields above each searchable column. When the filtering option of a table is enabled, you can enter QBE-style search criteria for each column to filter the query results. For more information about tables, see Chapter 29, "Creating ADF Databound Tables."

For more information about individual query and table components, see the "Using Query Components" and the "Using Tables, Trees, and Other Collection-Based Components" chapters of Developing Web User Interfaces with Oracle ADF Faces.

### 33.1.1 Implicit and Named View Criteria

When you create data controls, all data collections will automatically include a Named Criteria node with an All Queriable Attributes criteria. This is the default view criteria that includes all the searchable attributes or columns of the data collection. You cannot edit or modify this view criteria. These implicit view criteria can be used in the same way as declaratively created (or named) view criteria during the creation of query and quick query search forms. For more information about creating named view criteria, see Section 5.9, "Working with Named View Criteria."

When you add additional named view criteria for that view object or collection, the new view criteria will be added to the Named Criteria node.

---

**Note:** Query search forms have certain restrictions for working with expressions that have nested view criteria and may not work with all types of nested expressions. For more information about the nested expressions supported by search forms, see Section 5.9.4, "What You May Need to Know About Nested View Criteria Expressions."

In the Data Controls panel, a data collection’s Named Criteria node will always include the implicit view criteria, regardless of whether any named view criteria were defined. The implicit view criteria is always available for every data collection.

### 33.1.2 List of Values (LOV) Input Fields

List of values (LOV) components are input components that allow the user to enter values by picking from a list that is generated by a query. ADF Faces provides the `af:inputListOfValues` and `af:inputComboboxListOfValues` components. If you are using dependent LOVs as part of your search form, you must use them with the `af:query` component. For more information about LOV components, see Section 32.2, "Creating List of Values (LOV) Components."

If an attribute is defined as an LOV, you can set the Support Multiple Value Selection control hint in its view criteria to enable users to make multiple selections in the search criteria field. If multiple selection is enabled on an LOV attribute, and the Equal to or Not equal to operator is chosen, a `selectManyChoice` component will render in the query panel. The user can select multiple items as the search criteria.

When the LOV is in a query component, if the Support Multiple Value Selection hint is not set and the Equal to or Not equal to operator is chosen, the query component will render a search criteria component according to the Default List Type control hint for the corresponding attribute in the view object.

The quick query component does not support multiple selection. It will always render the component specified by the Default List Type control hint. Table 33–1 shows the control hint selection and the default list component.

---

Note: Query search forms have certain restrictions for working with expressions that have nested view criteria and may not work with all types of nested expressions. For more information about the nested expressions supported by search forms, see Section 5.9.4, "What You May Need to Know About Nested View Criteria Expressions."
About Creating Search Forms

Creating ADF Databound Search Forms

For more information about view criteria options, see Section 5.9.1, "How to Create Named View Criteria Declaratively," and Section 5.9.3, "What You May Need to Know About Bind Variables in View Criteria."

33.1.3 Search Form Use Cases and Examples

The search forms are based on the model-driven af:query and af:quickQuery components. Because these underlying components are model-driven, the search form will change automatically to reflect changes in the model. The view layer does not need to be changed. For example, if you define a list of values (LOV) on an attribute in the view object or entity object, the LOV will automatically show up in the search form as an LOV component. Or, if you modify a view criteria to include a new attribute for the WHERE clause, the search panel using this view criteria will automatically reflect that change by adding a search field for that attribute.

Figure 33–1 shows a quick query component.

For more complex searches, such as including criteria for product name, price ranges, and availability, a query component is used. You can create the query component in several different modes to give the user different capabilities, as shown in Figure 33–2. The user can even add their own search criteria using the Add Fields button. The user can save the searches that were created to be used later.

Table 33–1 Query and Quick Query Search Criteria Field Input Components

<table>
<thead>
<tr>
<th>Default List Type Control</th>
<th>Hint</th>
<th>Component</th>
</tr>
</thead>
<tbody>
<tr>
<td>Input Text with List of Values</td>
<td></td>
<td>af:inputListOfValues</td>
</tr>
<tr>
<td>Combo Box with List of Values</td>
<td></td>
<td>af:inputComboboxListOfValues</td>
</tr>
<tr>
<td>Choice List, Combo Box, List Box, Radio Group</td>
<td></td>
<td>af:selectOneChoice</td>
</tr>
</tbody>
</table>

For simple searches, you can use the filtered table to provide Query-by-Example (QBE) searches, as shown in Figure 33–3.
33.1.4 Additional Functionality for Search Forms

You may find it helpful to understand other ADF features before you configure or use the ADF Model layer. Additionally, you may want to read about what you can do with your model layer configurations. Following are links to other functionality that may be of interest.

- Both the query and quick query components are based on the view criteria defined in a view object. You use the view criteria to set up the initial search fields and search criteria. You use control hints to further define the query component. For more information about creating named view criteria, see Section 5.9, "Working with Named View Criteria."

- Since filtered tables also provide search functions, you should consider them for simple searches. For more information about tables, see Chapter 29, "Creating ADF Databound Tables."

- List of value components use the query component in their search panel for creating the list of values selection list. For more information about LOV components, see Section 32.2, "Creating List of Values (LOV) Components."

- If your application is set up with a Metadata Storage (MDS), you can persist saved searches across transactions and personalize your searches. For more information about using MDS, see Chapter 45, "Customizing Applications with MDS."

33.2 Creating Query Search Forms

The query search form is the standard form for complex transactional searches. You can build complex search forms with multiple search criteria fields each with a dropdown list of built-in operators. You can also add custom operators and customize the list. The query search form supports lists of values, AND and OR conjunctions, and saving searches for future use.

A query is associated with the view object that it uses for its query operation. In particular, a query component is the visual representation of the view criteria defined for that view object. For more information on creating view criteria, see Section 5.9, "Working with Named View Criteria." The view criteria items defined in the view criteria is the source for the search criteria in the search panel of the query component. The Rendered Mode option in the view criteria editor controls the search criteria will be displayed.

Search criteria can be grouped together to provide a logical grouping of attributes. For instance, you can group the address attributes together.

A query search form has a basic mode and an advanced mode. The user can toggle between the two modes using the basic/advanced button. At design time, you can declaratively specify form properties (such as setting the default state) to be either basic or advanced. Figure 33–4 shows an advanced mode query search form with three search criteria.
The advanced mode query form features are:

- Selecting search criteria operators from a dropdown list
- Adding custom operators and deleting standard operators
- Selecting \texttt{WHERE} clause conjunctions of either \texttt{AND} or \texttt{OR} (match all or match any)
- Dynamically adding and removing search criteria fields at runtime
- Saving searches for future use
- Personalizing saved searches

Typically, the query search form in either mode is used with an associated results table or tree table. In the Summit sample application for Oracle ADF, the query panel and results table is shown in Figure 33–5.

The basic mode has all the features of the advanced mode except that it does not allow the user to dynamically add search criteria fields. Figure 33–6 shows a basic mode query search form with three search criteria field. Notice the lack of a dropdown list next to the \texttt{Save} button used to add search criteria fields in the advanced mode.
In either mode, each search criteria field can be modified by selecting operators such as Greater Than and Equal To from a dropdown list, and the entire search panel can be modified by the Match All/Any radio buttons. Partial page rendering is also supported by the search forms in almost all situations. For example, if a Between operator is chosen, another input field will be displayed to allow the user to select the upper range.

A Match All selection implicitly uses AND conjunctions between the search criteria in the WHERE clause of the query. A Match Any selection implicitly uses OR conjunctions in the WHERE clause. Example 33–1 shows how a simplified WHERE clause may appear (the real WHERE in the view criteria is different) when Match All is selected for the search criteria shown in Figure 33–4.

Example 33–1  Simplified WHERE Clause Fragment When "Match All" Is Selected

WHERE (Id < 4) AND (InStock > 20) AND (Name="Shoes")

Example 33–1 shows a simplified WHERE clause if Match Any is selected for the search criteria shown in Figure 33–4.

Example 33–2  Simplified WHERE Clause Fragment When "Match Any" Is Selected

WHERE (Id < 4) OR (InStock > 20) OR (Name="Shoes")

If the view criteria for the query has mixed AND and OR conjunctions between the criteria items, then neither Match All nor Match Any will be selected when the component first renders. However, the user can select Match All or Match Any to override the conjunctions defined as the initial state in the view criteria.

Advanced mode query forms allow users to dynamically add search criteria fields to the query panel to perform more complicated queries. These user-created search criteria fields can be deleted, but the user cannot delete existing fields. You use the Add Fields dropdown list to add a search criteria field or all the fields within the group.

Figure 33–7 shows how the Add Fields dropdown list is used to add the WhlslUnits criteria field to the search form.

Figure 33–7  Dynamically Adding Search Criteria Fields at Runtime

Figure 33–8 shows a user-added search criteria with the delete icon to its right. Users can click the delete icon to remove the criteria.
If either Match All or Match Any is selected and then the user dynamically adds the second instance of a search criterion, then both Match All and Match Any will be deselected. The user must reselect either Match All or Match Any before clicking the Search button.

If you intend for a query search form to have both a basic and an advanced mode, you can define each search criteria field to appear only for basic, only for advanced, or for both. When the user switches from one mode to the other, only the search criteria fields defined for that mode will appear. For example, suppose three search fields for basic mode (A, B, C) and three search fields for advanced mode (A, B, D) are defined for a query. When the query search form is in basic mode, search criteria fields A, B, and C will appear. When it is in advanced mode, then fields A, B, and D will appear. Any search data that was entered into the search fields will also be preserved when the form returns to that mode. If the user entered 35 into search field C in basic mode, switched to advanced mode, and then switched back to basic, field C would reappear with value 35.

Along with using the basic or advanced mode, you can also determine how much of the search form will display. The default setting displays the whole form. You can also configure the query component to display in compact mode or simple mode. The compact mode has no header or border, and the Saved Search dropdown lists moves next to the expand/collapse icon. Figure 33–9 shows a query component set to compact mode.

The simple mode displays the component without the header and footer, and without the buttons normally displayed in those areas. Figure 33–10 shows the same query component set to simple mode.
If there are multiple view criteria defined, each can be selected from the Saved Search dropdown list. These saved searches are created at design time and are called system searches. For example, if you have defined two view criteria in the view object, both view criteria are available for selection, as shown in Figure 33–11.

**Note:** Be aware that opening and closing the query panel by clicking the panel expansion/collapse icon does not reset the applied view criteria. You can click the Reset button to reset the applied view criteria.

**Figure 33–11 Query Form Saved Search Dropdown List**

If there are no explicitly defined view criteria for a view object, you can use the default implicit view criteria.

Users can also create saved searches at runtime to save the state of a search for future use. The entered search criteria values, the basic/advanced mode state, and the layout of the results table/component can be saved by clicking the Save button to open a Save Search dialog, as shown in Figure 33–12. Saved searches appear in alphabetical order in the Saved Search dropdown list. User-created saved searches persist for the session. If they are intended to be available beyond the session, you must configure a persistent data store to store them. For Oracle ADF, you can use an access-controlled data source such as MDS. For more information about using MDS, see Chapter 45, "Customizing Applications with MDS."

When you perform a saved search, you can specify whether the layout of the results component is also saved. Creating saved searches and saving the results components layout require that MDS is configured. If you set the query component’s saveResultsLayout attribute to always, the results component layout will be saved. If saveResultsLayout is set to never, the layout is not saved.

**Example 33–3 web.xml Entry for Saving Query Results Component Layout**

```xml
<context-param>
  <description>Saving results layout</description>
  <param-name>oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT</param-name>
  <param-value>true</param-value>
</context-param>
```

If saveResultsLayout is not defined, saving layout defaults to the application-level property oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT in the web.xml file. The default value of oracle.adf.view.rich.query.SAVE_RESULTS_LAYOUT is true.

If the user made changes to the layout of a saved search and proceeds without saving, a warning message appears to remind the user to save, otherwise the changes will be lost. In addition, if the user adds or deletes search fields and proceeds without saving, a warning message also appears.
Table 33–2 shows the saveResultsLayout and SAVE_RESULTS_LAYOUT values and their resultant action. Note that MDS must be configured to save layout.

<table>
<thead>
<tr>

Figure 33–12  Runtime Saved Search Dialog Window

Table 33–1 lists the possible scenarios for creators of saved searches, the method of their creation, and their availability.

<table>
<thead>
<tr>
<th>Creator</th>
<th>Created at Design time as View Criteria</th>
<th>Created at Runtime with the Save Button</th>
</tr>
</thead>
<tbody>
<tr>
<td>Developer</td>
<td>Developer-created saved searches (system searches) are created during application development and typically are a part of the software release. They are created at design time as view criteria. They are usually available to all users of the application and appear in the lower part of the Saved Search dropdown list.</td>
<td></td>
</tr>
<tr>
<td>Administrator</td>
<td>Administrator-created saved searches are created during predeployment by site administrators. They are created before the site is made available to the general end users. Administrators can create saved searches (or view criteria) using the JDeveloper design time when they are logged in with the appropriate role. These saved searches (or view criteria) appear in the lower part of the Saved Search dropdown list.</td>
<td></td>
</tr>
</tbody>
</table>
You can use the `runQueryAutomatically` property as listed in the Property Inspector to specify whether a saved search will run the query automatically. Setting the property to `allSavedSearches` means all system and user-created saved searches will run automatically when the query component is initially loaded, whenever the saved search has changed, or the reset button is pressed. If you set the `runQueryAutomatically` property to `searchDependent`, you can specify at design time whether that specific query will run automatically. `searchDependent` is the default value.

For new user-created saved searches with `runQueryAutomatically` property set to `searchDependent`, the Create Saved Search dialog, as shown in Figure 33–12, will have the `Run Automatically` option set as the default. For new user-created saved searches with `runQueryAutomatically` property set to `allSavedSearches`, the Create Saved Search dialog will not display the `Run Automatically` option, but it will be set implicitly.

End users can manage their saved searches by using the Personalize function in the Saved Search dropdown list to bring up the Personalize Saved Searches dialog, as shown in Figure 33–13.

End users can use the Personalize function to:

- Update a saved search. Users can add and/or remove search criterion, update operators, update values, modify conjunctions and save it using the existing saved search name. In other words, overriding an existing saved search.
- Delete a saved search (including the currently active Saved Search)
- Duplicate an existing saved search
- Set a saved search as the default
- Set a saved search to run automatically
- Set the saved search to show or hide from the Saved Search dropdown list
Creating ADF Databound Search Forms

You create a query search form by dropping a named view criteria item from the Data Controls panel onto a page. You have a choice of dropping only a search panel, dropping a search panel with a results table, or dropping a search panel with a tree table.

If you choose to drop the search panel with a table, you can select the filtering option in the dialog to turn the table into a filtered table.

Typically, you would drop a query search panel with the results table or tree table. JDeveloper will automatically create and associate a results table or tree table with the query panel.

If you drop a query panel by itself and want a results component or if you already have an existing component for displaying the results, you will need to match the query panel’s `ResultsComponentId` with the results component’s `Id`.

### 33.2.1 Named Bind Variables in Query Search Forms

Instead of specifying a literal operand in a view criteria to be used in a search form, you have the option of specifying a named bind variable. The named bind variable performs like a parameter whose value can change at runtime without the need to change the SQL statement. It must be defined in the view object before it can be used in a view criteria.

If you specify a literal operand in the view criteria and leave the value blank, it will not appear in the SQL preview. When the view criteria is applied as a search form at runtime, that attribute is rendered as a blank input search field. If a value is specified for the literal operand, then the SQL preview will generate a SQL clause for it. When the view criteria is applied as a search form at runtime, the SQL statement is not automatically applied even though the value specified in the view criteria appears in the input search field. The SQL statement won’t get applied until the user clicks **Search** (or when auto-execute is set to true).

If a named bind variable is used in the query defined in the view criteria, the SQL preview will display the `WHERE` clause with the bind variable. When the view criteria is applied as a search form at runtime, the bind variable will be rendered with a prompt and an input search field based on the name of the attribute (not on the name of the bind variable). The named bind variable input field may be `NULL`, it may contain the default value, or it may contain a value that has loaded from previous processing, such as from another page. The user can enter values for the named bind variable as in any other search criteria. When the search is executed, the value of the named bind

---

**Note:** If in you are changing the value of a view criteria item programmatically, you must invoke the `ViewCriteria.saveState()` method to prevent the searchRegion binding from resetting the value of the view criteria item to the value that was specified at design time.

**Note:** When you drop a named view criteria onto a page, that view criteria will be the basis for the initial search form. All other view criteria defined against that data collection will also appear in the **Saved Search** dropdown list. Users can then select any of the view criteria search forms, and also any end-user created saved searches.
variable will be evaluated with the other criteria, as defined by the SQL query statement.

If the bind variable is used more than once in the same view criteria, each occurrence of the bind variable will be rendered as an individual input field. Because there is only one bind variable backing all the input fields, the value of all the fields will be synchronized. For instance, if you specify a view criteria that uses the same bind variable three times, then three input fields will be rendered. When the user enters a value into one input field, the other two input fields will have the same value. Using bind variables in this way eliminates the need for the user to enter the same value multiple times.

Another use of the bind variable is to pass a value from the base row into a search for an LOV search form.

Bind variables can also be used to pass parameter values from one page to another, such as when a customer ID is passed to another page for more detail processing. And, depending on the construct of the SQL statement, using the named bind variable may speed up the query because it may lessen the need to prepare a new statement, which means that the database does not need to reparse. For more information about creating and using named bind variables, see Section 5.10, “Working with Bind Variables.”

For example, in the listCustomerAddresses view criteria, the WHERE clause checks to see whether the AssociatedOwnerId is the same as the value of the paramCustomerId named bind variable. This view criteria is in the AddressesLookupVO view object. The listCustomerAddresses view criteria as defined in the Edit View Criteria dialog is shown in Figure 33–14.

**Figure 33–14  View Criteria with Named Bind Variable**

![Figure 33–14 View Criteria with Named Bind Variable](image)

A query search form for a view criteria with a named bind variable will render with a search field for the variable using the inputText component. Figure 33–15 shows the AssociatedOwnerId search field displayed as an inputText component.
33.2.2 How to Create a Query Search Form with a Results Table or Tree Table

You create a search form by dragging and dropping a view criteria from the Data Controls panel onto the page. You have the option of having a results table or only the query panel.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.2, "Creating Query Search Forms."

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, “Additional Functionality for Search Forms.”

You will need to complete these tasks:
1. Create a view object. For more information about view objects, see Section 5.2, "Populating View Object Rows from a Single Database Table," and Section 5.6, "Working with Multiple Tables in Join Query Results."
2. Create view criteria if you intend to create search forms based on view criteria. You can also use the default implicit view criteria, which would include all queriable attributes in the collection. For more information about view criteria, see Section 5.9, "Working with Named View Criteria."
3. Set the search form default properties. For more information about setting the default state of the search form, see Section 33.3.1, "How to Set Search Form Properties on the View Criteria.” For information on how to create view criteria, see Section 5.9, "Working with Named View Criteria."

To create a query search form with a results table or tree table:
1. From the Data Controls panel, select the data collection and expand the Named Criteria node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose Create > Query > ADF Query Panel with Table or Create > Query > ADF Query Panel with Tree Table, as shown in Figure 33–16.
33.2.3 How to Create a Query Search Form and Add a Results Component Later

You create a search form by dragging and dropping a view criteria from the Data Controls panel onto the page. You have the option of having a results table or only the query panel.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.2, "Creating Query Search Forms."

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, "Additional Functionality for Search Forms."

You will need to complete these tasks:

1. Create a view object.
2. Create view criteria if you intend to create search forms based on view criteria. You can also use the default implicit view criteria, which would include all queriable attributes in the collection.
3. Set the search form default properties. For more information about setting the default state of the search form, see Section 33.3.1, "How to Set Search Form Properties on the View Criteria." For information on how to create view criteria, see Section 5.9, "Working with Named View Criteria."

To create a query search form and add a results component in a separate step:

1. From the Data Controls panel, select the data collection and expand the Named Criteria node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose Create > Query > ADF Query Panel, as shown in Figure 33–16.
4. If you do not already have a results component, then drop the data collection associated with the view criteria as a component.
5. In the Properties window for the table, copy the value of the Id field.
6. In the Properties window for the query panel, paste the value of the table’s ID into the query’s ResultsComponentId field.
After you have created the search form, you may want to set some of its properties or add custom functions. See Section 33.3, "Setting Up Search Form Properties," for more information.

### 33.2.4 How to Persist Saved Searches into MDS

If you want saved searches to be persisted to MDS, you need to define the /persdef namespace in the adf-config.xml file. In addition, you need to perform the regular MDS configuration, such as specifying metadatapath. Example 33–4 shows an adf-config.xml file with the /persdef namespace defined.

**Example 33–4  Sample adf-config.xml with /persdef Namespace**

```xml
<persistence-config>
  <metadata-namespaces>
    <namespace path="/persdef" metadata-store-usage="mdsstore"/>
  </metadata-namespaces>
  <metadata-store-usages>
    <metadata-store-usage id="mdsstore" deploy-target="true"
      default-cust-store="true">
    </metadata-store-usage>
  </metadata-store-usages>
</persistence-config>
```

In order for the added saved searches to be available the next time the user logs in, cust-config needs to be defined as part of the MDS configuration. For more information about setting cust-config and MDS, see Section 45.2.1, "How to Create Customization Classes."

If you are also saving the layout of the results component, the application must have the ADF PageFlow Runtime and ADF Controller Runtime libraries installed. Set the project’s technology scope to include ADF Page Flow or automatically include these libraries by using the ADF Fusion Web Application application template.

### 33.2.5 What You May Need to Know about Default Search Binding Behavior

A search binding provides the model-driven behavior for a search form at runtime. The search binding is related to a particular iterator and the view criteria on that iterator, whose runtime defaults are specified by the Binds and Criteria properties of the search binding, respectively. The behavior of the search binding depends on the Query Automatically control hint. For more information about creating named view criteria, see Section 5.9, "Working with Named View Criteria."

The first time a search form is rendered in a task flow, the search binding’s runtime behavior, also known as the initial AutoQuery-or-ClearRowSet behavior, is as follows:

- **If Query Automatically is set to true**: The search binding automatically executes the iterator when the search binding is initialized in a task flow. The user will be presented with the results of the search based on the view criteria.
- **If Query Automatically is set to false**: The search binding clears the row set related to its iterator. The user will be presented with an empty search results component, which allows the user to enter search criteria and click the Search button to execute the search.

The Query Automatically control hint is available declaratively only for named view criteria. For the All Queriable Attributes view criteria, you can use the `setProperty()` method on the view criteria API interface to configure the hint at runtime. You can also use this method to set the hint on named view criteria. In the
Creating Query Search Forms

method, set the ViewCriteriaHints.CRITERIA_AUTO_EXECUTE property to true.

If the user changes the search form by selecting a different view criteria from the dropdown Saved Search list, the runtime behavior is as follows:

- If Query Automatically is set to true: The search binding automatically executes the iterator after applying the new view criteria. The user will be presented with the results of the newly selected saved search.
- If Query Automatically is set to false: The search binding applies the new view criteria only, leaving any existing search results intact. The user is presented with the results of the previous search.

The search binding’s queryPerformed property evaluates to true if the search binding has performed the query, either automatically or by the user clicking the Search button. Clicking the Reset button in the search form resets the view criteria and sets the queryPerformed property to false.

The search binding offers two properties that allow you to customize its default behavior: TrackQueryPerformed and InitialQueryOverridden. You can set the TrackQueryPerformed and the InitialQueryOverridden properties in the Properties window.

A search binding’s TrackQueryPerformed property controls whether it manages its queryPerformed property during runtime at the page flow level or at the individual page or page fragment level. The valid values for TrackQueryPerformed are pageFlow and page, and the default is pageFlow. The search binding’s behavior is as follows:

- If TrackQueryPerformed is set to pageFlow, then queryPerformed is initialized once per page flow and tracked at the page flow level. The user can navigate away from the search form page, return to the page within the life of the page flow, and the value of the queryPerformed flag will remain the same.
- If TrackQueryPerformed is set to page, then queryPerformed is initialized each time the user navigates to the page or page fragment. This happens when the page is navigated to for the first time and when the page is returned from another page within the page flow.

When TrackQueryPerformed of a search binding is set to pageFlow, its initial AutoQuery-or-ClearRowSet behavior is performed once during the page flow. In contrast, when TrackQueryPerformed is set to page, the initial AutoQuery-or-ClearRowSet behavior is performed each time the user visits the page or page fragment.

A search binding’s InitialQueryOverridden property controls whether it should suppress its initial AutoQuery-or-ClearRowSet behavior the first time the search binding is used in a page flow. If InitialQueryOverridden is true, then all valid values, including true, false, or a boolean-valued EL expression, are suppressed. The default value is false.

When you set the InitialQueryOverridden property to true, you are responsible for writing custom application logic to execute the query. Typically, the query should execute after the code applies some view criteria, sets some bind variables, or performs some other programmatic query setup. If your custom code fails to execute the query as expected with InitialQueryOverridden set to true, unless Query Automatically is set to false, the framework will still implicitly execute your query the first time during a user session in which there is an iterator binding reference. This occurs because when Query Automatically is not set to false, the iterator binding’s default executeQueryIfNeeded behavior takes effect and executes the query.
When `InitialQueryOverridden` evaluates to `true` or boolean `true`, then the initial AutoQuery-or-ClearRowSet behavior is suppressed the first time the search binding is used in a page flow. If `TrackQueryPerformed` is set to `pageFlow`, then only the initial AutoQuery-or-ClearRowSet behavior (that would have occurred for this search binding) is suppressed.

In contrast, if a search binding’s `TrackQueryPerformed` property is set to `page`, then only the initial AutoQuery-or-ClearRowSet behavior is suppressed. Subsequent initial AutoQuery-or-ClearRowSet behaviors that occur due to the user’s navigating back to the same page (or page fragment) are not affected by the `InitialQueryOverridden` property.

If you want to avoid the search binding’s performing any initial AutoQuery-or-ClearRowSet behavior, then leave the `TrackQueryPerformed` set to `pageFlow` and set `InitialQueryOverridden` to `true`.

You should not use the `RefreshCondition` property of an iterator to reference the `queryPerformed` property of a search binding. Doing so will inadvertently prevent new rows from being created in that iterator’s row set until after the search binding’s query has been performed.

### 33.2.6 What You May Need to Know About Dependent Criterion

There are situations when one search criteria is dependent on the value of another criteria. For example, a bug database has a search form with a Component and a Subcomponent search criteria, both defined as LOVs. When the user selects a value from the Component search criteria, that value must be submitted to the model so that Subcomponent can be filtered and populated with the appropriate search list for the user to choose from.

If you have a search criteria that has dependents, you must set the root and dependent criteria’s underlying view attribute’s Auto Submit control hint to `true`. You can create a custom listener to trigger a partial submit to update the model and refresh the search panel when the query component detects a value change for the root criteria. You need to create a custom listener because the standard `QueryOperationListener` does not handle this event type. You can create a custom `QueryOperationListener` class using the `QueryOperationListener` interface. You then register this class by implementing it in a managed bean or by directly setting it in the JSF page.

### 33.2.7 What Happens When You Create a Query Form

When you drop a query search form onto a page, JDeveloper creates an `af:query` tag on the page. If you drop a query with table or tree table, then an `af:table` tag or `af:treeTable` tag will follow the `af:query` tag.

Under the `af:query` tag are several attributes that define the query properties. They include:

- The `id` attribute, which uniquely identifies the query.
- The `resultsComponentId` attribute, which identifies the component that will display the results of the query. Typically, this will be the table or tree table that was dropped onto the page together with the query. You can change this value to be the `id` of a different results component. For more information, see Section 33.2.3, ”How to Create a Query Search Form and Add a Results Component Later.”

In the page definition file, JDeveloper creates an iterator and a `searchRegion` entry in the `executables` section. Example 33–5 shows the sample code for a page.
definition file that was created when the `CustomerViewCriteria` from the Customers collection of the `BackOfficeAppModuleDataControl` is dropped onto the page.

In the page definition file executable section:

- The iterator `binds` property is set to the name of the data collection. In the example, the value is set to `Customers`.
- The iterator `id` property is set to a data collection iterator. In the example, the value is set to `CustomersIterator`.
- If there is more than one view criteria defined for that data collection, the `searchRegion Criteria` property is set to the name of the view criteria that was dropped. In the example, the value is set to `CustomerViewCriteria`. If there is only one view criteria defined, then there will not be a `Criteria` property.
- The `searchRegion Binds` property is set to the same value as the `iterator id` property. In the example, the value is set to `CustomersIterator`.
- The `searchRegion id` property is set to the name of the view criteria concatenated with `Query`. In the example, the value is set to `CustomerViewCriteria`.

If the query was dropped onto the page with a table or tree, then in the page definition file `bindings` section, a tree element is added with the `Iterbinding` property set to the search iterator. In this example, the value is set to `CustomersIterator`. This should be the same iterator defined in the executable section.

**Example 33–5  Search Form Code in the Page Definition File**

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel" version="12.1.2.66.41" id="searchPageDef" Package="oracle.summit.view.pageDefs">
  <parameters/>
  <executables>
    <variableIterator id="variables"/>
    <iterator Binds="Customers" RangeSize="25"
      DataControl="BackOfficeAppModuleDataControl" id="CustomersIterator"/>
    <searchRegion Criteria="CustomerViewCriteria"
      Customizer="oracle.jbo.uicli.binding.JUSearchBindingCustomizer"
      Binds="CustomersIterator" id="CustomerViewCriteriaQuery"/>
  </executables>
  <bindings>
    <tree IterBinding="CustomersIterator" id="Customers">
      <nodeDefinition DefName="oracle.summit.model.views.CustomerVO"
        Name="Customers0">
        <AttrNames>
        </AttrNames>
      </nodeDefinition>
    </tree>
  </bindings>
</pageDefinition>
```
33.2.8 What Happens at Runtime: Search Forms

At runtime, the search form displays as a search panel on the page. The search panel will display in either basic mode or advanced mode, depending on the mode control hint when its corresponding view criteria was created. The Saved Search dropdown list will contain all the view criteria that are enabled (Show in List control hint enabled). The Match All/Any conjunction radio button may be enabled.

A search criteria field will be rendered for each search criteria defined in the view criteria. If the Default List Type control hint in the view object has been declared as an LOV or a selection list component, the search criteria field component is as shown in Table 33–1.

After the user enters the search criteria and clicks Search, a query against the view criteria is executed and the results are displayed in the associated table, tree table, or component.

33.3 Setting Up Search Form Properties

A query search form is based on a view criteria defined in a view object. When you create the view criteria, you also specify some of the search form properties. Later on, when you drop the named criteria onto the page to create a query component, you can specify other search form properties.

Search form properties that can be set on the view object include grouping related and dependent fields together in the query panel. For more information on setting hints in the view object, see Section 5.13.5, "How to Define UI Category Hints."

Search form properties that can be set when the view criteria is being created include:

- Default mode in basic or advanced mode
- Automatic query execution when the page loads
- Rendering of the search criteria field
- Enabling multiple selections for attributes defined as an LOV

Search form properties that can be set after the query component has been added to the JSF page include:

- id of the results table or results component
- Show or hide of the basic/advanced button
- Position of the mode button
- Default, simple, or compact mode for display

Search form attribute properties that can be set when the view object is being created include:

- timezone control hint for a timestamp attribute

33.3.1 How to Set Search Form Properties on the View Criteria

When you are creating a view criteria, you can declaratively set the initial state of several properties. Figure 33–17 shows the Edit View Criteria dialog for setting default options. For more information about view criteria, see Section 5.9, "Working with Named View Criteria."
You must select the default mode of the query search form as either basic or advanced. The default is basic.

You also must declare whether each individual search criteria field will be available only in basic mode, only in advanced mode, available in both modes, or never displayed. If a search criteria field is declared only for basic mode, it will not appear when the user switches to advanced mode, and the reverse is true. If the field is declared for all, then it will appear in all modes. The default for search criteria field rendering is all modes.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.3, "Setting Up Search Form Properties."

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, "Additional Functionality for Search Forms."

You will need to complete this task:

Create a view criteria for the query search form, as described in Section 5.9, "Working with Named View Criteria."

**To set the default mode and search criteria field display option:**
1. In the Applications window, double-click the view object that contains the view criteria you created for the query search form.
2. In the overview editor for the view object, click the View Criteria navigation tab.
3. In the View Criteria page, select the view criteria from the list and click **Edit**.
4. In the Edit View Criteria dialog, click the **UI Hints** tab.
5. From the **Search Region Mode** dropdown list, select either **Basic** or **Advanced**.
6. In the **Criteria Item UI Hints** section, select the criteria item you want to set.

7. In the **Rendered Mode** dropdown list, select **All**, **Basic**, **Advanced**, or **Never**.

8. Click OK.

### 33.3.2 How to Set Search Form Properties on the Query Component

After you have dropped the query search form onto a page, you can edit other form properties in the Properties window, as shown in Figure 33–18. Some of the common properties you may set are:

- Enabling or disabling the basic/advanced mode button
- Setting the ID of the query search form
- Setting the ID of the results component (for example, a results table)
- Selecting the default, simple, or compact mode for display
- Setting the criterionFeatures to matchCaseDisplayed to require all string-based search criterion to be case-sensitive or to requiredDisplayed to require all the criterion to be displayed.

*Figure 33–18  Properties window for a Query Component*

One common option is to show or hide the basic/advanced button. For more information on some of the other properties, see the "How to Add the Query Component" section in *Developing Web User Interfaces with Oracle ADF Faces*.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.3, "Setting Up Search Form Properties."
You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, "Additional Functionality for Search Forms."

**To enable or hide the basic/advanced button in the query form:**
1. In the Structure window, double-click `af:query`.
2. In the Properties window, click the Appearance tab.
3. To enable the basic/advanced mode button, select `true` from the `ModeChangeVisible` field. To hide the basic/advance mode button, select `false` from the `ModeChangeVisible` field.

**33.3.3 How to Set Timezone Control Hint for Timestamp Attribute**

If a query includes a `Date` attribute, you can set its `timezone` using control hints on the view object or entity object where the attribute is defined. For instance, you can set the `Hiredate` of an employee to have the correct `timezone` for the employee’s local office.

**Before you begin:**
Create the desired view objects as described in Section 5.2.1, "How to Create an Entity-Based View Object," and Section 5.8.1, "How to Create an Expert Mode View Object."

**To customize view object timestamp attribute with control hints:**
1. In the Applications window, double-click the view object.
2. In the overview editor, click the Attributes navigation tab and select the `Date` attribute that you want to customize with control hints.
3. Click the UI Hints tab to expose the `Timezone` property.
4. Select a time zone from the `Timezone` dropdown list.

   The time zone values are listed as Universal Time Coordinated (UTC) +/- hours.

**33.3.4 How to Create Custom Operators**

You can create custom operators for each view criteria item by adding code to the view object XML file. For example, you can create a new operator called `more than a year`, which operates on a date attribute (greater than 365 days from the current date).

You can add custom operators for a view object attribute by adding code for that attribute in the view object XML file.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.3, "Setting Up Search Form Properties."

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, "Additional Functionality for Search Forms."
To add a custom operator:

1. In the Applications window, select the view object for the view criteria in which you want to add a custom operator.

2. In the overview editor, click the **Source** tab.

3. In the XML editor, locate the code for the view criteria attribute, and add the CompOper code statements after the last item within the ViewCriteriaItem group.

   In Example 33–6, the CompOper code statements appear in bold.

### Example 33–6  Adding the Custom Operator Code to the View Object XML

```xml
<ViewCriteriaRow
    Name="vcrow50"
    UpperColumns='1'>
    <ViewCriteriaItem
        Name="LastUpdateDate"
        ViewAttribute="LastUpdateDate"
        Operator="="
        Conjunction="AND"
        Required='Optional'>
        <CompOper
            Name="LastUpdateDate"
            ToDo="1"
            OperDescStrCode="LastUpdateDate_custOp_grt_year"
            Oper=">Y"
            MinCardinality="0"
            MaxCardinality="0">
            <TransientExpression><![CDATA[ return ' > SYSDATE - 365']]></TransientExpression>
        </CompOper>
    </ViewCriteriaItem>
</ViewCriteriaRow>
```

The **CompOper** properties are:

- **Name**: Specify an id for the operation.
- **ToDo**: Set to 1 to add this custom operator. Set to -1 to remove an operator.
- **OperDescStrCode**: Specify the id used in the message bundle to map to the description string, as described in Step 4.
- **Oper**: Set to a value that will be used programmatically to denote this operation in the SQL statement. In Example 33–6, **Oper** was set to >Y to denote greater than 1 year.
- **MinCardinality**: If there is an input range, set this property to the minimum value for the range. For example, if the range is months in a year, this value should be set to 1. If there is no range, set it to 0.
- **MaxCardinality**: If there is an input range, set this property to the maximum value for the range. For example, if the range is months in a year, this value should be set to 12. If there is no range, set it to 0.
- **TransientExpression**: Set the expression to perform the custom operator function. In Example 33–6, the expression is ![CDATA[ return ' > SYSDATE - 365']]>, which returns the string " > SYSDATE -365". 
4. Open the message bundle file for the view object and add an entry for the custom operator, using the OperDescStrCode identifier defined in the view object XML in Step 3.

   Example 33–7 shows the message bundle code for the LastUpdateDate custom operator described in Example 33–6.

Example 33–7   Adding the Custom Operator Entry for LastUpdateDate to the Message Bundle

   public class AvailLangImplMsgBundle extends JboResourceBundle {
     static final Object[][] sMessageStrings =
     {
       { "LastUpdateDate_custOp_grt_year", "more than a year old" },
     },

33.3.5 How to Remove Standard Operators

You can remove standard operators from a view criteria item. For example, you can remove the standard operator before from the list.

For a list of standard operators, see the "Using Query Components” chapter of Developing Web User Interfaces with Oracle ADF Faces.

You can remove standard operators for a view object attribute by adding code for that attribute in the view object XML file.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.3, “Setting Up Search Form Properties.”

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, “Additional Functionality for Search Forms.”

To remove a standard operator:
1. In the Applications window, select the view object for the view criteria in which you want to remove a standard operator.

   Note: Before you attempt to remove the standard operator, make sure you do not remove the default operator for that view criteria item.

2. In the overview editor, click the Source tab.

3. In the XML editor, locate the code for the view criteria attribute, and add the CompOper code statements after the last item within the ViewCriteriaItem group.

   In Example 33–8, the CompOper code statements appear in bold. The code in this example removes the BEFORE operator from the list of operators for the LastUpdateDate attribute.
Example 33–8  Removing a Standard Operator Code in the View Object XML

```
<ViewCriteriaRow
  Name="vcrow50"
  UpperColumns="1">
  <ViewCriteriaItem
    Name="LastUpdateDate"
    ViewAttribute="LastUpdateDate"
    Operator="="
    Conjunction="AND"
    Required='Optional'>
    <CompOper
      Name="LastUpdateDate"
      ToDo="-1"
      Oper="BEFORE">
    </CompOper>
  </ViewCriteriaItem>
</ViewCriteriaRow>
```

The `CompOper` properties are:

- **Name**: Specify an id for the operation.
- **ToDo**: Set to -1 to remove an operator. Set to 1 to add an operator. Do not set **ToDo** to -2, which would remove all the operators.
- **Oper**: Set to the standard operator you want to remove from the list.

### 33.4 Creating Quick Query Search Forms

A quick query search form is intended to be used in situations where a single search will suffice or as a starting point to evolve into a full query search. Both the query and quick query search forms are ADF Faces components. A quick query search form has one search criteria field with a dropdown list of the available searchable attributes from the associated data collection. Typically, the searchable attributes are all the attributes in the associated view object. You can exclude attributes by setting the attribute's Display Hint property in the Control Hints page of the Edit Attribute dialog to Hide. The user can search against the selected attribute or search against all the displayed attributes. The search criteria field type will automatically match the type of its corresponding attribute. An Advanced link built into the form offers you the option to create a managed bean to control switching from quick query to advanced mode query search form. For more information, see the "Using Query Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.

You can configure the form to have a horizontal layout, as shown in Figure 33–19.

**Figure 33–19  Quick Query Search Form in Horizontal Layout**

You can also choose a vertical layout, as shown in Figure 33–20.

**Figure 33–20  Quick Query Search Form in Vertical Layout**
You can use quick query search forms to let users search on a single attribute of a
collection. Quick query search form layout can be either horizontal or vertical. Because
they occupy only a small area, quick query search forms can be placed in different
areas of a page. You can create a managed bean to enable users to switch from a quick
query to a full query search. For more information about switching from quick query
to query using a managed bean, see the “Using Query Components” chapter in
Developing Web User Interfaces with Oracle ADF Faces.

If you drop a quick query panel with a results table or tree, JDeveloper will
automatically create the results table, as described in Section 33.4.1, "How to Create a
Quick Query Search Form with a Results Table or Tree Table." If you drop a quick
query panel by itself and subsequently want a results table or component or if you
already have one, you will need to match the quick query id with the results
component’s partialTrigger value, as described in Section 33.4.2, "How to Create a
Quick Query Search Form and Add a Results Component Later."

---

**Note:** A quick query search creates a dropdown list of all searchable
attributes defined in the underlying view object. If you want to show
only a subset of those attributes, you can set the attribute’s Display
control hint to Hide for those attributes you want to exclude. For more
information about setting control hints on view objects, see Chapter 5,
"Defining SQL Queries Using View Objects."

---

### 33.4.1 How to Create a Quick Query Search Form with a Results Table or Tree Table

You can create quick query searches using the full set of searchable attributes and
simultaneously add a table or tree table as the results component.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you
when you create a query search form. For more information, see Section 33.4, "Creating
Quick Query Search Forms."

You may also find it useful to understand functionality that can be used with query
search forms. For more information, see Section 33.1.4, "Additional Functionality for
Search Forms."

You will need to complete this task:

Create a view object to be the basis of the search form.

**To create a quick query search form with a results table:**

1. From the Data Controls panel, select the data collection and expand the Named
   Criteria node to display a list of named view criteria.

2. Drag the All Queriable Attributes item and drop it onto the page or onto the
   Structure window.

3. From the context menu, choose Create > Quick Query > ADF Quick Query Panel
   with Table or Create > Quick Query > ADF Quick Query Panel with Tree Table,
   as shown in Figure 33–21.

4. In the Edit Table Columns dialog, you can rearrange any column and select table
   options. If you choose the filtering option, the table will be a filtered table.

5. Click OK.
33.4.2 How to Create a Quick Query Search Form and Add a Results Component Later

You can create quick query searches using the full set of searchable attributes and add a table or tree table as the results component later.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.4, "Creating Quick Query Search Forms."

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, "Additional Functionality for Search Forms."

You will need to complete this task:

To create a quick query search form and add a results component in a separate step:
1. From the Data Controls panel, select the data collection and expand the Named Criteria node to display a list of named view criteria.
2. Drag the All Queriable Attributes item and drop it onto the page or onto the Structure window.
3. From the context menu, choose Create > Quick Query > ADF Quick Query Panel.
4. If you do not already have a results component, then drop the data collection associated with the view criteria as a component.
5. In the Properties window for the quick query panel, copy the value of the Id field.
6. In the Properties window for the results component (for example, a table), paste or enter the value into the PartialTriggers field.

33.4.3 How to Set the Quick Query Layout Format

The default layout of the form is horizontal. You can change the layout option using the Properties window.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.4, "Creating Quick Query Search Forms."

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, "Additional Functionality for Search Forms."
To set the layout:
1. In the Structure window, double-click `af:quickQuery`.
2. In the Properties window, on the Commons page, select the Layout field using the dropdown list to specify default, horizontal, or vertical.

### 33.4.4 What Happens When You Create a Quick Query Search Form

When you drop a quick query search form onto a page, JDeveloper creates an `af:quickQuery` tag. If you have dropped a quick query with table or tree table, then an `af:table` tag or `af:treeTable` tag is also added.

Under the `af:quickQuery` tag are several attributes and facets that define the quick query properties. Some of the tags are:

- **The id attribute**, which uniquely identifies the quick query. This value should be set to match the results table or component's `partialTriggers` value. JDeveloper will automatically assign these values when you drop a quick query with table or tree table. If you want to change to a different results component, see Section 33.4.2, "How to Create a Quick Query Search Form and Add a Results Component Later."
- **The layout attribute**, which specifies the quick query layout to be default, horizontal, or vertical.
- **The end facet**, which specifies the component to be used to display the Advanced link (that changes the mode from quick query to the query). For more information about creating this function, see the "Using Query Components" chapter of Developing Web User Interfaces with Oracle ADF Faces.

### 33.4.5 What Happens at Runtime: Quick Query

At runtime, the quick query search form displays a single search criteria field with a dropdown list of selectable search criteria items. If there is only one searchable criteria item, then the dropdown list box will not be rendered. An input component that is compatible with the selected search criteria type will be displayed, as shown in Table 33-4. For example, if the search criteria type is date, then `inputDate` will be rendered.

<table>
<thead>
<tr>
<th>Attribute Type</th>
<th>Rendered Component</th>
</tr>
</thead>
<tbody>
<tr>
<td>DATE</td>
<td><code>af:inputDate</code></td>
</tr>
<tr>
<td>VARCHAR</td>
<td><code>af:inputText</code></td>
</tr>
<tr>
<td>NUMBER</td>
<td><code>af:inputNumberSpinBox</code></td>
</tr>
</tbody>
</table>

If the Default List Type control hint in the view object has been declared as an LOV or a selection list component, the search criteria field component appears as shown in Table 33-1 in Section 33.1.2, "List of Values (LOV) Input Fields."

In addition, a Search button is rendered to the right of the input field. If the end facet is specified, then any components in the end facet are displayed. By default, the end facet contains an Advanced link.
33.5 Creating Standalone Filtered Search Tables from Named View Criteria

A filtered table can be created standalone or as the results table of a query or quick query search form. Filtered table searches are based on Query-by-Example and use the QBE text or date input field formats. The input validators are turned off to allow for entering characters such as > and <= to modify the search criteria. For example, you can enter >1500 as the search criteria for a number column. Wildcard characters may also be supported. If a column does not support QBE, the search criteria input field will not render for that column. The input field rendered will depend on the attribute’s data type. For instance, a date column will have a date picker component rendered and a column for an attribute defined as a List of Values will have the corresponding List of Values component rendered.

The filtered table search criteria input values are used to build the query WHERE clause with the AND operator. If the filtered table is associated with a query or quick query search panel, the composite search criteria values are also combined to create the WHERE clause.

**Note:** If the filtered table is used with a query component in a search form and the search region is using an existing named criteria, the results of the query will be filtered by all the view criteria rows in an iterative manner. For example, a filtered table has two view criteria rows: PersonId and DeptId. The first view criteria row has PersonId > 1. When the user enters >100 in the filter field, then the second view criteria row DeptId is used to accept input to further filter the results. This process iterates through all the view criteria rows until the final query result is reached.

Figure 33–22 shows a filtered table. When the user enters a QBE search criteria, such as >10 for the Id field, the query result is the AND of the query search criteria and the filtered table search criteria.

**Figure 33–22 Filtered Table**

<table>
<thead>
<tr>
<th>Id</th>
<th>Lastname</th>
<th>Firstname</th>
</tr>
</thead>
<tbody>
<tr>
<td>20</td>
<td>Magee</td>
<td>Colin</td>
</tr>
<tr>
<td>12</td>
<td>Gilum</td>
<td>Harry</td>
</tr>
<tr>
<td>22</td>
<td>Sadeghi</td>
<td>Yosmin</td>
</tr>
<tr>
<td>34</td>
<td>Nguyen</td>
<td>Mai</td>
</tr>
<tr>
<td>25</td>
<td>Dunne</td>
<td>Andre</td>
</tr>
</tbody>
</table>

Table 33–5 lists the acceptable QBE search operators that can be used to modify the search value.

**Table 33–5 Query-by-Example Search Criteria Operators**

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&gt;</td>
<td>Greater than</td>
</tr>
<tr>
<td>&lt;</td>
<td>Less than</td>
</tr>
<tr>
<td>&gt;=</td>
<td>Greater than or equal to</td>
</tr>
<tr>
<td>&lt;=</td>
<td>Less than or equal to</td>
</tr>
</tbody>
</table>
Creating Standalone Filtered Search Tables from Named View Criteria

You use query search forms for complex searches, but you can also perform simple QBE searches using the filtered table. You can create a standalone ADF-filtered table without the associated search panel and perform searches using the QBE-style search criteria input fields. For more information about filtered tables, see Section 33.5.1, "How to Create Filtered Table and Query-by-Example Searches."

You can set the QBE search criteria for each filterable column to be a case-sensitive or case-insensitive search using the `filterFeature` attribute of `af:column` in the `af:table` component. For more information, see the "Enabling Filtering in Tables" section of Developing Web User Interfaces with Oracle ADF Faces.

### 33.5.1 How to Create Filtered Table and Query-by-Example Searches

When creating a table, you can make almost any table a filtered table by selecting the filtering option if the option is enabled. There are three ways to create a standalone filtered table:

- You can drop a table onto a page from the Components window, bind it to a data collection, and set the filtering option. For more information, see the "Using Query Components" chapter of Developing Web User Interfaces with Oracle ADF Faces.
- You can create a filtered table by dragging and dropping a data collection onto a page and setting the filtering option. For more information, see Section 29.2.1, "How to Create a Basic Table."
- You can also create a filtered table or a read-only filtered table by dropping named criteria onto a page. You can use either the implicitly created named criteria All Queriable Attributes or any declaratively created named view criteria. The resulting filtered table will have a column for each searchable attribute and an input search field above each column.

### Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a query search form. For more information, see Section 33.5, "Creating Standalone Filtered Search Tables from Named View Criteria."

You may also find it useful to understand functionality that can be used with query search forms. For more information, see Section 33.1.4, "Additional Functionality for Search Forms."

### To create a filtered table using named view criteria:

1. From the Data Controls panel, select the data collection and expand the Named Criteria node to display a list of named view criteria.
2. Drag the named view criteria item and drop it onto the page or onto the Structure window.
3. From the context menu, choose Create > ADF Filtered Table.
4. In the Edit Table Columns dialog, you can rearrange any column and select table options.

---

**Table 33–5 (Cont.) Query-by-Example Search Criteria Operators**

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>AND</td>
<td>And</td>
</tr>
<tr>
<td>OR</td>
<td>Or</td>
</tr>
</tbody>
</table>

---

**Table 33–5 (Cont.) Query-by-Example Search Criteria Operators**

<table>
<thead>
<tr>
<th>Operator</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>AND</td>
<td>And</td>
</tr>
<tr>
<td>OR</td>
<td>Or</td>
</tr>
</tbody>
</table>
Because the table is created by JDeveloper during quick query creation, the filtering option is automatically enabled and not user-selectable, as shown in Figure 33–23.

**Figure 33–23  Edit Table Columns Dialog for Filtered Table**
Using More Complex Databound ADF Faces Components

This chapter describes how to create calendar and carousel components from data modeled with ADF Business Components, using ADF data controls and ADF Faces components.

This chapter includes the following sections:

- Section 34.1, "About More Complex Databound ADF Faces Components"
- Section 34.2, "Using the ADF Faces Calendar Component"
- Section 34.3, "Using the ADF Faces Carousel Component"

34.1 About More Complex Databound ADF Faces Components

ADF Faces calendar and ADF Faces carousel are complex components that you can use to include calendar functions or display rotating images in your application. The ADF Faces calendar displays activities in daily, weekly, monthly, or list views for a given provider. The calendar is configurable to display only some of the views. The calendar includes a toolbar with built-in functionality that allows a user to change the view (between daily, weekly, monthly, or list), go to the previous or next day, week, or month, and return to today. The toolbar is customizable and allows you to choose which buttons and text to display, and you can also add buttons or other components.

The ADF Faces carousel displays images in a revolving loop that the user can select by using the slider or clicking on images. It can be configured to have either a horizontal or vertical orientation. You can use other components in conjunction with the carousel. You can add a toolbar or menu bar, and then add buttons or menu items that allow users to perform actions on the current object.

34.1.1 Complex Databound ADF Faces Components Use Cases and Examples

The ADF Faces calendar can be used whenever you want to add a calendar feature to your application. You will need to have the relevant data in your data store that represents the content provided by the calendar, such as the date, time, title, location, and owner. You can use the familiar patterns of entity objects and view objects to model the data and then use drag and drop from the Data Controls panel to create the calendar.

The carousel component gives the user the ability to view an image from a series of images. The user can see partial views of the images before and after the image being viewed and can scroll through each image in the sequence. The user can do so using a slider or navigation buttons. The carousel is useful for showing objects that require a
highly visual presentation. For example, it can be used to display a photographic collection or merchandise in a catalog.

34.1.2 Additional Functionality of Complex Databound ADF Faces Components

You may find it helpful to understand other Oracle ADF features before you configure or use complex ADF Faces components. Additionally, you may want to read about what you can do with your complex components. Following are links to other functionality that may be of interest.

- You can customize the calendar for individual users so that the calendar appears in the selected configuration when that user accesses the calendar. For more information, see Chapter 46, “Allowing User Customizations at Runtime.”

- Calendars are based on entity objects. For information on creating entity objects, see Chapter 4, “Creating a Business Domain Layer Using Entity Objects.”

- For more information about partial page rendering and the partialTriggers attribute, see the "Rerendering Partial Page Content" chapter of Developing Web User Interfaces with Oracle ADF Faces.

- The carousel component uses a tree binding to iterate over the data. For more information about the tree binding, see Section 29.2.2.1, "Iterator and Value Bindings for Tables."

34.2 Using the ADF Faces Calendar Component

ADF Faces includes a calendar component that displays activities in daily, weekly, or monthly views. Figure 34–1 shows an ADF Faces calendar in weekly view mode with some sample activities.

Figure 34–1 ADF Faces Calendar

The calendar component also includes the following functionality:

- A toolbar that allows users to switch between monthly, weekly, daily, and list views.
Tip: When these toolbar buttons are used, attribute values on the calendar are changed. You can configure these values to be persisted so that they remain for a particular user whenever they access the calendar. For more information, see Chapter 46, "Allowing User Customizations at Runtime."

- Configurable start of the week days and start of the day hours. For example, a calendar’s week might start on Sunday and the day might show 8:00 am at the top.
- Configurable styles using skinning keys.

Additionally, you can implement the following functionality using other ADF Faces components and the rich client framework:

- Popup functionality: Components placed in supported facets that respond to certain events and allow the user to act on activities or the calendar. For example, when a user clicks an activity in the calendar, the CalendarActivityEvent is invoked and any popup component in the ActivityDetail facet is displayed. You might use a dialog component that contains a form where users can view and edit the activity, as shown in Figure 34–2.

Figure 34–2  Edit Dialog for ActivityDetail Facet

- Drag and drop capability: You can add the calendarDropTarget tag that allows a user to drag an activity to another place on the calendar. You then implement the functionality so that the time is actually changed on the activity and persisted to the data store.
- Toolbar customization: By default, the toolbar contains buttons that allow the user to switch between the different views, along with previous and next buttons and a button that returns to the current date. The toolbar also displays the current date range (or the date when in day view). You can customize the toolbar by adding facets that contain additional buttons of your choosing.
- Skinning: The calendar uses skinning keys to determine things like colors and icons used. You can extend the skin to change the appearance of the calendar.

Details for configuring the built-in functionality or for implementing additional functionality can be found in the “Using a Calendar Component” chapter of Developing Web User Interfaces with Oracle ADF Faces.
An ADF Faces Calendar component must be bound to a CalendarModel class. This class can be created for you when you use ADF Business Components to manage your calendar’s data. For example, say you have data in your data store that represents the details of an activity, such as the date, time, title, location, and owner. When you create an entity object to represent that data, and then a view object to display the data, you can drag and drop the associated collection from the Data Controls panel to create the calendar. JDeveloper will declaratively create the model and bind the view to that model so that the correct data will display when the calendar is launched. However, in order for the model to be created, your entity objects in the data model project with ADF Business Components and your view objects in the same project must contain date-effective attributes. Additionally, the view objects must contain variables that will be used to modify the query to return the correct activities for the given date range.

### 34.2.1 How to Use the ADF Faces Calendar

Before you can create a calendar on a JSF page, you must first create an entity object with specific attributes that represent attributes on a calendar. You then must create a view object from that entity object, and modify the query to use named bind variables that represent the date range and current time zone to display. This will allow the query to return only the activities that should be displayed in the given view on the calendar.

For example, say you have a database table that represents an activity. It has a column for title, start time, end time, and a reference to a provider object that represents the owner. You would create an entity object and a view object based on that table (ensuring that it meets the requirements, as described in the following steps). To the view object, you would then add named bind variables for the start and end times currently displayed on the calendar, along with the time zone currently in use by the calendar, so that the query returns only those activities that fall within that time range.

Once you add the calendar component to a JSF page, you can configure it and add functionality.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create a calendar. For more information, see Section 34.2, "Using the ADF Faces Calendar Component."

**To create an ADF Faces calendar:**

1. Create an entity object based on your data source. The entity object must include the attributes shown in Table 34–1. The attributes do not have to use the names shown in the table; they can be named anything. However, they must be of one of the types noted. You will map these attributes to attributes in the CalendarModel in a later step.

**Table 34–1 Required Attributes for a Calendar**

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Valid Types</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Start time</td>
<td>java.util.Date, java.sql.Date, oracle.jbo.domain.Date, oracle.jbo.domain.TimeStamp</td>
<td>Start time for the activity</td>
</tr>
<tr>
<td>End time</td>
<td>java.util.Date, java.sql.Date, oracle.jbo.domain.Date, oracle.jbo.domain.TimeStamp</td>
<td>End time for the activity</td>
</tr>
</tbody>
</table>
The entity object can also contain the known (but not required) attributes shown in Table 34–2:

Table 34–2 Optional Attributes for a Calendar

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Recurring</td>
<td>String or CalendarActivity.Recurring</td>
<td>Status of recurrence for the activity. Valid values are SINGLE (does not recur), RECURRING, or CHANGED (this activity was part of the recurring activity but has been modified to be different from parent activity).</td>
</tr>
<tr>
<td>Reminder</td>
<td>String or CalendarActivity.Reminder</td>
<td>Whether or not the activity has an associated reminder. Valid values are ON or OFF.</td>
</tr>
<tr>
<td>Time Type</td>
<td>String or CalendarActivity.TimeType</td>
<td>Type of time associated with the activity. Valid values are ALLDAY and TIME. Activities that have a value of ALLDAY do not have any time associated with them. They are considered to span the entire day. Activities with a value of TIME have a specific time duration.</td>
</tr>
<tr>
<td>Location</td>
<td>String</td>
<td>Location of an activity.</td>
</tr>
<tr>
<td>Tags</td>
<td>Set of String values or a semicolon-separated list of String values</td>
<td>Keywords for the activity.</td>
</tr>
</tbody>
</table>

Your entity objects can also contain other attributes that the CalendarModel has no knowledge of. You will be able to add these to the model as custom properties in a later step.

For information on creating entity objects, see Chapter 4, "Creating a Business Domain Layer Using Entity Objects."

2. Create an associated view object. In the Query page of the overview editor, create named bind variables for the following:

- A string that represents the time zone
- A date that represents the start time for the current date range shown on the calendar
- A date that represents the end time for the current date range shown on the calendar

**Tip:** Dates in an ADF Faces calendar are "half-open," meaning that the calendar returns all activities that start on or after the start time and before (but not on) the end time.
For more information about creating named bind variables, see Section 5.10, "Working with Bind Variables."

3. Create an entity object that represents the provider (owner) of activities. The entity object must include the attributes shown in Table 34–3. The attributes do not have to use the names shown in the table; they can be named anything. However, they must be of the type noted. You will map these attributes to attributes in the CalendarProvider class in a later step.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Id</td>
<td>String</td>
<td>Unique ID.</td>
</tr>
<tr>
<td>Display Name</td>
<td>String</td>
<td>The name of the provider that can be displayed in the calendar.</td>
</tr>
</tbody>
</table>

4. Create a view object for the provider.

5. Ensure that the new view objects are part of the application module, and if needed, refresh the Data Controls panel.

6. Create your JSF page, as documented in Section 26.3, "Creating a Web Page."

7. From the Data Controls panel, drag the collection that represents the view object for the activity created in Step 2 and drop it as a Calendar.

   **Tip:** The Calendar option will appear in the context menu only if the view object contains the required attributes documented in Table 34–1 and the bind variables described in Step 2.

8. Complete the Calendar Bindings dialog to map the bind variables and attributes to the CalendarModel and the CalendarProvider classes. For additional help, click Help or press F1.

9. By default, the calendar will be read-only and will return only those activities currently in the data store. You will need to configure the calendar and implement additional functionality as described in the "Using a Calendar Component" chapter of Developing Web User Interfaces with Oracle ADF Faces.

   For example, to allow creation of a new activity, you might create an input form in a dialog (as described in the "How to Create a Dialog" section of Developing Web User Interfaces with Oracle ADF Faces) using the same data control collection used to create the calendar. For more information about creating input forms, see Section 28.8, "Creating an Input Form."

### 34.2.2 What Happens When You Create a Calendar

When you drop a collection as a calendar, JDeveloper:

- Defines an iterator binding to the collection of activities, and another iterator binding to the collection of providers.

- Defines an action binding to the `executeWithParams` operation on the activities collection. It is this operation that will be invoked to execute the query to return the activities to display. Because the operation requires parameters to determine the date range and time zone, `NamedData` elements are also created for each of the parameters (created as named bind variables on the view object). For more information about `NamedData` elements, see Section 30.2.2.2, "Method Parameters."
Using the ADF Faces Calendar Component

- Defines a calendar binding. This binding contains a node element that represents a row in the collection and maps the data control attributes to the calendar activity’s attributes, as defined when using the wizard. The value is the data control attribute and the type is the calendar attribute. For any custom defined attributes, the type will be custom and value will be the data control attribute. Each row (node) is represented by a rowKey, which is the activity ID.

There is also a providerDefinition element that determines the source and mapping of available providers. This mapping allows the calendar model to filter activities based on the state of the provider (either enabled or disabled).

**Tip:** To access a custom attribute, use the CalendarActivity.getCustomAttributes() method, passing in the name of the attribute as defined by the value element.

Example 34–1 shows the page definition code for a calendar.

**Example 34–1  Page Definition Code for a Calendar Binding**

```xml
<executables>
  <iterator Binds="ActivityView1" RangeSize="-1"
    DataControl="AppModuleDataControl" id="ActivityView1Iterator"/>
  <iterator Binds="EmployeesView1" RangeSize="25"
    DataControl="AppModuleDataControl" id="EmployeesView1Iterator"/>
</executables>

<bindings>
  <action IterBinding="ActivityView1Iterator" id="ExecuteWithParams"
    RequiresUpdateModel="true" Action="executeWithParams">
    <NamedData NDName="startTime" NDValue="#{bindings.ActivityView1.startDate}" NDType="oracle.jbo.domain.Date"/>
    <NamedData NDName="endTime" NDValue="#{bindings.ActivityView1.endDate}" NDType="oracle.jbo.domain.Date"/>
    <NamedData NDName="timeZone" NDValue="#{bindings.ActivityView1.timeZoneId}" NDType="java.lang.String"/>
  </action>
  <calendar IterBinding="ActivityView1Iterator" id="ActivityView1"
    xmlns="http://xmlns.oracle.com/adf/faces/binding"
    ActionBindingName="ExecuteWithParams">
    <nodeDefinition DefName="model.ActivityView">
      <AttrNames>
        <Item Type="id" Value="Id"/>
        <Item Type="providerId" Value="ProviderId"/>
        <Item Type="title" Value="Title"/>
        <Item Type="startTime" Value="StartTime"/>
        <Item Type="endTime" Value="EndTime"/>
      </AttrNames>
    </nodeDefinition>
    <providerDefinition IterBindingName="EmployeesView1Iterator">
      <AttrNames>
        <Item Type="id" Value="EmployeeId"/>
        <Item Type="displayName" Value="FirstName"/>
      </AttrNames>
    </providerDefinition>
  </calendar>
</bindings>
```
JDeveloper inserts code onto the JSF page that binds the calendar value to the CalendarModel class, as shown in Example 34–2.

Example 34–2  JSF Page Code for a Calendar

```xml
<af:form>
  <af:calendar value="#{bindings.ActivityView1.calendarModel}"/>
</af:form>
```

The CalendarModel class uses CalendarActivityDefinition class to access the calendar binding.

34.2.3 What Happens at Runtime: How the Calendar Binding Works

When the calendar is accessed, the executeWithParams operation is invoked, with the value of the startDate and endDate parameters determined by the value of the calendar component’s view and activeDay attributes. For example, if the view attribute is set to month and the activeDay is set to the current date (say, May 5, 2013), then the value for the startDate would be May 1, 2013 and the endDate value would be May 31, 2013. By default, the time zone value is taken from the time-zone setting in the trinidad-config.xml file (for more information, see the "Configuration in trinidad-config.xml" section of Developing Web User Interfaces with Oracle ADF Faces). Therefore, the query would be restricted to return only activities that fall within that date range.

When the query returns data, because the calendar component is bound to the CalendarModel, the CalendarModel uses the CalendarActivityDefinition class to access the calendar binding class and map the values from the data source to the calendar, using the mappings provided by the binding.

34.3 Using the ADF Faces Carousel Component

You can display images in a revolving carousel, as shown in Figure 34–3. Users can change the image at the front by using either the slider at the bottom or by dragging another image to the front.
Instead of containing a child carouselItem component for each image to be displayed, and then binding these components to the individual images, the carousel component is bound to a complete collection and repeatedly renders one carouselItem component by stamping the value for each item, similar to the way a tree stamps out each row of data. As each item is stamped, the data for the current item is copied into a property that can be addressed using an EL expression using the carousel component’s var attribute. Once the carousel has completed rendering, this property is removed or reverted back to its previous value. Carousels contain a nodeStamp facet, which is a holder for the carouselItem component used to display the text and short description for each item, and is also the parent component to the image displayed for each item. For more information about the carousel component, see the "Displaying Images in a Carousel" section of Developing Web User Interfaces with Oracle ADF Faces.

### 34.3.1 How to Create a Databound Carousel Component

When using a carousel component in a Fusion web application, you create the component using the Data Controls panel. You also use a managed bean to handle the carousel spin event and for other logic you may need to display your items.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create a carousel. For more information, see Section 34.3, “Using the ADF Faces Carousel Component.”

You may also find it useful to understand functionality that can be used with carousels. For more information, see Section 34.1.2, “Additional Functionality of Complex Databound ADF Faces Components.”

Perform the following in JDeveloper:

1. Create a view object for the collection to be displayed in the carousel. For example, to create the carousel shown in Figure 34–3, you use the Inventory view object.
2. Create a managed bean to hold a method that handles the spinning of the carousel. Example 34–3 shows the handler method that might be used to display items in the carousel.

**Example 34–3 Handler for the CarouselSpinEvent**

```java
public void handleCarouselSpin(CarouselSpinEvent event) {
    // This method is invoked when there is a spin event on the carousel in // InventoryControl.jsff. The purpose is to get the newly selected item in the // carousel and update the iterator current row with the value

    // get the bindingContainer
    DCBindingContainer dcBindings = (DCBindingContainer)
    BindingContext.getCurrent().getCurrentBindingsEntry();
    // get the NewItemKey from the event object. The first entry in the list is the
    // currently selected item
    List itemKeyList = (List) event.getNewItemKey();
    // create a Key object instance and set it to the first key in the list
    Key currentItemKey = (Key) itemKeyList.get(0);
    // get the iteratorBinding
    DCIteratorBinding inventoryIterator =
    dcBindings.findIteratorBinding("InventoryIterator");
    // set the iterator
    inventoryIterator.setCurrentRowWithKey(currentItemKey.toStringFormat(true));
}
```

To create a databound carousel component:

1. From the Data Controls panel, drag the collection for the view object on to the page and choose **Carousel** from the context menu.

2. In the Properties window, in the Behavior section, bind the **CarouselSpinListener** to a handler method that you created in the prerequisites.

3. In the Structure window, expand the **carousel** component and the **nodeStamp** facet, and select the **carouselItem** component.

4. Bind the CarouselItem component’s **text** attribute to the associated property on the view object using variable value set on the carousel’s **var** attribute, which by default is set to **item**. So for example, to use the Name attribute on the view object, the value of the carouselItem’s **text** attribute might be `#{item.Name}`. You can also bind other properties to the **text** attribute if you want to display more information. For example, the inventory carousel binds both the **Name** and the **AmountInStock** properties to the **text** attribute.

5. In the ADF Faces page of the Components window, from the General Controls panel, drag an **Image** and drop it as a child to the carouselItem.

In the Insert Image dialog, enter the path to the source for the images, being sure to use the variable for the item in the carousel. For example, the path to the image files for the products would normally be:

```
/images/products/#{item.Filename}
```

Bind the **shortDesc** attribute to the text you want to appear when the mouse hovers over the image. For example:

```
#{item.Name}
```
For information about setting other attributes of the carousel and carouselItem components, see the "How to Create a Carousel" section of Developing Web User Interfaces with Oracle ADF Faces.

6. If you want to provide additional information about the items in the carousel, you can drag and drop the same view object onto the page, for example, as a table. For the components in the table to redisplay the information for the current item displayed once the carousel is spun, you need to set the partialTrigger attribute of the component containing the form to the carousel component’s ID. For example, a table displays the information for each item in Figure 34–3. The partialTrigger attribute for the table component is set to t1, which is the carousel component’s ID. This means that whenever the carouselItem invokes the CarouselSpinEvent, the table will be refreshed, causing the row that displays information about the item that was just made current in the carousel is also made current in the table.

Additionally, the partialTrigger attribute for the carousel and carousel item is set to t1, which is the table’s ID. This means that whenever a selection event occurs on the table, the carousel is refreshed to make the item that was just made current in the table, the current item in the carousel.

For more information about partial page rendering and the partialTriggers attribute, see the "Rerendering Partial Page Content" chapter of Developing Web User Interfaces with Oracle ADF Faces.

Example 34–4 shows the page code for the carousel displayed in Figure 34–3.

Example 34–4  Partial Trigger Updates the Form to Match the Displayed Carousel Item

```xml
<af:carousel currentItemKey="#{bindings.Inventory.treeModel.rootCurrencyRowKey}" value="#{bindings.Inventory.treeModel}" var="item" id="c1" carouselSpinListener="#{InventoryControl.handleCarouselSpin}"
    partialTriggers="::t1">
    <f:facet name="nodeStamp">
        <af:carouselItem id="ci1" text="#{item.Name} #{item.AmountInStock}" partialTriggers="::t1">
            <af:image source="/images/products/#{item.Filename}" shortDesc="#{item.Name}" id="i1"/>
        </af:carouselItem>
    </f:facet>
</af:carousel>

<af:table value="#{bindings.Inventory.collectionModel}" var="row"
    rows="#{bindings.Inventory.rangeSize}"
    emptyText="#{bindings.Inventory.viewable ? 'No data to display.' : 'Access Denied.'}"
    fetchSize="#{bindings.Inventory.rangeSize}" rowBandingInterval="0"
    selectedRowKeys="#{bindings.Inventory.collectionModel.selectedRow}"
    selectionListener="#{bindings.Inventory.collectionModel.makeCurrent}"
    rowSelection="single" id="t1" partialTriggers="::c1" columnStretching="last"/>
```

34.3.2 What Happens When You Create a Carousel

When you drop a collection from the Data Controls panel as a carousel, a tree value binding is created. A tree consists of a hierarchy of nodes, where each subnode is a branch off a higher-level node.
The tree binding iterates over the data exposed by the iterator binding. The carousel wraps the result set from the iterator binding in a treeModel object, which is an extension of the collectionModel. The collectionModel allows each item in the collection to be available within the carousel component using the var attribute. For more information about the tree binding, see Section 29.2.2.1, "Iterator and Value Bindings for Tables."

JDeveloper adds both a carousel component and its child carouselItem component onto the page, as shown in Example 34–5.

**Example 34–5  Page Code for a Carousel Component**

```xml
<af:carousel
    currentItemKey="#{bindings.Products.treeModel.rootCurrencyRowKey}"
    value="#{bindings.Products.treeModel}" var="item"
    id="c1"
    carouselSpinListener="#{InventoryControl.handleCarouselSpin}"
>
    <f:facet name="nodeStamp">
        <af:carouselItem id="ci1" text="#{item.Name}"/>
    </f:facet>
</af:carousel>
```

The carousel value is bound to the treeModel for the associated collection, and the currentItemKey attribute of the carousel is bound to the rootCurrencyRowKey of the binding object. In this example, the carousel iterates over the items in the Products iterator binding. The iterator binding binds to a rowKeySet that keeps track of the current product. By default, the currentItemKey attribute of the carousel is bound to the rootCurrencyRowKey of the binding object, which causes the product currently displayed at the front of the carousel to be the root and the current item. The carouselItem component accesses the current data object for the current item presented to the carousel tag using the item variable.
Creating Databound Graph and Gauge Components

This chapter describes how to create graphs or gauges from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization areaGraph, barGraph, horizontalBarGraph, bubbleGraph, comboGraph, funnelGraph, lineGraph, paretoGraph, pieGraph, radarGraph, scatterGraph, sparkChart, stockGraph, and gauge components to create graphs and gauges that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.

If you are designing your page using simple UI-first development, then you can add the graph or gauge to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the graph and gauge components, see the "Using Graph Components" and "Using Gauge Components" chapters in Developing Web User Interfaces with Oracle ADF Faces.

This chapter includes the following sections:

- Section 35.1, "About ADF Data Visualization Graph and Gauge Components"
- Section 35.2, "Creating Databound Graphs"
- Section 35.3, "Creating Databound Gauges"

### 35.1 About ADF Data Visualization Graph and Gauge Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

Both graph and gauge components render graphical representations of data. However, graphs, which support more than 50 types of charts, allow you to evaluate multiple data points on multiple axes in a variety of ways. Many graph types assist in the comparison of results from one group with the results from another group. In contrast, gauges focus on a single data point and examine that point relative to minimum, maximum, and threshold indicators to identify problems.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.
35.1.1 End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the following:

- Graph components: "End User and Presentation Features" section in Developing Web User Interfaces with Oracle ADF Faces.
- Gauge components: "End User and Presentation Features of Gauge Components" section in Developing Web User Interfaces with Oracle ADF Faces.

35.1.2 Data Visualization Components Use Cases and Examples

For detailed descriptions of data visualization use cases and examples, see the following:

- Graph components: "Graph Component Use Cases and Examples" section in Developing Web User Interfaces with Oracle ADF Faces.
- Gauge components: "Gauge Component Use Cases and Examples" section in Developing Web User Interfaces with Oracle ADF Faces.

35.1.3 Additional Functionality for Data Visualization Components

You may find it helpful to understand other Oracle ADF features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the “Rerendering Partial Page Content” chapter in Developing Web User Interfaces with Oracle ADF Faces.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the "Allowing User Customization on JSF Pages" chapter in Developing Web User Interfaces with Oracle ADF Faces.
- Accessibility: You can make your data visualization components accessible. For more information, see the "Developing Accessible ADF Faces Pages" chapter in Developing Web User Interfaces with Oracle ADF Faces.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (styleClass or inlineStyle). For more information, see the "Customizing the Appearance Using Styles and Skins" chapter in Developing Web User Interfaces with Oracle ADF Faces.
- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using
developed data controls. For more information, see Chapter 19, "Designing a Page Using Placeholder Data Controls."

### 35.2 Creating Databound Graphs

When you create a graph using a data collection inserted from the Data Controls panel, a Component Gallery allows you to choose from a wide number of graph categories, graph types, and layout options. Graph categories group together one or more types of graph. For example, the Bar category includes the following types of graphs:

- Bar
- Dual-Y Bar
- Split Dual-Y Bar
- Percent
- Stacked Bar
- Dual-Y Stacked Bar
- Split Dual-Y Stack Bar
- Floating Stacked Bar

Explore the Component Gallery that appears when you create a graph to view available graph categories, types, and descriptions for each one. Figure 35–1 shows the Component Gallery that appears for ADF graphs when you use the Data Controls panel.

*Figure 35–1  ADF Graphs Component Gallery from Data Controls Panel*
You can also create a graph by dragging a graph component from the Components window. This approach allows you the option of designing the graph’s user interface before binding the component to data. A Create Graph dialog appears to view graph types, descriptions, and quick layout options. For more information about creating graphs using UI-first development, see the “Using Graph Components” chapter in Developing Web User Interfaces with Oracle ADF Faces.

Table 35–1 lists the categories that appear in the Component Gallery for graphs. Each category has one or more graph types associated with it.

<table>
<thead>
<tr>
<th>Category</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Area</td>
<td>Creates a graph in which data is represented as a filled-in area. Use area graphs to show trends over time, such as sales for the last 12 months. Area graphs require at least two groups of data along an axis. The axis is often labeled with time periods such as months.</td>
</tr>
<tr>
<td>Bar</td>
<td>Creates a graph in which data is represented as a series of vertical bars. Use to examine trends over time or to compare items at the same time, such as sales for different product divisions in several regions.</td>
</tr>
<tr>
<td>Bar (Horizontal)</td>
<td>Creates a graph that displays bars horizontally along the y-axis. Use to provide an orientation that allows you to show trends or compare values.</td>
</tr>
<tr>
<td>Bubble</td>
<td>Creates a graph in which data is represented by the location and size of round data markers (bubbles). Use to show correlations among three types of values, especially when you have a number of data items and you want to see the general relationships. For example, use a bubble graph to plot salaries (x-axis), years of experience (y-axis), and productivity (size of bubble) for your workforce. Such a graph allows you to examine productivity relative to salary and experience.</td>
</tr>
<tr>
<td>Combination</td>
<td>Creates a graph that uses different types of data markers (bars, lines, or areas) to display different kinds of data items. Use to compare bars and lines, bars and areas, lines and areas, or all three.</td>
</tr>
<tr>
<td>Funnel</td>
<td>Creates a graph that is a visual representation of data related to steps in a process. The steps appear as vertical slices across a horizontal cylinder. As the actual value for a given step or slice approaches the quota for that slice, the slice fills. Typically a funnel graph requires actual values and target values against a stage value, which might be time. For example, use this component to watch a process (such as a sales pipeline) move towards a target across the stage of the quarters of a fiscal year.</td>
</tr>
<tr>
<td>Line</td>
<td>Creates a graph in which data is represented as a line, as a series of data points, or as data points that are connected by a line. Line graphs require data for at least two points for each member in a group. For example, a line graph over months requires at least two months. Typically a line of a specific color is associated with each group of data such as the Americas, Europe, or Asia. Use to compare items over the same time.</td>
</tr>
</tbody>
</table>
Creating Databound Graphs

Creating Databound Graph and Gauge Components

Figure 35–2 shows the vertical bar graph that appears on the Orders Dashboard page in the Summit ADF sample application. This graph displays the number of days it took to ship each order for a given customer so that you can easily identify any trends in ship times.

### Table 35–1 (Cont.) ADF Graph Categories in the Component Gallery

<table>
<thead>
<tr>
<th>Category</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pareto</td>
<td>Creates a graph in which data is represented by bars and a percentage line that indicates the cumulative percentage of bars. Each set of bars identifies different sources of defects, such as the cause of a traffic fatality. The bars are arranged by value, from the largest number to the lowest number of incidents. A pareto graph is always a dual-y graph in which the first y-axis corresponds to values that the bars represent and the second y-axis runs from 0 to 100% and corresponds to the cumulative percentage values. Use the pareto graph to identify and compare the sources of defects.</td>
</tr>
<tr>
<td>Pie</td>
<td>Creates a graph in which one group of data is represented as sections of a circle causing the circle to look like a sliced pie. Use to show relationship of parts to a whole such as how much revenue comes from each product line.</td>
</tr>
<tr>
<td>Radar</td>
<td>Creates a graph that appears as a circular line graph. Use to show patterns that occur in cycles, such as monthly sales for the last three years.</td>
</tr>
<tr>
<td>Scatter/Polar</td>
<td>Creates a graph in which data is represented by the location of data markers. Use to show correlation between two different kinds of data values such as sales and costs for top products. Scatter graphs are especially useful when you want to see general relationships among a number of items.</td>
</tr>
<tr>
<td>Sparkchart</td>
<td>Creates a simple, condensed graph that displays trends or variations, often in the column of a table, or inline with text.</td>
</tr>
<tr>
<td>Stock</td>
<td>Creates a graph in which data shows the high, low, and closing prices of a stock and, optionally, the opening price and trading volume of the stock.</td>
</tr>
</tbody>
</table>

Figure 35–2 shows the vertical bar graph that appears on the Orders Dashboard page in the Summit ADF sample application. This graph displays the number of days it took to ship each order for a given customer so that you can easily identify any trends in ship times.

For information about customizing graphs after the data binding is completed, see the "Configuring Graphs" chapter in Developing Web User Interfaces with Oracle ADF Faces.
35.2.1 How to Create an Area, Bar, or Line Graph Using Data Controls

Graphs are based on data collections. Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a collection from the Data Controls panel onto the JSF page and use a dialog to bind the data collection attributes in the graph.

The graph requires a simple grid of numeric data points to plot a graph. The grid’s row and column labels are used to identify components within the graph. By default, the rows appear as the series and the columns appear as the groups.

The attributes in a data collection can be data values or categories of data values. Data values are numbers represented by markers, like bar height, or points in a scatter graph. Categories of data values are members represented as axis labels, or appear as additional properties in a tooltip. The role that an attribute plays in the bindings (either data values or identifiers) is determined by both its data type (Graph requires numeric data values) and where it gets mapped (e.g., Bars vs. X Axis).

Before you begin:

It may be helpful to have an understanding of databound data visualization graphs. For more information, see Section 35.2, "Creating Databound Graphs."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 35.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."
- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

To create a databound area, bar, or line graph:

1. From the Data Controls panel, select a collection.

   For example, to create the bar graph that displays the shipping times for each order on the Orders Dashboard page of the Summit ADF sample application, select the OrdersForCustomer collection. Figure 35–3 shows the OrdersForCustomer collection in the Data Controls panel.
2. Drag the collection onto a JSF page and, from the context menu, choose **Graphs**.

3. In the Component Gallery, select a graph category and a graph type and click **OK**.

   For information about the graph categories and graph types that appear in the Component Gallery, see **Table 35–1**.

   The name of the dialog and the input field labels that appear depend on the category, type of graph, and data collection that you select. For example, if you select **Bar** as the graph category and **Bar** as the graph type, then the name of the dialog that appears is Create Bar Graph and the input fields are labeled **Bars** and **X Axis**.

4. Do the following in the dialog to configure the graph to display data:

   - Drag attributes from the **Available** list to the **Bars** or **X Axis** input fields, depending on where you want the values for the attributes to appear at runtime.

     For example, to configure the bar graph in the Summit ADF sample application to display the order dates along the **X Axis**, drag the **DateOrdered** attribute from the **Available** list to the **X Axis** field in the Create Bar Graph dialog. To configure the graph to display the time to ship as bars, drag the **TimeToShip** attribute from the **Available** list to the **Bar** field in the Create Bar Graph dialog.

   - In the **Attribute Labels** table, accept the default value or select a value from the dropdown list in the **Label** field to specify the label that appears at runtime.

     The underlying data type determines the choices available in the **Label** field. The choice you make determines how that attribute's label is rendered in the graph. For more information, see **Section 35.2.3, “What You May Need to Know About Using Attribute Labels.”**
If you want to change the display of the data represented in the bars to the Y-Axis, click the **Swap Bars with Y-Axis** button. This action switches the hidden data layer between the graph series and groups, not a simple manual swap of the bars and y-axis attributes.

If you want to change from the default selection of **Typed Attributes** to **Name-Value Pairs** to configure how data points are stored in a collection, then click the **Change Data Shape** button. A dialog appears that presents you with the following options:

- **Typed Attributes**
  
  Each kind of data point in the collection is represented by a different attribute. This option is also valid when there is only a single kind of data point in the graph.
  
  For example, if you have data points for **Estimated Value** and **Actual Value**, then select **Typed Attributes** only if you have one attribute for the estimated value and a second attribute for the actual value.

- **Name-Value Pairs**
  
  Indicates that there are two or more kinds of data points represented by exactly two attributes; a **Name** attribute that specifies the kind of data point, and a **Value** attribute that specifies the data value.
  
  For example, the **Name** attribute might have the value **EST** for a **Value** attribute that represents an estimated value, or the **Name** attribute might have a value **ACT** for a **Value** attribute that represents an actual value.
  
  For more information about using name-value pairs, see Section 35.2.5, "What You May Need to Know About Using Name-Value Pairs."

- **Select Set the current row for master-detail** to use the graph’s row selection listener to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component.

  For more information, see Section 35.2.4, "What You May Need to Know About Using a Graph’s Row Selection Listener for Master-Detail Processing."

---

**Note:** If the data collection is the child collection in a master-detail relationship, the dialog includes the option to **Include Child Accessors (Hierarchical Graph)**. This option is included for backwards compatibility with older data models that mapped Tree collections onto the graph’s cube model, and you normally would not check this box.

---

**Figure 35–4** shows the Create Bar Graph dialog that generates the Summit ADF sample application ship times bar graph using data from the **DateOrdered** and **TimeToShip** attributes in the **OrdersForCustomer** data collection.
5. Optionally, click the **Preview** tab to display a live preview of the bar graph and its data. If necessary, go back to the **Configuration** tab so that you can adjust the bar graph specifications.

6. Click **OK**.

After completing the data binding dialog, you can use the Properties window to specify settings for the graph attributes and you can also use the child tags associated with the graph tag to customize the graph further. For more information, see "Configuring Graphs" in *Developing Web User Interfaces with Oracle ADF Faces*.

---

**Note:** Use the `emptyText` attribute to specify the text to display when there is no data to return in the graph. The default message is **No data to display**. The attribute accepts HTML for formatting the message and an EL expression that evaluates to the viewable property of the data. If the graph is not viewable (for example, if there are authorization restrictions set against the graph), it displays **Access Denied**.

---

### 35.2.2 What Happens When You Use the Data Controls Panel to Create a Graph

Dropping a graph from the Data Controls panel has the following effect:

- Creates the bindings for the graph and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

The data binding XML that JDeveloper generates varies depending on the type of graph you select. The XML represents the physical model of the specific graph type you create. Example 35–1 shows the bindings that JDeveloper generated in the page definition file where a vertical bar graph was created using data from the
DateOrdered and TimeToShip attributes in the OrdersForCustomer data collection.

**Example 35–1  Binding XML for an ADF Bar Graph**

```xml
<graph IterBinding="OrdersForCustomerIterator" id="OrdersForCustomer"
    xmlns="http://xmlns.oracle.com/adfm/dvt" type="BAR_VERT_CLUST">
    <graphDataMap convert="false" leafOnly="true">
        <series>
            <data>
                <item value="TimeToShip"/>
            </data>
        </series>
        <groups>
            <item value="DateShipped"/>
        </groups>
    </graphDataMap>
</graph>
```

**Example 35–2** shows the code generated for a vertical bar graph when you drag the OrdersForCustomer data collection onto a JSF page.

**Example 35–2  JSF Code for an ADF Bar Graph**

```xml
<dvt:barGraph id="graph2" value="#{bindings.OrdersForCustomer.graphModel}"
    subType="BAR_VERT_CLUST">
    <dvt:background>
        <dvt:specialEffects/>
    </dvt:background>
    <dvt:graphPlotArea/>
    <dvt:seriesSet>
        <dvt:series/>
    </dvt:seriesSet>
    <dvt:o1Axis/>
    <dvt:y1Axis/>
    <dvt:legendArea automaticPlacement="AP_NEVER"/>
    <dvt:attributeFormat name="TimeToShip" id="af3">
        <af:convertNumber
            pattern="#{bindings.OrdersForCustomer1.hints.TimeToShip.format}"
            groupingUsed="false"/>
    </dvt:attributeFormat>
    <dvt:attributeFormat name="DateOrdered" id="af4">
        <af:convertDateTime
            pattern="#{bindings.OrdersForCustomer1.hints.DateOrdered.format}"/>
    </dvt:attributeFormat>
</dvt:barGraph>
```

**Note:** When you create a graph using data-first development, JDeveloper adds a `dvt:attributeFormat` tag to the page for every non-string categorical attribute. In this example, the TimeToShip attribute represents a numerical value, and the DateOrdered attribute represents a date. Therefore, JDeveloper added the `dvt:attributeFormat` tags for both attributes.

You can update the `dvt:attributeFormat` tag after the graph is created. For additional information, see "Formatting Data Values in Graphs" in Developing Web User Interfaces with Oracle ADF Faces.
35.2.3 What You May Need to Know About Using Attribute Labels

When you configure attribute labels in the Create Graph dialog, the underlying data type determines the choices available in the Label field. The choice you make determines how that attribute's label is rendered in the graph.

If an attribute represents data values, then the choices in the Label field are:

- **Use Attribute Name**: Select to render the value as a string using the label from the UIHints for that attribute in the underlying ViewObject. This is the default selection.
- **No Label**: Select to render no label. This choice is useful if there is a single metric and you want to provide your own descriptive text on the page to describe the resulting graph.
- **Select Text Resource**: Select to open a Select Text Resource dialog to select or add a text resource to use for the label. The text resource is a translatable string from an application resource bundle. If you need help, press F1 or click Help.
- **Expression Builder**: Select to open the Expression Builder dialog to create an expression to be executed at runtime for the label. If you need help, press F1 or click Help.

If the attribute represents a category of data values, then the choices are:

- **Use Attribute Value**: Select to render the attribute values as category labels. This is the default selection.
- **From the dropdown list, choose an alternate attribute for the label. For example, use Employee Names for labels instead of Employee IDs.**

35.2.4 What You May Need to Know About Using a Graph’s Row Selection Listener for Master-Detail Processing

You can use the row selection listener of a graph (which serves as a master view) to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component (which serves as a detail view). For example, clicking on a bar that represents sales for a given product in a graph might cause the display of the detailed sales data for that product in a pivot table.

The following requirements must be met to achieve this master-detail processing declaratively:

1. You must use the same data control to provide data for both views as follows:
   a. Bind the graph as a row set to the parent collection in the data control, for example, DepartmentsView.
   b. Bind the other ADF view (such as a table or pivot table) to the dependent detail collection in the data control, for example EmployeesView.

2. Select **Set the current row for master-detail** in the Create Graph dialog to set a value automatically for the clickListener attribute of the graph tag and use the processClick method that is already part of the graph binding.

For example, if the value attribute of the graph tag is value="#{bindings.myGraph.graphModel}" , then the clickListener attribute is set to clickListener="#{bindings.myGraph.graphModel.processClick}".
You do not have to write Java code for handling clicks on data elements in the graph. The `processClick` event on the graph binding recognizes click events on data component in a graph and performs the necessary processing.

### 35.2.5 What You May Need to Know About Using Name-Value Pairs

When you configure a graph using data controls, by default the data binding dialog supports typed attributes, where each kind of data point in the collection is represented by a different attribute. For example, if you have data points for the sales and costs of multiple products, use typed attributes only if you have one attribute for the sales data of each product, and a second attribute for the cost of each product in the data collection.

Typed attributes data shape is also valid when there is only a single kind of data point in the graph. Figure 35–5 shows a typed attribute data shape.

**Figure 35–5  Typed Attribute Data Shape**

<table>
<thead>
<tr>
<th>Product</th>
<th>Sales</th>
<th>Costs</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>50</td>
<td>80</td>
</tr>
<tr>
<td>B</td>
<td>20</td>
<td>120</td>
</tr>
<tr>
<td>C</td>
<td>30</td>
<td>150</td>
</tr>
<tr>
<td>D</td>
<td>40</td>
<td>200</td>
</tr>
</tbody>
</table>

You can select **Change Data Shape** in the data binding dialog to change the dialog to support name-value pairs, where there are two or more kinds of data points represented by exactly two attributes: a **Name** attribute that specifies the name of the data point and a **Value** attribute that specifies the data value. In this case, each dedicated attribute has values that identify each kind of data point. For example, the metrics attribute might have values for sales and costs for each product in a data collection. Figure 35–6 shows a data collection in a name-value pairs data shape.

**Figure 35–6  Name-Value Pairs Data Shape**

<table>
<thead>
<tr>
<th>Product</th>
<th>Metric</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>Sales</td>
<td>100</td>
</tr>
<tr>
<td>A</td>
<td>Costs</td>
<td>80</td>
</tr>
<tr>
<td>B</td>
<td>Sales</td>
<td>200</td>
</tr>
<tr>
<td>B</td>
<td>Costs</td>
<td>120</td>
</tr>
</tbody>
</table>

When using a name-value pairs data shape, specify these values in the graph data binding dialog:

- **Name Attribute**: the attribute in the data collection representing the **Name** attribute, when its unique values categorize data points into different metrics.
- **Value Attribute**: the attribute in the data collection representing the numeric data points plotted on the graph. Each data point is categorized as belonging to a particular metric by the corresponding **Name** attribute value.
- **Specify the values for the Value attribute**: in the relevant fields for the graph type as defined in the dialog, for example, **Bubble Colors** and **Bubble Tooltips** for a bubble graph. Values can be attributes in the data collection, or data values, representing a unique value of the **Name** attribute to be used at runtime to categorize data points into specific metrics.

You must add one or more data values by selecting **Data Value** from the field **Add** dropdown list. Each data value represents a unique value of the **Name** Attribute to be used at runtime to categorize data points into specific metrics. You are not required to select all the metrics available in the **Name** Attribute.
After specifying attributes or data values for the input field, you can right-click any attribute to display a context menu for actions such as **Move Right**, **Move Left**, **Delete**, or **Edit Data Value**.

For example, you can create a stock graph that displays open, high, low, and close stock values bound to a data collection with a single numeric column of data in a name-value pairs shape as displayed in Figure 35–7.

**Figure 35–7  Stock Graph Created With Name-Value Pairs**

![Figure 35–7](image)

**35.2.6 How to Create a Stock Graph Using Name-Value Pairs**

You can create a graph where the data collection is arranged in a series of name-value pairs instead of typed attributes. For example, stock values may be arranged in a single numeric column of data with multiple data points and multiple attributes to designate these points. **Figure 35–8** shows an example of a data collection arranged in name-value pairs. For each **MarketDate**, the **Measure** attribute contains the names for the values stored in the **Data** attribute: **OPEN**, **HIGH**, **LOW**, **CLOSE**, and **VOLUME**.

**Figure 35–8  Stock Values in Name-Value Pairs Data Shape**

![Figure 35–8](image)

**Before you begin:**

It may be helpful to have an understanding of databound data visualization graphs. For more information, see Section 35.2, "Creating Databound Graphs."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 35.1.3, "Additional Functionality for Data Visualization Components."
It may also be helpful to understand name-value pairs data shapes. For information, see Section 35.2.5, "What You May Need to Know About Using Name-Value Pairs."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."
- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

To create a graph using a name-value pairs data shape:

1. From the Data Controls panel, select a collection.

   In the example to create a graph that displays the open, high, low, and close stock values over a week’s time, select the collection SStockPriceView1. Figure 35–9 shows the SStockPriceView1 collection in the Data Controls panel.

   **Figure 35–9 Data Collection for Stock Values in Single Column**

2. Drag the collection onto a JSF page and, from the context menu, choose Graphs.

3. In the Component Gallery, select the Stock graph category, then the Open-Hi-Lo-Close Candle with Volume graph type, and click OK.

4. Do the following to change the dialog to support a name-value pairs data shape:
   - Click Change Data Shape.
   - In the Change Chart Data Shape dialog, select Name-Value Pairs, and click OK.
   - If prompted, confirm your selection.

5. Do the following in the modified dialog to configure the graph to display data:
   - For Name Attribute, select the attribute containing the names of the name-value pairs.
     For example, choose Measure from the dropdown list to create a stock graph using the data collection in Figure 35–8.
   - For Value Attribute, specify the attribute containing the data for the name-value pairs.
     For example, choose Data from the dropdown list to create a stock graph using the data collection in Figure 35–8.
   - In the Chart Values table, accept the default value or select a value from the dropdown list in the Label field to specify the label that appears at runtime.
   The underlying data type determines the choices available in the Label field. The choice you make determines how that attribute's label is rendered in the
Creating Databound Graphs

For more information, see Section 35.2.3, "What You May Need to Know About Using Attribute Labels."

- **Set the current row for master-detail**: Select to use the graph’s row selection listener to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component. For more information see Section 35.2.4, "What You May Need to Know About Using a Graph’s Row Selection Listener for Master-Detail Processing."

---

**Note:** If the data collection is the child collection in a master-detail relationship, the dialog includes the option to **Include Child Accessors (Hierarchical Graph)**. This option is included for backwards compatibility with older data models that mapped Tree collections onto the graph’s cube model, and you normally would not check this box.

---

Figure 35–10 shows the Create Stock Graph dialog that generates a graph using the Measure attribute in the $StockPriceView1$ collection.

*Figure 35–10 Create Stock Graph for StockSingleFactColView1*

6. Optionally, click the **Preview** tab to display a live preview of the stock graph and its data. If necessary, go back to the **Configuration** tab so that you can adjust the stock graph specifications.

7. Click **OK**.

### 35.2.7 Creating a Databound Spark Chart Using Data Controls

Spark charts are simple, condensed graphs that display trends or variations, often in the column of a table, or inline with text. Line, bar, and area spark charts require a single series of data values. Figure 35–11 shows an example of a line spark chart in a table column.
Floating bar spark charts require two series of data values, one for the float offset, and one for the bar value. Figure 35–12 shows an example of a floating bar sparkchart.

You can create a sparkchart by inserting a data control from the Data Controls Panel. Figure 35–13 shows the Component Gallery that displays when you drag a sparkchart component onto your page from the Data Controls panel.

A binding dialog prompts you to specify the value you wish to display for the selected sparkchart type. Line, bar, and area spark charts require a single series of data values, for example the changing value of a stock. Floating bar sparkcharts require two series of data values, one for the float offset, and one for the bar value. For example, in the Create Floating Stacked Bar Sparkchart dialog you specify:
Creating Databound Graphs

■ **Bar Height**: Use to select the data value to use for the bar value.

■ **Bar Float**: Use to select the data value to use for the float offset, the distance between the axis and the floating bar.

Figure 35–14 shows a completed Create Floating Stacked Bar Sparkchart dialog.

![Sparkchart Binding Dialog](image)

In a simple UI-first development scenario you can insert a sparkchart using the Components window and bind it to data afterwards.

You can provide data to sparkcharts in any of the following ways:

■ Specify data statically in child `dvt:sparkItem` tags. Example 35–3 shows an example of providing static data to a sparkchart.

**Example 35–3  Static Data in Sparkchart**

```xml
<dvt:sparkChart>
  <dvt:sparkItem value="20"/>
  <dvt:sparkItem value="15"/>
  <dvt:sparkItem value="30"/>
</dvt:sparkChart>
```

■ Specify data using EL Expression in child `dvt:sparkItem` tags. Example 35–4 shows an example of providing data using EL Expressions.

**Example 35–4  EL Expression Data in Sparkchart**

```xml
<af:table value="#{sample.tableModel}" var="row">
  <af:column>
    <dvt:sparkChart>
      <dvt:sparkItem value="#{row.col1}"/>
      <dvt:sparkItem value="#{row.col2}"/>
      <dvt:sparkItem value="#{row.col3}"/>
    </dvt:sparkChart>
  </af:column>
</af:table>
```

■ Specify data using a child accessor in a table. Example 35–5 shows an example of using `af:iterator` to provide sparkchart data from the data collection model, `row.stockValues`.

**Example 35–5  Sparkchart Data in Table Child Accessor**

```xml
<af:table value="#{sample.tableModel}" var="row">
  <af:column>
    <dvt:sparkChart>
      <af:iterator value="#{row.stockValues}" var="data">
        <dvt:sparkItem value="#{data.closeValue}"/>
      </af:iterator>
    </dvt:sparkChart>
  </af:column>
</af:table>
```
35.2.8 How to Create Databound Pie Graphs

A pie graph displays one group of data, each slice representing a different series. This graph type requires one column, with multiple rows, one for each slice. Multiple pie graphs show one pie for each group, or column, of data. Pie graphs can be drawn with just one data point, though such graphs may not be useful. In the case of pie bar graphs, each slice represents a series total. The data for one such slice is represented in further detail by a percentage stacked bar.

Figure 35–15 shows a pie graph in the Summit ADF sample application that displays the inventory available for the ordered item at each stock location as a percentage of the total available inventory for the item. As the user moves the mouse over each slice, a tooltip shows the actual quantity at the location. The column of data in this example represents the total inventory for the ordered item, and the slices represent the inventory levels at each stocking location.

Figure 35–15  Pie Graph Showing Inventory Levels at Stock Locations

Before you begin:

It may be helpful to have an understanding of databound data visualization graphs. For more information, see Section 35.2, "Creating Databound Graphs."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 35.1.3, "Additional Functionality for Data Visualization Components."
You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."
- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

**To create a databound pie graph:**

1. From the Data Controls panel, select a collection.
2. Drag the collection onto a JSF page and, from the context menu, choose **Graphs**.
3. In the Component Gallery, select the **Pie** graph category and a graph type and click **OK**.
4. Do the following in the Create Pie Graph dialog to configure the pie graph to display data:
   - From the **Pie** field’s dropdown menu, select an attribute to represent the column of data.
   - Drag attributes from the Available list to the Slices field, depending on where you want the values for the attributes to appear at runtime.
For example, to configure the pie graph in the Summit ADF sample application to display the ordered item's inventory levels at each stock location, drag the City attribute from the Available list to the Slices field in the Create Pie Graph dialog.

- In the Attribute Labels table, accept the default value or select a value from the dropdown list in the Label field to specify the label that appears at runtime.

  The underlying data type determines the choices available in the Label field. The choice you make determines how that attribute's label is rendered in the graph. For more information, see Section 35.2.3, "What You May Need to Know About Using Attribute Labels."

- Select Set the current row for master-detail to use the graph's row selection listener to enable clicks on a bar, slice, or other graph data element to update the data in another ADF component.

  For more information, see Section 35.2.4, "What You May Need to Know About Using a Graph’s Row Selection Listener for Master-Detail Processing."

---

**Note:** If the data collection is the child collection in a master-detail relationship, the dialog includes the option to Include Child Accessors (Hierarchical Graph). This option is included for backwards compatibility with older data models that mapped Tree collections onto the graph’s cube model, and you normally would not check this box.

---

- If you want to change from the default selection of Typed Attributes to Name-Value Pairs to configure how data points are stored in a collection, then click the Change Data Shape button.

  For more information about using name-value pairs, see Section 35.2.5, "What You May Need to Know About Using Name-Value Pairs."

Figure 35–17 shows the Create Pie Graph dialog that generates a pie graph using the AmountInStock and City attributes in the InventoryForOrderItem collection.
5. Optionally, click the **Preview** tab to display a live preview of the pie graph and its data. If necessary, go back to the **Configuration** tab so that you can adjust the stock graph specifications.

6. Click **OK**.

After completing the data binding dialog, you can use the Properties window to specify settings for the graph attributes and you can also use the child tags associated with the graph tag to customize the graph further. For more information, see “Configuring Graphs” in *Developing Web User Interfaces with Oracle ADF Faces*.

### 35.2.9 Configuring Databound Graphs for Drilling

You can configure a databound graph to display a detailed view of data displayed by an area, line, or marker.

**Figure 35–18** shows a simple example of a bar graph that displays the total salaries of all employees in each department within the Summit organization. When the user moves the mouse over the department’s ID, a tooltip appears to indicate that the ID is drillable. If the user clicks the department ID, the page changes to display the name and salary of each employee in the department.
35.2.9.1 How to Configure Databound Graphs for Drilling

To make a databound graph drillable, set the `drillingEnabled` attribute for the graph to `true`. The default value is `false`.

You must also update the graph’s page definition file to define the drilling hierarchy and specify how you want the aggregated data displayed.

The graph in Figure 35–18 is bound to a data control in the Summit sample application for ADF DVT components that contains the department ID, last name, and salary for each employee. To make the graph drillable, the page definition file for the graph was modified to add the hierarchy details and to specify total salary for the aggregated value on the initial page.

Example 35–6 shows the binding in the page definition file before drilling configuration.

**Example 35–6  Code Sample Showing Page Definition Before Drilling**

```xml
<graph IterBinding="SEmpView1Iterator" id="SEmpView1"
     xmlns="http://xmlns.oracle.com/adfm/dvt"
     type="BAR_VERT_CLUST">
  <graphDataMap convert="false" leafOnly="true">
    <series>
      <data>
        <item value='Salary'/>
      </data>
    </series>
    <groups>
      <item value='DeptId'/>
    </groups>
  </graphDataMap>
</graph>
```

Example 35–7 shows the same page definition file configured for drilling support, with the additional entries to enable drilling support highlighted.

**Example 35–7  Code Sample Showing Page Definition Configured for Drilling**

```xml
<graph IterBinding="SEmpView1Iterator" id="SEmpView1"
     xmlns="http://xmlns.oracle.com/adfm/dvt"
     type="BAR_VERT_CLUST">
  <graphDataMap convert="false" leafOnly="true">
```

---

**Figure 35–18  Bar Graph Configured for Drilling**
Creating Databound Graphs

Creating Databound Graph and Gauge Components

Before you begin:
It may be helpful to have an understanding of databound graphs. For more information, see Section 35.2, "Creating Databound Graphs."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 35.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

1. Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

2. Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

3. Create a databound graph as described in Section 35.2, "Creating Databound Graphs."

   The sample bar graph in Figure 35–18 uses a data control from the Summit ADF DVT sample application that contains information about each employee in an organization. Figure 35–19 shows the sample data control.

   **Figure 35–19  Data Control for Drilled Bar Graph Example**

   ![Data Control for Drilled Bar Graph Example](image)

   To configure drilling support for a databound graph:

   1. In the Structure window, right-click the `dvt:typeGraph` node and choose Go to Page Definition.
In the page definition’s source view, add a **hierarchies** element to the **graphDataMap** and define the parent-child relationship for the drilling hierarchy.

In Example 35–7, the **DeptId** item is the top level of the hierarchy and will be displayed when the graph is initially rendered. The child is defined as **LastName** and will be displayed when the user drills a department ID on the graph.

To add an additional drill level, add another **item** to **hierarchies**. Use the value of the child from the first **item** as the new value for the second **item**, and add the additional value for the drill level as a child to the second **item**. Example 35–8 shows the **hierarchies** entry for a graph configured for two levels of drilling. In this example, the user can drill from yearly data to quarterly data and from quarterly data to monthly data.

**Example 35–8  Hierarchies in Page Definition File Showing Two Drill Levels**

```xml
<hierarchies>
  <item value="year">
    <child value="quarter"/>
  </item>
  <item value="quarter">
    <child value="month"/>
  </item>
</hierarchies>
```

3. Add a **drills** element to the **graphDataMap** and set the type to **REPLACE**:

```xml
<drills type="REPLACE"/>
```

This type of drilling filters the rowset on the drilled target and replaces the target and its siblings with the target’s children. This is the only drilling type supported for graph.

4. Add the **defaultAggregateType** to **data** in **graphDataMap**.

The **defaultAggregateType** determines how the data is aggregated when the graph is initially displayed. In Example 35–7, the **defaultAggregateType** is set to SUM, and the graph will display the total salary for all employees within the department.

You can also set the **defaultAggregateType** to AVERAGE, COUNT, MAX, MEDIAN, MIN, NONE, STDDEV, or VARIANCE.

5. If you want all duplicates to be aggregated, add **aggregateDuplicates** to **data** and set it to **true** as shown in Example 35–7.

6. Save the modified page definition file.

7. In the Structure window, right-click the **dvt:<type>Graph** component and choose **Go to Properties**.

8. Expand the **Behavior** section, and select **true** from the **DrillingEnabled** attribute’s dropdown menu.

### 35.3 Creating Databound Gauges

A gauge plots one data point with indication of whether the data point falls in an acceptable or unacceptable range. One databound gauge component can create a single gauge or an entire set of gauges, depending on the number of rows in the data collection used. In a collection, each row contains the values for a single gauge.
The Component Gallery for gauges allows you to choose from the following categories of gauges:

- **Dial**: Indicates the metric value of a task along a configurable arc.
- **Status Meter**: Indicates the progress of a task or the level of some measurement along a rectangular bar.
- **Status Meter (Vertical)**: Indicates the progress of a task or the level of some measurement along a rectangular bar.
- **LED**: Depicts graphically a measurement such as a key performance indicator (KPI). Several styles of graphics are available for LED gauges such as arrows that indicate good (up arrow), fair (left- or right-pointing arrow), and poor (down arrow).

Each of these categories contains a number of different types of gauge. Explore the Component Gallery that appears when you create a single gauge to view all available gauge and category types, and descriptions for each one. Figure 35–20 shows the Component Gallery that appears for ADF gauges.

*Figure 35–20  ADF Gauges Component Gallery*

The data binding process is essentially the same regardless of which type of gauge you create. Only the metric value (that is, the measurement that the gauge is to indicate) is required. However, if a row in a data collection contains range information such as maximum, minimum, and thresholds, then these values can be bound to the gauge to provide dynamic settings. If information that you want to use in a gauge’s upper or lower labels is available in the data collection, then you can bind these values to the gauge also.
35.3.1 How to Create a Databound Dial Gauge

You can use the ADF gauge component to create a dial gauge against a background that specifies ranges of values (also called thresholds) that vary from poor to excellent. The gauge indicator specifies the current value of the metric while the graphic allows you to evaluate the status of that value easily.

Figure 35–21 shows a single dial gauge that appears if you create a gauge from the AmountInStock data for inventory items in the Summit ADF DVT sample application. The value of the AmountInStock metric (which is 650) appears in a label below the gauge. The range of values in the gauge is displayed as 0 to 1500. Threshold ranges are defined at the values stored for the item’s ReorderPoint (625) and MaxInStock (1100) attributes and are filled with the colors red for poor (below the reorder point), green for adequate (between the reorder point and maximum inventory level), and yellow for values above the item’s maximum inventory level.

Figure 35–21  The Amount in Stock Dial Gauge

To create a dial gauge using a data control, you bind the gauge component to an attribute in a data collection. JDeveloper allows you to do this declaratively by dragging and dropping an attribute from the Data Controls panel. After you drag and drop the attribute, use the Create Dial Gauge dialog to configure the gauge.

Figure 35–22 shows the Create Dial Gauge dialog configured for the Amount in Stock dial gauge shown in Figure 35–21 and using the gauge type and quick start layout shown in Figure 35–20.
Creating Databound Gauges

Before You Begin:

It may be helpful to have an understanding of databound data visualization gauges. For more information, see Section 35.3, "Creating Databound Gauges."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 35.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

To create a databound dial gauge:

1. From the Data Controls panel, select an attribute from a collection.

   For example, to create a dial gauge in the Summit ADF DVT sample application to display the stock levels for an inventory item, you would select the AmountInStock attribute in the ProductInventoryView1 collection. Figure 35–23 shows the ProductInventoryView1 collection in the Data Controls panel with the AmountInStock attribute selected.
2. Drag the attribute onto a JSF page and, from the context menu, choose Gauges.

3. In the Component Gallery, choose the category, type of gauge, and quick start layout, and then click OK.

4. In the Create Dial Gauge dialog, click the Configuration tab and do the following:
   - In the Metric box, confirm the column in your data collection that contains the actual value that the gauge is to plot. This is the only required value in the dialog.
   - In the Minimum box, if your data collection stores a minimum value for the gauge range, select the column that contains this value. Alternatively, specify a minimum number for the range. If you do not specify a value, the minimum value is calculated automatically and defaults to 0.
   - In the Maximum box, if your data collection stores a maximum value for the gauge range, select the column that contains this value. Alternatively, specify a maximum number for the range. If you do not specify a value, the maximum value is calculated automatically and defaults to 100.
   - In the Show Top Label section, if your data collection stores a value that you want to display in the top label of the gauge, select the Show Top Label check box.
     Choose the label to display from the Label dropdown menu. Optionally, from the Position dropdown menu, choose Inside Gauge to position the label inside the gauge.
   - In the Show Bottom Label section, if your data collection stores a value that you want to display in the bottom label of the gauge, select the Show Bottom Label check box.
     Choose the label to display from the Label dropdown menu. Optionally, from the Position dropdown menu, choose Inside Gauge to position the label inside the gauge.
   - In the Show Metric Label box, if your data collection stores a metric value that you want to display in the metric label of the gauge, select the Show Metric Label check box.
     From the Show Metric Label dropdown list, choose Inside Gauge to position the label inside the gauge or Below Gauge to position the label below the gauge. To display the metric label with the bottom label, choose With Bottom Label and select Show Bottom Label in the Show Bottom Label section.
   - If you selected a quick start layout that includes thresholds, in the Threshold Attributes list, specify the value for threshold1 and threshold2. You can enter
either a static value or choose an available attribute from the threshold’s dropdown menu.

---

**Note:** Gauge top, bottom, and threshold labels can also be configured to specify a text resource from a resource bundle using the Select Text Resource dialog, or use the EL Expression builder to evaluate the label text at runtime. Use the dropdown menu for the label field to open both dialogs.

---

5. Optionally, click the **Preview** tab to display a live preview of the gauge and its data. If necessary, go back to the **Configuration** tab so that you can adjust the gauge specifications.

6. **Click OK.**

In the Properties window, after you complete the binding of the gauge, you can set values for additional attributes in the gauge tag and its child tags to customize the component. For example, to configure the Amount In Stock gauge to show inventory amounts without scaling, set the `scaling` attribute of the metric and tick labels to `none`.

You can also examine and adjust the existing gauge bindings by clicking the **Edit** icon in the Properties window for the gauge component.

For additional information about customizing a gauge after the data binding is completed, see the "Using Gauge Components" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

### 35.3.2 What Happens When You Create a Dial Gauge from a Data Control

Dropping a gauge from the Data Controls panel has the following effect:

- Creates the bindings for the gauge and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

**Example 35–9** shows the bindings that JDeveloper generated for the dial gauge that displays the inventory levels for a product in a warehouse. This code example shows that the gauge metric receives its value dynamically from the `AmountInStock` attribute in the `ProductInventoryView1` data collection and its threshold values dynamically from the `ReorderPoint` and `MaxInStock` attributes in the same collection.

**Example 35–9  ** Bindings for a Dial Gauge

```xml
<parameters/>
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="ProductInventoryView1" RangeSize="1"
           DataControl="AppModuleDataControl"
           id="ProductInventoryView1Iterator"/>
</executables>
<bindings>
  <attributeValues IterBinding="ProductInventoryView1Iterator" id="AmountInStock">
    <AttrNames>
      <Item Value="AmountInStock"/>
    </AttrNames>
  </attributeValues>
```

**Note:** Gauge top, bottom, and threshold labels can also be configured to specify a text resource from a resource bundle using the Select Text Resource dialog, or use the EL Expression builder to evaluate the label text at runtime. Use the dropdown menu for the label field to open both dialogs.
Creating Databound Gauges

Example 35–10 shows the code that JDeveloper generated in the JSF page for a dial gauge. The `<dvt:thresholdSet>` element specifies one `<dvt:threshold>` element for each threshold.

Example 35–10 Code on the JSF Page for a Dial Gauge

```xml
<dvt:gauge id="gauge1" value="#{bindings.AmountInStock.inputValue}"
    gaugeType="DIAL" minValue="0"
    maxValue="1500" shortDesc="Amount In Stock Gauge">
    <dvt:gaugeBackground>
        <dvt:specialEffects/>
    </dvt:gaugeBackground>
    <dvt:thresholdSet>
        <dvt:threshold fillColor="#d62800"
            thresholdMaxValue="#{bindings.ReorderPoint.inputValue}"/>
        <dvt:threshold fillColor="#63a500"
            thresholdMaxValue="#{bindings.MaxInStock.inputValue}"/>
        <dvt:threshold fillColor="#e7e700"/>
    </dvt:thresholdSet>
    <dvt:gaugeFrame/>
    <dvt:indicator/>
    <dvt:indicatorBase/>
    <dvt:gaugePlotArea/>
    <dvt:tickLabel scaling="none"/>
    <dvt:tickMark/>
    <dvt:topLabel position="LP_ABOVE_GAUGE" text="#{bindings.Name.inputValue}"/>
    <dvt:bottomLabel position="LP_BELOW_GAUGE"
        text="#{bindings.AmountInStock.hints.label}"/>
    <dvt:metricLabel position="LP_WITH_BOTTOM_LABEL" scaling="none">
        <af:convertNumber pattern="#{bindings.AmountInStock.format}"/>
    </dvt:metricLabel>
</dvt:gauge>
```

**Note:** You can also bind a gauge to a collection instead of an attribute in the data collection. For example, you could drag the `ProductInventoryView1` collection to create the dial gauge instead of dragging the `AmountInStock` attribute. This feature is still available for backwards compatibility and for configuring gauge sets, but its use is discouraged in favor of the simpler standard attribute binding.
35.3.3 How to Create a Databound Status Meter Gauge Set

You can use the ADF gauge component to create a status meter gauge where the inner rectangle shows the current level of a measurement against the ranges marked in the outer rectangle. The graphic of the status meter gauge allows you to evaluate the condition or progress of a measurement easily.

Figure 35–24 shows a set of status meter gauges that represent the inventory levels at each warehouse that carries the product. As the user cycles through the list of products using the navigation controls on the left side of the page, the gauge set changes to reflect the warehouses that carry the selected product and the inventory levels for each of those warehouses.

This set of gauges results from binding one gauge component to a data collection (SInventoryView2). This data collection contains a row of data for each warehouse that carries the product. Each row produces one gauge in the set. The form on the left side of the page is an ADF form that is bound to the SProductView1 data collection.

Figure 35–25 shows the data control for the ADF form and gauge set displayed in Figure 35–24. Note the hierarchical relationship between the SProductView1 and SInventoryView2 data collections. Because of this relationship, the gauge set data updates automatically as the user cycles through the form’s navigation controls.
To create a status meter gauge set using a data control, you bind the gauge component to a data collection that contains multiple rows of data. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**Before you begin:**
It may be helpful to have an understanding of databound data visualization gauges. For more information, see Section 35.3, "Creating Databound Gauges."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 35.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

- Add any additional components needed to support the gauge.

For example, the gauge set in Figure 35–24 displays data based on the row selected in the ADF form. To create the form based on this example, drag the SProductView1 collection to the page and from the context menu, choose Form -> ADF Form.

Figure 35–26 shows the completed Edit Form Fields dialog. If you need help with the dialog, press F1 or click Help. For additional information about ADF forms, see Section 28.3.1, "How to Create a Form Using a Data Control Collection."
To create a databound status meter gauge set:

1. From the Data Controls panel, select a collection.
   
   For example, to create a status meter gauge set in the Summit ADF DVT sample application that displays the quantity of stock on hand in all warehouses that carry the given product, select the `SInventoryView2` collection.

2. Drag the collection onto a JSF page and, from the context menu, choose Gauges.

3. In the Component Gallery, choose the following:
   
   - Status Meter or Status Meter (Vertical) in the Categories list
   - The type of gauge that you want to create

   To specify a gauge set, choose the gauge type that includes a gauge set. Figure 35–27 shows the Component Gallery with the horizontal status meter gauge set selected.
4. Click OK.

5. In the Create Gauge dialog that appears, select values as described in the following list:
   - Select an attribute binding from the Metric dropdown list. This attribute binding contains the actual value that the gauge is to plot.
     For example, to duplicate the Summit ADF DVT gauge set example, select the AmountInStock attribute.
   - Input a minimum value in the Minimum field if your data collection stores a minimum value for the gauge range.
   - Input a maximum value in the Maximum field if your data collection stores a maximum value for the gauge range.
   - In the Show Top Label section, if your data collection stores a value that you want to display in the top label of the gauge, select the Show Top Label check box.
     Choose the label to display from the Label dropdown menu. Optionally, from the Position dropdown menu, choose Inside Gauge to position the label inside the gauge.
   - In the Show Bottom Label section, if your data collection stores a value that you want to display in the bottom label of the gauge, select the Show Bottom Label check box.
Choose the label to display from the Label dropdown menu. Optionally, from the Position dropdown menu, choose **Inside Gauge** to position the label inside the gauge.

- In the **Show Metric Label** box, if your data collection stores a value that you want to display in the metric label of the gauge, select the **Show Metric Label** check box.

  From the **Show Metric Label** dropdown list, choose **Inside Gauge** to position the label inside the gauge or **Below Gauge** to position the label below the gauge. To display the metric label with the bottom label, choose **With Bottom Label** and select **Show Bottom Label** in the **Show Bottom Label** section.

- If you chose a quick-start layout that includes thresholds, enter values for **threshold1** and **threshold2**. Do not enter a value for the threshold equal to the maximum value for the gauge because the gauge automatically treats the maximum value as a threshold setting.

---

**Note:** Gauge Top, Bottom, and Threshold labels can be configured to specify a text resource from a resource bundle using the Select Text Resource dialog, or use the EL Expression builder to evaluate the label text at runtime. Use the dropdown menu for the label field to open both dialogs.

---

6. Optionally, click the **Preview** tab to display a live preview of the gauge and its data. If necessary, click the **Configuration** tab so that you can adjust the gauge specifications.

   Figure 35–28 shows the settings for the set of status meter gauges that appears in Figure 35–24. In addition to setting values for the required metric value, this dialog sets values for thresholds based on the **ReorderPoint** and **MaxInStock** attributes of the data collection and specifies the placement, data source, and visibility of top, bottom, and metric labels.
7. Click OK.

In the Properties window, after you complete the binding of the gauge, you can set values for additional attributes in the gauge tag and its child tags to customize the component as needed.

For additional information about customizing a gauge after the data binding is completed, see “Using Gauge Components” in Developing Web User Interfaces with Oracle ADF Faces.

35.3.4 What Happens When You Create a Status Meter Gauge Set from a Data Control

Dropping a gauge set from the Data Controls panel has the following effect:

- Creates the bindings for the gauge set and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

Example 35–11 shows the row set bindings that were generated for the status meter gauge set that displays inventory levels for each warehouse as illustrated in Figure 35–24. This example shows the value binding created between the gauge metric attribute and the QuantityOnHand value in the data collection. It also shows the value binding between the Bottom Label attribute and the WarehouseName value in the data collection.

Example 35–11 Bindings Code for the ADF Status Meter Gauge Set

```xml
<gauge IterBinding="SInventoryView2Iterator" id="SInventoryView2" xmlns="http://xmlns.oracle.com/adfm/dvt" type="STATUSMETER">
  <gaugeDataMap convert="false">
    <item type="metric" value="AmountInStock"/>
    <item type="topLabel" value="WarehouseId"/>
    <item type="bottomLabel" value="Name"/>
  </gaugeDataMap>
</gauge>
```
Example 35–12 shows the code generated on the JSF page for the status meter gauge set that shows inventory levels at warehouses for a given product. The gaugeSetColumnCount attribute specifies that gauges should be displayed in two columns.

**Example 35–12  Code on the JSF Page for the ADF Status Meter Gauge Set**

```xml
<dvt:gauge id="gauge1" value="#{bindings.SInventoryView2.gaugeModel}"
    gaugeType="STATUSMETER" gaugeSetDirection="GSD_ACROSS"
    gaugeSetColumnCount="2" shortDesc="Sample Gauge Set"
    inlineStyle="width:500px; height:500px;" gaugeSetAlignment="GSA_TOP">
    <dvt:gaugeBackground>
        <dvt:specialEffects/>
    </dvt:gaugeBackground>
    <dvt:thresholdSet>
        <dvt:threshold fillColor="#d62800" text="Reorder Time"/>
        <dvt:threshold fillColor="#63a500" text="Levels OK"/>
        <dvt:threshold fillColor="#e7e700" text="Over Stock"/>
    </dvt:thresholdSet>
    <dvt:indicatorBar/>
    <dvt:gaugePlotArea/>
    <dvt:tickLabel scaling="none"/>
    <dvt:tickMark/>
    <dvt:topLabel position="LP_ABOVE_GAUGE"/>  
    <dvt:bottomLabel position="LP_BELOW_GAUGE"/>
    <dvt:gaugeLegendTitle text="Legend"/>
    <dvt:gaugeLegendArea position="LAP_RIGHT"/>
    <dvt:metricLabel position="LP_WITH_BOTTOM_LABEL" scaling="none"/>
</dvt:gauge>
```

### 35.3.5 Including Gauges in Databound ADF Tables

You can add databound dial, LED, or status meter gauges to a databound ADF table by choosing the gauge component when specifying column content during table editing or creation.

Figure 35–29 shows a portion of a table that displays all the products in a warehouse in the Summit ADF DVT sample application. In this example, the AmountInStock column includes a status meter gauge that shows the amount in stock for each product.
35.3.5.1 How to Include a Gauge in a Databound ADF Table

To add a gauge to a databound ADF table, drag a data collection that includes the gauge metric from the Data Controls panel to the JSF page and specify the type of gauge to create.

Before you begin:

It may be helpful to have an understanding of databound data visualization gauges. For more information, see Section 35.3, "Creating Databound Gauges."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 35.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.
To include a gauge in a databound ADF table:

1. From the Data Controls panel, select the collection to use for the ADF table.

   For example, to create the table that displays the inventory levels for each product in a warehouse in the Summit ADF DVT sample application, select the ProductInventoryView1 collection. Figure 35–30 shows the ProductInventoryView1 collection in the Data Controls panel.

2. Drag the collection onto a JSF page and, from the context menu, choose Table -> ADF Table.

3. In the Edit Table Columns dialog, select the column that represents the gauge metric.

   For example, select the AmountInStock column to use as the gauge metric.

4. From the Component to Use dropdown menu, choose the type of gauge to create.

   For example, choose Gauge Status Meter to add a status meter to the table.

5. Complete the table configuration.

   If you need help, press F1 or click Help.

   Figure 35–31 shows the completed dialog for the table displayed in Figure 35–29, with the Gauge Status Meter selected for the AmountInStock column.
6. Click **OK** to add the table to the JSF page.

In the Properties window, after you complete the binding of the table, you can set values for additional attributes in the gauge tag and its child tags to customize the component. For example, to configure the gauge to show inventory amounts without scaling, set the `scaling` attribute of the metric label to `none`.

You can also examine and adjust the existing table bindings by clicking the **Edit** icon in the Properties window for the table component.

For additional information about customizing a gauge after the data binding is completed, see the "Using Gauge Components" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

For additional information about creating and configuring databound ADF tables, see Chapter 29, "Creating ADF Databound Tables."

### 35.3.5.2 What Happens When You Include a Gauge in an ADF Table

When you include a gauge in a databound ADF table, the gauge’s metric attribute is added to the page definition file, and the UI components are updated on the JSF page. Example 35–13 shows the binding for the ADF table shown in Figure 35–29.

**Example 35–13  Binding for Status Meter Gauge in ADF Table**

```xml
<parameters/>
<executables>
  <variableIterator id='variables'/>
  <iterator Binds='ProductInventoryView2' RangeSize='25'
    DataControl='AppModuleDataControl'
    id='ProductInventoryView2Iterator'/>
  <searchRegion Binds='ProductInventoryView2Iterator' Criteria=''
    Customizer='oracle.jbo.ui.cli.binding.JUSBindingCustomizer'
    id='ProductInventoryView2Query'/>
</executables>
```
Example 35–14 shows the code added to the JSF page for the ADF table. The gauge elements are highlighted in bold. For the sake of brevity, only the first three table columns are displayed.

**Example 35–14  Sample Code on JSF Page Showing Gauge in Databound Table**

```xml
<af:table value="#{bindings.ProductInventoryView2.collectionModel}" var="row"
    rows="#{bindings.ProductInventoryView2.rangeSize}"
    emptyText="#{bindings.ProductInventoryView2.viewable ? 'No data to display.' : 'Access Denied.'}"
    fetchSize="#{bindings.ProductInventoryView2.rangeSize}"
    rowBandingInterval="0"
    filterModel="#{bindings.ProductInventoryView2Query.queryDescriptor}"
    queryListener="#{bindings.ProductInventoryView2Query.processQuery}"
    filterVisible="true" varStatus="vs"
    selectionListener="#{bindings.ProductInventoryView2.collectionModel.makeCurrent}"
    rowSelection="multiple" id="t1">
    <af:column sortProperty="#{bindings.ProductInventoryView2.hints.ProductId.name}"
        filterable="true" sortable="true"
        headerText="#{bindings.ProductInventoryView2.hints.ProductId.label}"
        id="c5" width="57">
        <af:outputText value="#{row.ProductId}"
            shortDesc="#{bindings.ProductInventoryView2.hints.ProductId.tooltip}"
            id="ot4">
            <af:convertNumber groupingUsed="false"
                pattern="#{bindings.ProductInventoryView2.hints.ProductId.format}"/>
        </af:outputText>
    </af:column>
    <af:column sortProperty="#{bindings.ProductInventoryView2.hints.Name.name}"
        filterable="true" sortable="true"
        headerText="#{bindings.ProductInventoryView2.hints.Name.label}"
        id="c1" width="143">
        <af:outputText value="#{row.Name}"
            shortDesc="#{bindings.ProductInventoryView2.hints.Name.tooltip}"
            id="ot1"/>
    </af:column>
    <af:column sortProperty="#{bindings.ProductInventoryView2.hints.ShortDesc.name}"
        filterable="true" sortable="true"
        headerText="#{bindings.ProductInventoryView2.hints.ShortDesc.label}"
        id="c10" width="100">
        <af:outputText value="#{row.ShortDesc}"/>
    </af:column>
</af:table>
```
Creating Databound Gauges

shortDesc="#{bindings.ProductInventoryView2.hints.ShortDesc.tooltip}"
   id="ot9"/>

<af:column sortProperty="#{bindings.ProductInventoryView2.hints.AmountInStock.name}"
    filterable="true" sortable="true"
    headerText="#{bindings.ProductInventoryView2.hints.AmountInStock.label}"
    id="c2" width="138">
    <dvt:gauge value="#{row.bindings.AmountInStock.inputValue}"
        gaugeType="STATUSMETER"
        inlineStyle="height:60px; width:80px;"
        shortDesc="#{bindings.ProductInventoryView2.hints.AmountInStock.tooltip}"
        id="g1" ledStyle="LS_RECTANGLE">
        <dvt:topLabel position="LP_NONE"/>
        <dvt:metricLabel position="LP_INSIDE_GAUGE" scaling="none">
            <af:convertNumber pattern="#{row.bindings.AmountInStock.format}"/>
        </dvt:metricLabel>
        <dvt:bottomLabel position="LP_NONE"/>
    </dvt:gauge>
</af:column>

... remaining columns omitted
</af:table>
Creating Databound Pivot Table and Pivot Filter Bar Components

This chapter describes how to create pivot tables from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization pivotTable and pivotFilterBar components to create pivot tables that visually represent business data. It describes how to use ADF data controls to create a pivot table with data-first development.

If you are designing your page using simple UI-first development, then you can add the pivot table to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the pivot table components, see the "Using Pivot Table Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.

This chapter includes the following sections:

- Section 36.1, "About ADF Data Visualization Pivot Table and Pivot Filter Bar Components"
- Section 36.2, "Creating Databound Pivot Tables"

36.1 About ADF Data Visualization Pivot Table and Pivot Filter Bar Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

The pivot table component produces a grid that supports multiple layers of data labels on the row edge or the column edge of the grid. An optional pivot filter bar represents a page edge that filters the available pivot table data. This component also provides the option of automatically generating subtotals and totals for grid data. Pivot tables let you pivot data layers from one edge to another to obtain different views of your data. For example, a pivot table might initially display total sales data for products within regions on the row edge, broken out by years on the column edge. If you pivot region and year at runtime, then you end up with total sales data for products within years, broken out by region. At runtime, end users can click buttons that appear in the inner column labels to sort rows in ascending or descending order.

The prefix dvt: occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.
36.1.1 Data Visualization Components Use Cases and Examples

For detailed descriptions of each data visualization use cases and examples, see the "Pivot Table and Pivot Filter Bar Component Use Cases and Examples" section in Developing Web User Interfaces with Oracle ADF Faces.

36.1.2 End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the "End User and Presentation Features of Pivot Table Components" section in Developing Web User Interfaces with Oracle ADF Faces.

36.1.3 Additional Functionality for Data Visualization Components

You may find it helpful to understand other Oracle ADF features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the "Rerendering Partial Page Content" chapter in Developing Web User Interfaces with Oracle ADF Faces.

- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the "Allowing User Customization on JSF Pages" chapter in Developing Web User Interfaces with Oracle ADF Faces.

- Accessibility: By default, data visualization components are accessible. You can make your application pages accessible for screen readers. For more information, see the "Developing Accessible ADF Faces Pages" chapter in Developing Web User Interfaces with Oracle ADF Faces.

- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (styleClass or inlineStyle). For more information, see the "Customizing the Appearance Using Styles and Skins" chapter in Developing Web User Interfaces with Oracle ADF Faces.

- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Chapter 19, "Designing a Page Using Placeholder Data Controls."

36.2 Creating Databound Pivot Tables

The ADF pivot table displays data in a grid layout with unlimited layers of hierarchically nested row header cells and column header cells. The pivot table
supports an optional pivot filter bar, representing a page edge that filters the available pivot table data. The pivot table has the following structure:

- **Column edge:** The horizontal axis above the pivot table containing one or more layers of information in the pivot table.
- **Row edge:** The vertical axis to the side of the pivot table containing one or more layers of information in the pivot table.
- **Page edge:** The optional pivot filter bar containing zero or more layers of information for filtering the display of data in the pivot table.
- **Data body:** One or more measures, or data values, displayed in the cells of the pivot table.

Figure 36–1 shows a Product Inventory pivot table that displays data values for the amount in stock and reorder point in the data body, a warehouse ID data layer on the column edge, and product category and product data layers on the row edge. A pivot filter bar displays a world region and region filter on the page edge.

**Figure 36–1  Product Inventory Pivot Table**

A Create Pivot Table wizard provides declarative support for data-binding and configuring the pivot table. In the wizard pages you can:

- Specify the initial layout of the pivot table
- Associate and configure a pivot filter bar
- Specify alternative labels for the data layers
- Configure insert or filter drilling
- Define aggregation of data values
- Configure category and data sorting
- View a live data preview of the pivot table

As you lay out the pivot table in the first page of the wizard, corresponding entries are initialized in the following wizard pages. You can use the Back and Next buttons to adjust the pivot table as you go through the wizard pages. You can also skip configuration options in later wizard pages by clicking Finish.
For information about customizing a pivot table after data binding is completed, see the "Using Pivot Table Components" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

### 36.2.1 How to Create a Pivot Table Using ADF Data Controls

To create a pivot table using a data control, you bind the pivot table component to a collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**Tip:** You can also create a pivot table by dragging a pivot table component from the Components window. This approach allows you the option of designing the pivot table user interface before binding the component to data.

**Before you begin:**

It may be helpful to have an understanding of databound pivot tables and pivot filter bars. For more information, see Section 36.2, "Creating Databound Pivot Tables."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 36.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the pivot table, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for Product Inventory pivot table shown in Figure 36–1 comes from a view object created for the Summit sample application for ADF DVT components.

- Create a JSF page as described in the "How to Create JSF Pages" section of *Developing Web User Interfaces with Oracle ADF Faces*.

**To create a databound pivot table:**

1. From the Data Controls panel, select a collection.

   For example, to create a pivot table and pivot filter bar that displays product inventory levels in warehouses throughout the World, you could select the *WorldProductInventory1* collection in the Data Controls panel, as shown in Figure 36–2.
2. Drag the data collection onto a JSF page and, from the context menu, choose Tables/List View > ADF Pivot Table.

3. In the Select Display Attributes page of the Create Pivot Table wizard, specify the initial layout of the pivot table by doing the following:
   a. If you want to associate a pivot filter bar with your pivot table, select Create Pivot Filter Bar. Optionally, you can drag attributes from the Available Attributes list to the page edge to configure the initial display of filters; otherwise, an empty pivot filter bar is created.

   **Note:** You can add a pivot filter bar after completing the wizard by right-clicking the pivotTable node in the Structure window, and choosing Insert Before Pivot Table > ADF Data Visualizations > Pivot Filter Bar.

   To remove a pivot filter bar, in the Structure window, right-click the pivotFilterBar node and choose Delete.

   b. For the initial layout, select the attributes for the pivot table's columns, rows, page edge, and data body by dragging the attributes from the Available Attributes list to the pivot table layout.

   In the pivot table layout, Data Labels refers to a layer of the pivot table that identifies the data in the cells (data values), and also appears as header labels in the row, column, or page edge. Labels for attributes that you drag to the data body of the pivot table appear in the data labels layer.

   You can drag data labels to any location on the row, column, or page edge. You can also drag attributes to different locations on the same edge or on another edge.
As an alternative to using a drag operation to place or move attributes in the layout, you can right-click the attribute or use Shift+F10 to display a context menu of options. Figure 36–3 shows the context menu options for the RegName attribute.

**Figure 36–3 Display Attributes Context Menu**

*Note:* Potential drill paths between attributes are defined as you lay out multiple attributes on the row, column, and page edges. These drill paths can later be enabled to support pivot table drilling at runtime.

c. If you want to change from the default selection of **Typed Attributes** to **Name-Value Pairs** to configure how data points are stored in a collection, then click the **Change Data Shape** button. A dialog appears that presents you with the following options:

- **Typed Attributes**
  
  Each kind of data point in the collection is represented by a different attribute. This option is also valid when there is only a single kind of data point in the pivot table.

  For example, if you have data points for **Estimated Value** and **Actual Value**, then select **Typed Attributes** only if you have one attribute for the estimated value and a second attribute for the actual value.

- **Name-Value Pairs**
  
  Indicates that there are two or more kinds of data points represented by exactly two attributes; a Name attribute that specifies the kind of data point, and a Value attribute that specifies the data value.

  For example, the Name attribute might have the value EST for a Value attribute that represents an estimated value, or the Name attribute might have a value ACT for a Value attribute that represents an actual value.

  For example, to specify the initial layout of the Product Inventory pivot table shown in Figure 36–1, you would drag the RegName and Country attributes to the page edge, Category and ProdName attributes to the row edge, AmountinStock
and ReorderPoint attributes to the data body (Data Labels), WarehouseID to the column edge, and select **Create Pivot Filter Bar**, as shown in Figure 36–4.

**Figure 36–4  Select Display Attributes Page of Create Pivot Table Wizard**

4. If you want to specify alternative values or labels for the attributes laid out in the Select Display Attributes page of the wizard, click **Next**, and use the Specify Attribute Properties page to do the following:

   a. By default, the data cells in a pivot table are not editable. An `af:outputText` component is automatically stamped for each data cell. If you wish to create a pivot table with editable data cells, deselect **Read-Only Pivot Table** and an `af:inputText` component option will be available for each data cell attribute in the **Component** column. You can then specify zero or more data values as editable by selecting the `af:inputText` component, and the tag and its corresponding `f:validator` tag will be stamped for that pivot table data cell. For more information, see **Section 36.2.5, “What You May Need to Know About Configuring Editable Data Cells.”**

   b. To specify alternative labels for data values in the **Data Values** area, change the default **Use Data Attribute Name** text label stamped in the header cell for the attribute at runtime. You can enter the text directly, select **No Label** to suppress the header cell as in the case of using a single data value for the pivot table, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime.

   c. To specify alternative labels for attribute categories in the **Categories** area, change the default **Use Attribute Name** text label stamped in the header cell for the attribute at runtime in the **Attribute Display Name** column. You can enter the text directly, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime. The label displays in the pivot handle at runtime.
You can also specify an alternative value for an attribute category by selecting a different attribute in the **Attribute Display Value** column. For example, you might use a `RegionId` attribute in the data collection to lay out the pivot table, but you want the `RegionName` attribute values to appear in the pivot table header at runtime to make the information more readable.

Setting a text resource enables your JSF page or application to display the correct language for the language setting of a user’s browser. Choose the **Select Text Resource** option for the **Data Values** labels and the **Categories** attribute display name fields to set a translatable text resource.

**Note:** If you configured **Project Properties > Resource Bundle page to Automatically Synchronize Bundle**, then you can type an alternate label string, and the design time code will create a translatable text resource for you.

For example, to set the Product Inventory pivot table shown in **Figure 36–1** to use text resources for labels and display names, complete the Specify Attributes Properties page of the wizard as shown in **Figure 36–5**.

**Figure 36–5 Specify Attribute Properties Page of Create Pivot Table Wizard**

5. If you want to expose drill operations in the pivot table at runtime, click **Next**, and use the **Configure Drilling** page of the Create Pivot Table wizard to enable one of the following options:

- Select **Insert Drilling** to provide a collapsed or expanded view of the detail data while preserving the sibling and aggregate data. At runtime, a drill icon is displayed in the parent attribute display label.
Use **Insert Parent Row** to specify whether the aggregate total for the parent attribute will be displayed before or after the child attributes in the expanded view.

To enable insert drilling you must also:

- Select the drill paths to enable. Drill paths are configured based upon the layout of the attributes in the Select Display Attributes page of the wizard.

- Configure aggregation in the Configure Aggregation page of the wizard.

For example, *Figure 36–6* shows a pivot table using insert drilling to expand the view for the Year data layer. The aggregated value of Sales (52,500 in 2007, 544,150 in 2006) and Units (410 in 2007, 507 in 2006) for each year is displayed in the row above the products.

*Figure 36–6  Pivot Table with Insert Drilling Enabled*

<table>
<thead>
<tr>
<th>Total</th>
<th>Sales</th>
<th>Units</th>
</tr>
</thead>
<tbody>
<tr>
<td>TOTAL</td>
<td>128,172</td>
<td>1,105</td>
</tr>
<tr>
<td>2007</td>
<td>52,500</td>
<td>410</td>
</tr>
<tr>
<td>2006</td>
<td>54,150</td>
<td>507</td>
</tr>
</tbody>
</table>

Select **Filter Drilling** to provide a collapsed or expanded view of the detail data without preserving the sibling or aggregate data. At runtime, a drill icon is enabled in the parent attribute display label.

Filter drilling focuses the view on the details of the data layer attribute. For example, *Figure 36–7* shows a pivot table using filter drilling to expand the view of the Year (2007) data layer, displaying the total Sales (52,500) and Units (410), while filtering out both the data for the other years and the aggregated total for all the years.

*Figure 36–7  Pivot Table with Filter Drilling Enabled*

<table>
<thead>
<tr>
<th>Total</th>
<th>Sales</th>
<th>Units</th>
</tr>
</thead>
<tbody>
<tr>
<td>TOTAL</td>
<td>128,172</td>
<td>1,105</td>
</tr>
<tr>
<td>2007</td>
<td>52,500</td>
<td>410</td>
</tr>
<tr>
<td>2006</td>
<td>54,150</td>
<td>507</td>
</tr>
</tbody>
</table>

To enable filter drilling you must select the drill paths to enable. Drill paths are configured based upon the layout of the attributes in the Select Display Attributes page of the wizard.

For example, to enable the insert drilling for the Product Inventory pivot table shown in *Figure 36–1*, complete the Configure Drilling page of the wizard, as shown in *Figure 36–8*.
6. If you want to define how data is aggregated in totals and subtotals for the pivot table, click **Next**, and use one or both of the Configure Aggregation pages of the Create Pivot Table wizard.

   By default, if the attributes displayed in the pivot table do not uniquely identify each row in the data collection, the data from duplicate rows is aggregated to collapse that data into a single pivot table cell. You can also override the default aggregate type for a particular data item.

   - If you want to specify how data is aggregated in the pivot table, in the Data Aggregation page, do the following:

     - If you want to change the default aggregation method for handling duplicate rows, use the **Default Function** dropdown list to specify the value. Valid values are **Sum**, **Average**, **Count**, **Maximum**, **Minimum**, **Standard Deviation**, **Median**, and **Variance**.

     - If you want to override the default aggregate type for a specific data value, click the **Add** icon to insert a row for the available attributes. Then, in the **Function** column for each attribute, select the mathematical operation that you want to use for the aggregation. Available options are **Sum**, **Average**, **Count**, **Maximum**, **Minimum**, **Standard Deviation**, **Median**, and **Variance**. This attribute is useful only when you have multiple data values (such as Sales and Units) bound to your pivot table.

   For example, to override the default aggregation type for the Units data value in the Sales pivot table shown in Figure 36–1, use the **Add** icon to add the Units attribute and select Average in the **Function** column in the Data Aggregation page, as shown in Figure 36–9.
You can also define totals and subtotals for attribute categories added to the column, row, or page edges in the pivot table. In the Categories Totals page, use the Add icon to insert each attribute or select Aggregate All to add all available attributes, and do the following:

- In the Attribute column, select the attribute that you want to total.
- In the Function column, select the mathematical operation that you want to use for the aggregation. Available options are Sum, Average, Count, Maximum, Minimum, Standard Deviation, Median, and Variance.
- In the Insert Total column, select the value that indicates where you want the aggregate display to appear relative to the item referenced in the Attribute column. Valid values are: Before, After, or Replace.
- In the Total Label column, enter the text that you want to use as a label for the aggregation. You can enter the text directly, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime.

**Note:** The read-only Insert Drill Totals table displays the category totals automatically defined as a consequence of enabling insert drilling on the pivot table.

For example, to define totals for the Geography and Year data layers in the Sales pivot table shown in Figure 36–1, select Sum in the Function column and After in the Insert Total column, and enter text (Total Geography and Total Year) in the Total Labels column respectively for each attribute in the Categories Totals page, as shown in Figure 36–10.
In the resulting pivot table at runtime, expanding a particular Year value will automatically preserve the aggregate total computed from its child value based on the layout and configuration of the insert drill option in the previous wizard page.

Figure 36–10 Categories Totals Page of the Create Pivot Table Wizard

7. If you want to configure sorting in the pivot table, click **Next**, and use one or both of the Configure Sorting pages in the Create Pivot Table wizard.

By default, a pivot table initially sorts data based on values in the outer row data layer. You can specify sort order on the data layer of any row, column, or page edge, called a *category sort*. At runtime, when the data layer is pivoted to a different edge, the specified category sort order is honored.

You cannot specify a category sort of data labels (data values), although you can order the attributes mapped to the data body in the Select Display Attributes page of the wizard. For example, **Figure 36–4** shows a pivot table layout with data values for Sales and Units. While you cannot specify a category sort of these measures, you can specify the order in which the values will appear in the data body of the pivot table at runtime, shown in **Figure 36–1**.

You can also specify an initial sort order of the data values in the data body when the pivot table is rendered, called a *data sort*.

- To configure sorting by category, in the Category Sort page, use the **Add** icon to add the attribute for each row, column, or page edge you wish to configure, and do the following:
  - In the **Sort Attribute** column, accept the default *Use Attribute Value* to specify an alphabetical sort based on the actual values in the pivot table header, or customize the sort order by specifying an alternate sort order attribute from the dropdown list. For example, if the underlying query
included a rank calculation for ranking products by profitability, you could choose to see products ordered by (ProductRank, Descending).

- In the Initial Sort Order column, select the initial direction of the sort. Valid values are ASCENDING or DESCENDING.

For example, Figure 36–11 shows the Category Sort page of the wizard configured to display the Category data layer ascending on the column edge.

**Figure 36–11  Category Sort Page of Create Pivot Table Wizard**

At runtime, the pivot table displays as shown in Figure 36–12.

**Figure 36–12  Category Sort Example**

<table>
<thead>
<tr>
<th></th>
<th>Sales</th>
<th>Units</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Indirect</td>
<td>Direct</td>
</tr>
<tr>
<td>2005</td>
<td>12272</td>
<td>9250</td>
</tr>
<tr>
<td>2006</td>
<td>356500</td>
<td>115500</td>
</tr>
<tr>
<td>2007</td>
<td>355000</td>
<td>159900</td>
</tr>
</tbody>
</table>

- To configure data sorting, in the Data Sort page, do the following:
  - Select **Sort by Columns** to specify an initial sort order of the data when the pivot table is rendered.
  - In the **Initial Sort Order** dropdown list select the initial direction of the sort. Valid values are ASCENDING and DESCENDING.
  - In the **Sequence Nulls** dropdown list, select **First** if you want the null values to appear at the beginning of a sort and select **Last** if you want the null values to appear at the end of the sort.
  - In the **Initial Sort Column** table, specify a data value in the **Value** column for each data layer displayed in the **Layer Attribute** column.
For example, Figure 36–13 shows the Data Sort page configured to sort the Channel data layer grouped by Year, based upon Units/World/Canoes data values.

**Figure 36–13  Data Sort Page of the Create Pivot Table Wizard**

At runtime, the pivot table initially renders as shown in Figure 36–14.

**Figure 36–14  Data Sort Example**

<table>
<thead>
<tr>
<th>Units</th>
<th>World</th>
<th>Expect</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>2007</td>
<td>75</td>
<td>50</td>
</tr>
<tr>
<td>Direct</td>
<td>5</td>
<td>20</td>
</tr>
<tr>
<td>2006</td>
<td>80</td>
<td>55</td>
</tr>
<tr>
<td>Direct</td>
<td>40</td>
<td>25</td>
</tr>
<tr>
<td>2005</td>
<td>50</td>
<td>20</td>
</tr>
<tr>
<td>Direct</td>
<td>10</td>
<td>20</td>
</tr>
</tbody>
</table>

8. In the Preview Your Pivot Table page of the Create Pivot Table wizard, see a live preview of the data that will be displayed in the pivot table. The preview does not require that you compile and run code. If you are not satisfied with the preview, alter the settings in the binding wizard pages and return again to the preview page to verify that your data looks as desired.

**Figure 36–15** shows the Preview Your Pivot Table page of the wizard for the Sales pivot table shown in Figure 36–1.
After completing the wizard to create the pivot table, use the tools in JDeveloper to customize the look and feel of the pivot table. For example, you can configure word wrapping for labels that do not fit into the default size of the header cell and add a page control as an alternative to scrollbars for the data set in the pivot table in Figure 36–1.

To customize pivot table display:
1. In the Structure window, right-click the dvt:pivotTable node and choose Go to Properties.
2. In the Properties window, expand the Common section and set the ScrollPolicy property to page to configure a page control as an alternative to the default scrollbars.
3. In the Structure window, right-click the dvt:headerCell node and choose Go to Properties.
4. In the Properties window, expand the Behavior section and set the WhiteSpace attribute to normal to configure word wrapping in the pivot table headers.

For additional information about customizing a pivot table after data binding is completed, see the "Using Pivot Table Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.

36.2.2 What Happens When You Use the Data Controls Panel to Create a Pivot Table

Dropping a pivot table from the Data Controls panel has the following effect:
- Creates the bindings for the pivot table and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page
When you create a pivot table from the Data Controls panel, the page definition file is updated with the bindings. Example 36–1 shows the row set bindings that were generated for the pivot table that displays product sales and units sold within geography by year. The pivot table data map contains the following elements:

- `<columns>`: Defines each column item in the appropriate sequence
- `<rows>`: Defines each row item in the appropriate sequence
- `<pages>`: Defines the items to be included in the pivot filter bar
- `<aggregatedItems>`: Defines the totals and subtotals of items
- `<hierarchies>`: Defines the potential drill paths between two items
- `<sorts>`: Defines category sorts and the initial sort order of pivot table data

The default data aggregation method for duplicate rows is specified in the `<data>` element. For more information about aggregating duplicates, see Section 36.2.3, "What You May Need to Know About Aggregating Attributes in the Pivot Table."

For more information about sorting operations, see Section 36.2.4, "What You May Need to Know About Specifying an Initial Sort for a Pivot Table."

**Example 36–1  Binding XML for the Pivot Table**

```xml
<pivotTable IterBinding="WorldProductInventory1Iterator"
    id="WorldProductInventory" xmlns="http://xmlns.oracle.com/adfm/dvt" ChangeEventPolicy="ppr">
    <pivotTableDataMap convert="false">
        <columns>
            <data aggregateDuplicates="true" defaultAggregateType="SUM">
                <item label="${adfBundle['view.ViewControllerBundle'].AMOUNT_IN_STOCK}" value="AmountInStock"/>
                <item label="${adfBundle['view.ViewControllerBundle'].REORDER_POINT}" value="ReorderPoint"/>
            </data>
            <item value="WarehouseId" itemLabel="${adfBundle['view.ViewControllerBundle'].WAREHOUSE_ID}/">
        </columns>
        <rows>
            <item value="Category" itemLabel="${adfBundle['view.ViewControllerBundle'].CATEGORY}"/>
        </rows>
        <pages>
            <item value="RegName" itemLabel="${adfBundle['view.ViewControllerBundle'].REGION}"/>
            <item value="Country" itemLabel="${adfBundle['view.ViewControllerBundle'].COUNTRY}"/>
        </pages>
        <aggregatedItems>
            <item aggregateLocation="AFTER" aggregateType="AVERAGE" value="Category" label="${adfBundle['view.ViewControllerBundle'].AVERAGE}"/>
        </aggregatedItems>
        <drills type="INSERT"/>
        <hierarchies>
            <item value="Category" location="BEFORE">
                <child value="ProdName" itemLabel="${adfBundle['view.ViewControllerBundle'].PRODUCT}"/>
            </item>
        </hierarchies>
        <sorts>
            <categorySort item="Category" direction="ASCENDING"/>
        </sorts>
    </pivotTableDataMap>
</pivotTable>
```
When the pivot table is created using the Data Controls panel, the necessary code is added to the page. **Example 36–2** shows the code generated on the JSF page for the sales pivot table and associated pivot filter bar.

**Example 36–2  Code on the JSP Page for the Pivot Table and Pivot Filter Bar**

```xml
<dvt:pivotFilterBar id="pfb1"
    value="#{bindings.WorldProductInventory1.pivotFilterBarModel}"
    modelName="pt1Model"/>
<dvt:pivotTable id="pt1"
    value="#{bindings.WorldProductInventory1.pivotTableModel}"
    modelName="pt1Model"
    var="cellData" varStatus="cellStatus"
    summary="#{viewcontrollerBundle.WorldProductInventoryPivotTable}"
    scrollPolicy="page">
  <dvt:headerCell whiteSpace="normal">
    <af:switcher facetName="#{cellData.layerName}" defaultFacet="Default" id="s1">
      <f:facet name="DataLayer">
        <af:outputText value="#{cellData.label}" id="ot1"/>
      </f:facet>
      <f:facet name="WarehouseId">
        <af:outputText value="#{cellData.dataValue}" id="ot2">
          <af:convertNumber groupingUsed="false"
            pattern="#{bindings.WorldProductInventory1.hints.WarehouseId.format}"/>
        </af:outputText>
      </f:facet>
      <f:facet name="Category">
        <af:outputText value="#{cellData.dataValue}" id="ot3"/>
      </f:facet>
      <f:facet name="ProdName">
        <af:outputText value="#{cellData.dataValue}" id="ot4"/>
      </f:facet>
      <f:facet name="RegName">
        <af:outputText value="#{cellData.dataValue}" id="ot5"/>
      </f:facet>
      <f:facet name="Country">
        <af:outputText value="#{cellData.dataValue}" id="ot6"/>
      </f:facet>
      <f:facet name="Default">
        <af:outputText value="#{cellData.dataValue}" id="ot7"/>
      </f:facet>
    </af:switcher>
  </dvt:headerCell>
  <dvt:dataCell>
    <af:switcher facetName="#{cellStatus.members.DataLayer.value}"
      defaultFacet="Default" id="s2">
      <f:facet name="AmountInStock">
        <af:outputText value="#{cellData.dataValue}" id="ot8">
          <af:convertNumber groupingUsed="false"
            pattern="#{bindings.WorldProductInventory1.hints.AmountInStock.format}"/>
        </af:outputText>
      </f:facet>
      <f:facet name="ReorderPoint">
        <af:outputText value="#{cellData.dataValue}" id="ot9"/>
      </f:facet>
    </af:switcher>
  </dvt:dataCell>
</dvt:pivotTable>
```
36.2.3 What You May Need to Know About Aggregating Attributes in the Pivot Table

If the attributes that you choose to display in your pivot table do not uniquely identify each row in your data collection, then you can aggregate the data from duplicate rows to collapse that data into a single pivot table cell.

For example, if the rows in the data collection shown in Figure 36–16 also contained a store identification, then the data rows from all stores in a given combination of Product, Channel, and Geography would have to be collapsed into a single cell in the pivot table.

The pivot table has the following optional data binding attributes available for controlling the calculation of duplicate data rows:

- aggregateDuplicates: Boolean property of the <data> element that determines whether special processing is enabled at binding runtime to aggregate data values in duplicate rows. If this attribute is not specified, then false is assumed.

- defaultAggregateType: String property of the <data> element that specifies a default aggregation method for handling duplicates. Valid values are SUM, AVERAGE, COUNT, MIN, MAX, STDDEV, MEDIAN, VARIANCE. If aggregateDuplicates is true and defaultAggregateType is unspecified, then SUM is assumed.

- aggregateType: String property of an <item> element that enables you to override the default aggregate type for a particular data item. This attribute is useful only when you have multiple data values (such as Sales and Units) bound to your pivot table.
36.2.3.1 Default Aggregation of Duplicate Data Rows

By default, the pivot table uses the SUM operation to aggregate the data values of duplicate data rows in a data collection to produce a single cell value in the pivot table. This means that the aggregateDuplicates attribute is set to true and the defaultAggregateType is assumed to be SUM.

The <data> element shown in Example 36–3 is an example of such default aggregation.

Example 36–3  Binding XML for the ADF Pivot Table

```xml
<pivotTable IterBinding="ptExampleDataIterator" id="ptExampleData"
xmlns="http://xmlns.oracle.com/adfm/dvt"
ChangeEventPolicy="ppr">
  <pivotTableDataMap>
    <columns>
      <item value="Geography" itemLabel="Location"/>
      <data aggregateDuplicates="true" defaultAggregateType="SUM">
        <item value="Sales"/>
        <item value="Units" aggregateType="AVERAGE"/>
      </data>
    </columns>
    <rows>
      <item value="Year"/>
    </rows>
    <pages>
      <item value="Channel"/>
    </pages>
    <aggregatedItems>
      <item aggregateLocation="AFTER" aggregateType="SUM" value="Geography"
aggregateLabel="Total Geography"/>
      <item aggregateLocation="AFTER" aggregateType="SUM" value="Year"
aggregateLabel="Total Across Years"/>
    </aggregatedItems>
    <drills type="INSERT"/>
    <hierarchies>
      <item value="Year" location="BEFORE">
        <child value="Product" label="Product"/>
      </item>
    </hierarchies>
    <sorts>
      <categorySort item="Channel" direction="DESCENDING"/>
      <categorySort item="Year" direction="ASCENDING"/>
      <qdrSliceSort direction="DESCENDING" edge="rows" grouped="true"
nullsFirst="true">
        <item name="Geography" value="World"/>
      </qdrSliceSort>
    </sorts>
  </pivotTableDataMap>
</pivotTable>
```

36.2.3.2 Custom Aggregation of Duplicate Rows

If you want the pivot table to use a different mathematical operation to aggregate the data values of duplicate rows, then you set the defaultAggregateType to the desired operation.

Example 36–4 shows a data element with the defaultAggregateType set to SUM. This operation would be appropriate if you want to see the total of sales from all stores for each unique combination of Product, Channel, and State.
Example 36–4  Binding XML for Custom Aggregation of Duplicate Rows

```xml
<pivotTable IterBinding="SalesPivotTable1Iterator" id="SalesPivotTable11"
xmlns="http://xmlns.oracle.com/adfm/dvt">
<pivotTableDataMap>
  <columns>
    <data aggregateDuplicates="true" defaultAggregateType="SUM">
      <item value="Sales"/>
    </data>
    <item value="Geography"/>
  </columns>
  <rows>
    <item value="Channel"/>
    <item value="Product"/>
  </rows>
  <aggregatedItems>
    <item aggregateLocation="After" aggregateType="AVERAGE"
      value="Product" aggregateLabel="Average"/>
  </aggregatedItems>
</pivotTableDataMap>
</pivotTable>
```

If you have a pivot table with multiple data values (such as sales and the average size of a store in square feet) and you want to sum the sales data values in duplicate rows, but you want to average the square feet data values, then do the following:

- On the `<data>` element, set the `defaultAggregateType` to `SUM`.
- On the `<item>` element for the square feet attribute, set the `aggregateType` to `AVERAGE`.

Example 36–5 shows the `<columns>` elements wrapped by a `PivotTableDataMap` element. The `<data>` element contains the default attributes for aggregation. These apply to all data items that do not have a specific custom `aggregateType` attribute specified.

Example 36–5  Data and Item Elements for Multiple Custom Aggregations

```xml
<columns>
  <data aggregateDuplicates="true" defaultAggregateType="SUM">
    <item value="Sales" label="Total Sales"/>
    <item value="StoreSqFeet" label="Avg Sq Feet" aggregateType="AVERAGE"/>
  </data>
  <item value="State"/>
</columns>
```

36.2.4 What You May Need to Know About Specifying an Initial Sort for a Pivot Table

By default, a pivot table initially sorts data based on values in the outer row data layer. You can specify sort order on the data layer of any row, column, or page item, called a category sort. At runtime, when the data layer is pivoted to a different edge, the specified category sort order is honored. Insert a `categorySort` element inside the `sorts` element and set values for the attributes as described in Table 36–1.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>item</code></td>
<td>Specify the column, row, or page item for which you are setting the category sort. A value for this attribute is required.</td>
</tr>
</tbody>
</table>
Creating Databound Pivot Tables

Creating Databound Pivot Table and Pivot Filter Bar Components

You can also specify the initial sort order of the data values in the data body when the pivot table is rendered, called a data sort. You can change the default behavior by inserting a sorts element inside the pivotTableDataMap element of a pivot table binding in the page definition file. Insert a qdrSliceSort element inside the sorts element and set values for the attributes as described in Table 36-2.

Table 36-2 Attribute Values for qdrSliceSort Element

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>direction</td>
<td>Specify the initial direction of the sort. Valid values are ASCENDING and DESCENDING. A value for this attribute is required.</td>
</tr>
<tr>
<td>edge</td>
<td>Specify columns or rows to determine which edge sorts data. A value for this attribute is required.</td>
</tr>
<tr>
<td>grouped</td>
<td>Specify true if you want to sort slices within their parent or false if you want to sort across the entire edge. A value for this attribute is optional. The default value is false.</td>
</tr>
<tr>
<td>nullsFirst</td>
<td>Specify true if you want null values to appear at the beginning of a sort and false if you want null values to appear at the end of a sort. The default value is false. A value for this attribute is optional.</td>
</tr>
</tbody>
</table>

Insert one or more item tags inside the qdrSliceSort tag. An item tag specifies the slice on the opposite edge from which the values to be sorted should be obtained. For example, if sorting rows based upon the data, then you must specify an item tag for each layer on the column edge. Set values for the attributes as described in Table 36-3.

Table 36-3 Attribute Values for item Tag

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>Specify the name of the layer to sort on. Typically, this is the column name in the row set. Specify DataLayer to identify the layer that contains the data columns in a row set (for example, Sales, Costs, and so on).</td>
</tr>
<tr>
<td>value</td>
<td>Specify the value of the specified layer on the desired slice.</td>
</tr>
</tbody>
</table>

36.2.5 What You May Need to Know About Configuring Editable Data Cells

By default, the data cells in a pivot table are not editable. When you create a pivot table using ADF data controls, an af:outputText component is automatically stamped for each data cell. You can also use the Create Pivot Table wizard to configure a data cell as editable by specifying an af:inputText component and the tag and its corresponding f:validator tag will be stamped in the data cell as illustrated in Example 36-6.

Example 36-6 Code Sample for Editable Data Cell

```xml
<dvt:dataCell>
  <af:switcher facetName="#{cellStatus.members.DataLayer.value}"
    defaultFacets="Default" id="s2">
    <f:facet name="AmountInStock">
      <af:inputText value="#{cellData.dataValue}"
```

Table 36-1 (Cont.) Attribute Values for categorySort Element

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>direction</td>
<td>Specify the initial direction of the sort. Valid values are ASCENDING and DESCENDING. A value for this attribute is required.</td>
</tr>
</tbody>
</table>

Table 36-1 (Cont.) Attribute Values for categorySort Element

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>direction</td>
<td>Specify the initial direction of the sort. Valid values are ASCENDING and DESCENDING. A value for this attribute is required.</td>
</tr>
<tr>
<td>edge</td>
<td>Specify columns or rows to determine which edge sorts data. A value for this attribute is required.</td>
</tr>
<tr>
<td>grouped</td>
<td>Specify true if you want to sort slices within their parent or false if you want to sort across the entire edge. A value for this attribute is optional. The default value is false.</td>
</tr>
<tr>
<td>nullsFirst</td>
<td>Specify true if you want null values to appear at the beginning of a sort and false if you want null values to appear at the end of a sort. The default value is false. A value for this attribute is optional.</td>
</tr>
</tbody>
</table>

36.2.5 What You May Need to Know About Configuring Editable Data Cells

By default, the data cells in a pivot table are not editable. When you create a pivot table using ADF data controls, an af:outputText component is automatically stamped for each data cell. You can also use the Create Pivot Table wizard to configure a data cell as editable by specifying an af:inputText component and the tag and its corresponding f:validator tag will be stamped in the data cell as illustrated in Example 36-6.

Example 36-6 Code Sample for Editable Data Cell

```
<dvt:dataCell>
  <af:switcher facetName="#{cellStatus.members.DataLayer.value}"
    defaultFacets="Default" id="s2">
    <f:facet name="AmountInStock">
      <af:inputText value="#{cellData.dataValue}"
```
Creating Databound Pivot Tables

You can also configure pivot table data cells to use most components that implement the `EditableValueHolder` or `ActionSource` interfaces as a child of the `dataCell` component, for example, `af:selectBooleanCheckbox` or `af:inputComboboxListofValues`. For more information, see the "How to Configure Header and Data Cell Stamps" section in the *Developing Web User Interfaces with Oracle ADF Faces*. 

```
label='#{bindings.WorldProductInventory1.hints.AmountInStock.label}'
required='#{bindings.WorldProductInventory1.hints.AmountInStock.mandatory}'
columns='#{bindings.WorldProductInventory1.hints.AmountInStock.displayWidth}'
maximumLength='#{bindings.WorldProductInventory1.hints.AmountInStock.precision}'
shortDesc='#{bindings.WorldProductInventory1.hints.AmountInStock.tooltip}'
id='it1'>
    <f:validator binding='#{cellData.bindings.AmountInStock.validator}'/>
</af:inputText>
</f:facet>
<f:facet name="ReorderPoint">
    <af:outputText value='#{cellData.dataValue}' id='ot8'>
        <af:convertNumber groupingUsed='false'
            pattern='#{bindings.WorldProductInventory1.hints.ReorderPoint.format}'/>
    </af:outputText>
</f:facet>
<f:facet name="Default">
    <af:outputText value='#{cellData.dataValue}' id='ot10'/> 
</f:facet>
</af:switcher>
</dvt:dataCell>

You can also configure pivot table data cells to use most components that implement the `EditableValueHolder` or `ActionSource` interfaces as a child of the `dataCell` component, for example, `af:selectBooleanCheckbox` or `af:inputComboboxListofValues`. For more information, see the "How to Configure Header and Data Cell Stamps" section in the *Developing Web User Interfaces with Oracle ADF Faces*. 

```
label='#{bindings.EmpView1.hints.Sal.label}'
required='#{bindings.EmpView1.hints.Sal.mandatory}'
columns='#{bindings.EmpView1.hints.Sal.displayWidth}'
maximumLength='#{bindings.EmpView1.hints.Sal.precision}'
shortDesc='#{bindings.EmpView1.hints.Sal.tooltip}'>
    <f:validator binding='#{cellData.bindings.Sal.validator}'/>
</af:inputText>
</f:facet>
<f:facet name="Default">
    <af:inputText value='#{cellData.dataValue}' id='ot6'/>
</f:facet>
</af:switcher>
</dvt:dataCell>

You can also configure pivot table data cells to use most components that implement the `EditableValueHolder` or `ActionSource` interfaces as a child of the `dataCell` component, for example, `af:selectBooleanCheckbox` or `af:inputComboboxListofValues`. For more information, see the "How to Configure Header and Data Cell Stamps" section in the *Developing Web User Interfaces with Oracle ADF Faces*. 

```
label='#{bindings.EmpView1.hints.Sal.label}'
required='#{bindings.EmpView1.hints.Sal.mandatory}'
columns='#{bindings.EmpView1.hints.Sal.displayWidth}'
maximumLength='#{bindings.EmpView1.hints.Sal.precision}'
shortDesc='#{bindings.EmpView1.hints.Sal.tooltip}'>
    <f:validator binding='#{cellData.bindings.Sal.validator}'/>
</af:inputText>
</f:facet>
<f:facet name="Default">
    <af:inputText value='#{cellData.dataValue}' id='ot6'/>
</f:facet>
</af:switcher>
</dvt:dataCell>

You can also configure pivot table data cells to use most components that implement the `EditableValueHolder` or `ActionSource` interfaces as a child of the `dataCell` component, for example, `af:selectBooleanCheckbox` or `af:inputComboboxListofValues`. For more information, see the "How to Configure Header and Data Cell Stamps" section in the *Developing Web User Interfaces with Oracle ADF Faces*. 

```
label='#{bindings.EmpView1.hints.Sal.label}'
required='#{bindings.EmpView1.hints.Sal.mandatory}'
columns='#{bindings.EmpView1.hints.Sal.displayWidth}'
maximumLength='#{bindings.EmpView1.hints.Sal.precision}'
shortDesc='#{bindings.EmpView1.hints.Sal.tooltip}'>
    <f:validator binding='#{cellData.bindings.Sal.validator}'/>
</af:inputText>
</f:facet>
<f:facet name="Default">
    <af:inputText value='#{cellData.dataValue}' id='ot6'/>
</f:facet>
</af:switcher>
</dvt:dataCell>

You can also configure pivot table data cells to use most components that implement the `EditableValueHolder` or `ActionSource` interfaces as a child of the `dataCell` component, for example, `af:selectBooleanCheckbox` or `af:inputComboboxListofValues`. For more information, see the "How to Configure Header and Data Cell Stamps" section in the *Developing Web User Interfaces with Oracle ADF Faces*. 

```
label='#{bindings.EmpView1.hints.Sal.label}'
required='#{bindings.EmpView1.hints.Sal.mandatory}'
columns='#{bindings.EmpView1.hints.Sal.displayWidth}'
maximumLength='#{bindings.EmpView1.hints.Sal.precision}'
shortDesc='#{bindings.EmpView1.hints.Sal.tooltip}'>
    <f:validator binding='#{cellData.bindings.Sal.validator}'/>
</af:inputText>
</f:facet>
<f:facet name="Default">
    <af:inputText value='#{cellData.dataValue}' id='ot6'/>
</f:facet>
</af:switcher>
</dvt:dataCell>

You can also configure pivot table data cells to use most components that implement the `EditableValueHolder` or `ActionSource` interfaces as a child of the `dataCell` component, for example, `af:selectBooleanCheckbox` or `af:inputComboboxListofValues`. For more information, see the "How to Configure Header and Data Cell Stamps" section in the *Developing Web User Interfaces with Oracle ADF Faces*. 

```
label='#{bindings.EmpView1.hints.Sal.label}'
required='#{bindings.EmpView1.hints.Sal.mandatory}'
columns='#{bindings.EmpView1.hints.Sal.displayWidth}'
maximumLength='#{bindings.EmpView1.hints.Sal.precision}'
shortDesc='#{bindings.EmpView1.hints.Sal.tooltip}'>
    <f:validator binding='#{cellData.bindings.Sal.validator}'/>
</af:inputText>
```
This chapter describes how to create geographic or thematic maps from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization map and thematicMap components to create geographic or thematic maps that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.

If you are designing your page using simple UI-first development, then you can add the geographic or thematic map to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the map components, see the "Using Map Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.

This chapter includes the following sections:

- Section 37.1, "About ADF Data Visualization Map Components"
- Section 37.2, "Creating Databound Geographic Maps"
- Section 37.3, "Creating Databound Thematic Maps"

### 37.1 About ADF Data Visualization Map Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

The geographic map component represents business data spatially, enabling you to superimpose multiple layers, also referred to as themes, of information on a single map. For example, a map of the United States might use a color theme that provides varying color intensity to indicate the popularity of a product within each state, a pie chart theme that shows sales within product category, and a point theme that identifies the exact location of each warehouse. When all three themes are superimposed on the United States map, you can easily evaluate whether there is sufficient inventory to support the popularity level of a product in specific locations. Geographic maps require a connection to an Oracle MapViewer service, and optionally, a geocoder service to display geographical and political detail.

Thematic map components represent business data as patterns in stylized areas or associated markers and does not require a connection to an Oracle MapViewer service. Thematic maps focus on data without the geographic details in a geographic map. The thematic map is packaged with prebuilt base maps including a USA base map, a world
About ADF Data Visualization Map Components

base map, and base maps for continents and regions of the world including EMEA and APAC. Each base map includes several sets of regions and one fixed set of cities. A set of regions or cities is referred to as a layer. Each layer can be bound to a data collection and stylized to represent the data with color and pattern fills, or a data marker, or both. At runtime, only one map layer and its associated data can be displayed at a time, unless the thematic map has been enabled for drilling.

The prefix `dvt:` occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

### 37.1.1 Use Cases and Examples

For detailed descriptions of each data visualization use cases and examples, see the "Map Component Use Cases and Examples" section in *Developing Web User Interfaces with Oracle ADF Faces*.

### 37.1.2 End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the "End User and Presentation Features of Maps" section in *Developing Web User Interfaces with Oracle ADF Faces*.

### 37.1.3 Additional Functionality for Data Visualization Components

You may find it helpful to understand other Oracle ADF features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the "Rerendering Partial Page Content" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the "Allowing User Customization on JSF Pages" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- Accessibility: By default, data visualization components are accessible. You can configure your application pages for accessibility to screen readers. For more information, see the "Developing Accessible ADF Faces Pages" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (`styleClass` or `inlineStyle`). For more information, see the "Customizing the Appearance Using Styles and Skins" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages
before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Chapter 19, "Designing a Page Using Placeholder Data Controls."

### 37.2 Creating Databound Geographic Maps

A geographic map is an ADF Data Visualization component that provides the functionality of Oracle Spatial within Oracle ADF. This component allows users to represent business data on a geographic map and to superimpose multiple layers of information (known as themes) on a single map. These layers can be represented as any of the following themes: bar graph, pie graph, color, point, and predefined theme.

Figure 37–1 shows a geographic map component that uses a base map for a region in the United States with the following themes:

- **Color theme**: For the selected product, this theme colors states based on product popularity. The colors range from green, representing the highest popularity for that product, to red, representing the lowest popularity for that product.
- **Pie graph theme**: This theme displays a pie graph in each state to indicate the popular product categories in that state. In this example, the pie graph shows the product categories as pie slices for Media, Office, and Electronics.
- **Point theme**: This theme identifies warehouses as points. For each point, it displays an icon to indicate the inventory level at that warehouse for the selected product. A separate icon is displayed for each of the following ranges of inventory: low inventory, medium inventory, and high inventory.

Figure 37–1  Geographic Map with Color Theme, Pie Graph Theme, and Point Theme

A geographic map component differs from other ADF Data Visualization components as you do not need to put multiple maps on a page to display multiple sets of data. This contrasts to components such as graphs where you can put multiple graphs on a page. Instead, you show how multiple sets of data relate to each other spatially or, for a specific point, you display different attributes layered in separate themes.
The geographic map component itself is not bound to data. However, each map theme has its own data bindings.

A base map forms the background on which the ADF geographic map component layers the themes that developers create.

In Oracle Spatial, administrators create base maps that consist of one or more themes. The administrator controls the visibility of the base map themes. When you zoom in and out on a base map, various base map themes are hidden or displayed. At the ADF geographic map component level, you cannot use zoom factor to control the display of the themes created by the administrator on the base map.

When you overlay themes on the ADF geographic map, you can control the visibility of your themes by setting the maxZoom and minZoom properties of the components related to these themes. At runtime, you can also hide or display your custom themes by using the View menu of the Map toolbar or by using other ADF components that you create on the page.

For information about customizing a geographic map after data-binding is completed, see the "Using Map Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.

### 37.2.1 How to Configure a Geographic Base Map

To create a geographic map, you first configure the map before you bind a point, pie or bar graph, or color theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel for the theme you want to create.

**Before you begin:**
It may be helpful to have an understanding of databound geographic maps. For more information, see Section 37.2, "Creating Databound Geographic Maps."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the pivot table, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for Product Inventory pivot table shown in Figure 37–1 comes from a view object created for the Summit sample application for ADF DVT components.

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

**To configure a geographic base map:**

1. From the Data Controls panel, select a collection.

   For example, to create a geographic map that displays product inventory levels in warehouses throughout the World, you could select the WorldProductInventory1 collection in the Data Controls panel, as shown in Figure 37–2.
2. Drag the data collection onto a JSF page and, from the context menu, choose Geographic Map > Map and Point, Pie Graph, Color, or Bar Graph Theme.

3. If you have not yet configured a map on the page, in the Create Geographic Map dialog, click the New icon to display the Create Geographic Map Configuration dialog and do the following:
   a. In the Id field enter the unique identifier for the map configuration. For example, mapConfig1.
   b. In the MapViewer URL field enter the URL for the Oracle MapViewer service. Use the dropdown list to select an existing connection, or click the Add icon to configure a new connection. In the Create URL Connection dialog use the address http://elocation.oracle.com/mapviewer for the URL endpoint and click Test Connection to confirm the connection. Figure 37–3 shows the completed Create URL dialog.
c. In the **Geocoder URL** field enter the URL for the Geocoder web service that converts street addresses into latitude and longitude coordinates for mapping.

---

**Note:** The Geocoder URL is needed only if you do *not* already have longitude and latitude information for addresses.

---

Use the dropdown list to select an existing connection, or click the Add icon to configure a new connection. In the Create URL Connection dialog use the address `http://elocation.oracle.com/geocoder/gcserver` for the URL endpoint and click **Test Connection** to confirm the connection. **Figure 37–4** shows the completed Create URL dialog.
d. Click OK. Figure 37–5 shows the completed Create Geographic Map Configuration dialog.

4. Click OK.
5. In the Create Geographic Map dialog, select the base map for the geographic map component and provide other settings to use with the map by doing the following:
   a. From the Data Source list select the collection of maps from which you will choose a base map.
   b. From the Base Map list select the map that will serve as the background for the geographic map component.
   c. To specify values for the StartingX field and the StartingY field click on the image of the map to center it within the Preview window.
Creating Databound Geographic Maps

You can use the arrows in the map navigator in the upper left-hand corner to move the map in the appropriate direction.

d. Optionally use the sliding arrow in the Preview window to adjust the zoom factor of the map.

e. Click OK. Figure 37–5 shows the completed Create Geographic Map dialog.

**Figure 37–6  Create Geographic Map Dialog**

6. Use the Create Theme dialog to data bind a map theme as follows:

- Create a point theme to represent data on the base map. For more information, see Section 37.2.2, "How to Create a Geographic Map with a Point Theme."

- Create a color theme to represent data on the base map. For more information, see Section 37.2.6, "How to Create a Geographic Map with a Color Theme."

- Create a pie or bar graph theme to represent data on the base map. For more information, see Section 37.2.9, "How to Create a Geographic Map with a Pie or Bar Graph Theme."

### 37.2.2 How to Create a Geographic Map with a Point Theme

You can create a geographic map with a point theme to display specific locations in a map, identified by latitude and longitude or address. For example, a point theme might identify the locations of warehouses in a map. If you customize the style of the point that is displayed, you could choose to use a different image for a warehouse product count (high, acceptable, low) in a set of warehouses to differentiate them from each other.

To create a geographic map with a point theme, you first configure the base map and then bind a point theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.
You can also layer a point theme on a base map that has already been configured and bound to another theme.

For example, the geographic map in Figure 37–7 has a point theme that identifies the location of warehouses and their product count levels in the United States.

**Figure 37–7 Geographic Map with Point Theme**

Before you begin:

It may be helpful to have an understanding of databound geographic maps. For more information, see Section 37.2, "Creating Databound Geographic Maps."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the geographic map with point theme, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for the geographic map point theme shown in Figure 37–7 comes from a view object created for the Summit ADF DVT sample application.

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

**To create a geographic map with a databound point theme:**

1. From the Data Controls panel, select a collection.
Figure 37–8 shows an example where you could select the SWarehouseView1 collection in the Data Controls panel to create a geographic map with a point theme that displays an image to identify the location of each warehouse, styled to represent the product count level.

**Figure 37–8  Data Collection for Warehouse Location and Product Count**

2. Drag the collection onto a JSF page and, from the context menu, choose **Geographic Map > Map and Point Theme**.

3. If you have not yet configured a map on the page, complete the Create Geographic Map dialog. For more information, see Section 37.2.1, "How to Configure a Geographic Base Map." Otherwise, do one of the following:
   - Use the dropdown list to select the map configuration you wish to use
   - Click **OK** to accept the available map configuration
   - Click **New** to configure a new base map
   - Click **Edit** to modify the available map configuration

4. If you are layering a point theme on a base map that has already been configured and bound to another theme, in the Create dialog select **Point Theme**.

5. In the Create Point Map Theme dialog, in the **Theme Id** field, enter the unique identifier for the point map theme.

6. In the **Location** section, choose whether the point location is to be specified by **Address** or by a pair of **x** and **y** coordinates (Longitude and Latitude).
   The choice you select for location will determine which controls appear in the Location section.

   **Tip:** Using **x** and **y** coordinates is a more efficient way to present data on the map rather than using the Address controls, which must be converted by a Geocoder to **x** and **y** coordinates. If the data collection has more than 100 rows, use **x** and **y** coordinates for better performance.

7. For the **x** and **y** point location, select attributes from the data collection that represents the following items:
   - **X** (Longitude): The horizontal location of the point on the map.
   - **Y** (Latitude): The vertical location of the point on the map.
Label: The labels for the points in the top section of the information window, which is displayed when you click a point.

8. In the Point Data section, provide the following information that identifies the data associated with the point, its label, and optionally the style for the point:

- In the Data field, select the data column that is associated with the point, such as ProductCount.

- In the Label field, enter the text that will appear in the information window before the data value when you click a point. You can enter a text resource to use for the label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click Help.

- Optionally, in the Category field, select a data column to use for finding the appropriate style for a point. If you select a value for Category, that value is stored in the binding for this point theme and then matched against the itemValue attribute of the mapPointStyleItem tags that you create for this point theme.

Note: If your data does not have a column that you want to use as a category for finding the style of a point, you can also use mapPointStyleItem tags to define styles related to data ranges (such as high, acceptable, and low) that are matched to the values in the column that you select in the Data field. For more information, see Section 37.2.3, “How to Create Point Style Items for a Point Theme”.

9. Select the Enable Row Selection if you want to enable master-detail relationships. This is useful when the data collection for the geographic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. Selecting this option enables both selectionListener and clickListener attributes.

10. Click OK.

Figure 37–9 shows the completed Create Point Map Theme dialog for a geographic map with a point theme that displays an image representing the location and product count levels for each warehouse point.
After you create a map point theme, you can further customize the style of the points that appear in the map to represent more detailed information. For example, the map point theme in Figure 37–7 uses a different image to represent the levels (high, acceptable, low) for the product count in each warehouse. For each different point style, use a mapPointStyleItem tag. For more information, see Section 37.2.3, "How to Create Point Style Items for a Point Theme."

37.2.3 How to Create Point Style Items for a Point Theme

There are a variety of options available for creating point style items for use in a given map point theme. These are:

- A single image for all data points
- Separate images for each data point category
- Images that represent low, medium, and high data value ranges

After you create the data binding for a map point theme, you have the option of selecting a single built-in image that should be used for all points in that map theme. In the Properties window, you can make this selection in the builtInImage attribute of the mapPointTheme tag. The default value for this attribute is an orange ball.

Alternatively, if you specify a value for Category in the Create Point Map Theme dialog, then you should also create a set of point style items to determine a separate image that represents data points in each category. In this case, you do not use the minimum and maximum values in the point style item tags. Instead, you set the itemValue attribute of point style item tags to a value that matches entries in the data column that you specified for Category.

In a point theme for a geographic map, if you do not specify a value for Category, you can still use the mapPointStyleItem child tags of the mapPointTheme tag to specify ranges of values (such as low, medium, and high) and the images that are to represent these ranges. If you do this, then each point will be represented by an image that identifies the range in which the data value for that point falls.
Before you begin:

It may be helpful to have an understanding of databound geographic maps. For more information, see Section 37.2, "Creating Databound Geographic Maps."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the geographic map with point theme, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for the geographic map point theme shown in Figure 37–7 comes from a view object created for the Summit ADF DVT sample application.

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

- Add a geographic map with a point theme to your page. For more information, see Section 37.2.2, "How to Create a Geographic Map with a Point Theme."

To add point style items to a map point theme to represent data value ranges:

1. In the Structure window, right-click the `dvt:mapPointTheme` tag and choose `Insert inside the Point Theme > Point Style Item`.

2. In the Point Style Item Properties window, set values as described Table 37–1, "Properties for Point Style Item".

Table 37–1 Properties for Point Style Item

<table>
<thead>
<tr>
<th>For this property</th>
<th>Set this value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Id</td>
<td>Specify a unique ID for the point style item.</td>
</tr>
<tr>
<td>MinValue</td>
<td>Specify the minimum value in a data range that you define.</td>
</tr>
<tr>
<td>MaxValue</td>
<td>Specify the maximum value in a data range that you define.</td>
</tr>
<tr>
<td>ShortLabel</td>
<td>Specify text to appear when a user hovers over the point item. For example, if you define a point item for low inventory, then enter Low Inventory as the value for this property.</td>
</tr>
<tr>
<td>ImageURL</td>
<td>Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears on the map to represent the data range identified by the MinValue and MaxValue properties. Alternatively, you can select one of a number of predefined images referenced by the BuiltInImage dropdown list that appears in the Other section.</td>
</tr>
<tr>
<td>HoverImageURL</td>
<td>Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears when a user hovers over the point item.</td>
</tr>
<tr>
<td>SelectedImageURL</td>
<td>Specify the URL to the image file or select it from the dropdown list. At runtime, the image you specify appears when a user selects the point item.</td>
</tr>
</tbody>
</table>

3. If you defined a data value range for a low data value range in Steps 1 and 2, then repeat Steps 1 and 2 to define medium and high data value ranges with appropriate values.
Creating Databound Geographic Maps

37.2.4 What Happens When You Create a Geographic Map with a Point Theme

Creating a geographic map with a point theme from the Data Controls panel has the following effect:

- Creates the bindings for the point theme and adds the bindings to the page definition file
- Adds the necessary tags to the JSF page for the geographic map component
- Adds the necessary point theme child tags within the geographic map tag to the JSF page

Example 37–1 shows the row set bindings that were generated for the geographic map with a point theme.

**Example 37–1 Point Theme Binding XML**

```xml
<bindings>
  <mapTheme xmlns="http://xmlns.oracle.com/adfm/dvt"></mapTheme>
  <mapTheme IterBinding="WorldProductInventory1Iterator" id="WorldProductInventory1"
            xmlns="http://xmlns.oracle.com/adfm/dvt">
    <mapThemeDataMap convert="false" mapThemeType="point">
      <data>
        <item value="AmountInStock"
              label="${adfBundle['view.ViewControllerBundle'].AMOUNT_IN_STOCK}"/>
        <item type="us_form_2" street="Address" city="City" state="State"
              zipCode="ZipCode" label="WarehouseId"/>
      </data>
    </mapThemeDataMap>
  </mapTheme>
  <mapTheme IterBinding="SWarehouseView1Iterator" id="SWarehouseView1"
            xmlns="http://xmlns.oracle.com/adfm/dvt">
    <mapThemeDataMap convert="false" mapThemeType="point">
      <data>
        <item value="ProductCount"
              label="${adfBundle['view.ViewControllerBundle'].PRODUCT_COUNT}"/>
        <item type="lat_long" longitude="Longitude" latitude="Latitude"
              label="ProductCount"/>
      </data>
    </mapThemeDataMap>
  </mapTheme>
</bindings>
```

Example 37–2 shows the XML code generated on the JSF page for the geographic map and its point theme.

**Example 37–2 Geographic Map and Point Theme XML Code on the JSF Page**

```xml
<dvt:map id="map" startingX="-104.15" mapServerConfigId="mapConfig1"
Note: The use of mapPointStyleItem child tags to customize the style of points is a declarative approach that lets you provide custom point images. For information about using a callback to provide not only custom images but also custom HTML, see Section 37.2.5, "What You May Need to Know About Adding Custom Point Style Items to a Map Point Theme".

37-14 Developing Fusion Web Applications with Oracle Application Development Framework
37.2.5 What You May Need to Know About Adding Custom Point Style Items to a Map Point Theme

If you want to provide custom HTML as well as custom images for map points, then you can use the `customPointCallback` attribute of the `mapPointTheme` tag to accomplish this customization.

---

**Important:** If you set the `customPointCallback` attribute for a map point theme, the map ignores any `dvt:mapPointStyleItem` child tags because the callback overrides these tags.

---

To use a callback to customize the style of map points:

1. Write a method in Java to perform the desired point customization.
2. Store this method in a managed bean for the map.
   
   For more information about managed beans, see the "Creating and Using Managed Beans" section in *Developing Web User Interfaces with Oracle ADF Faces*.
3. After you finish data-binding the map point theme, use the Properties window to specify a reference to the managed bean method in the `customPointCallback` attribute of the `dvt:mapPointTheme` tag.
   
   For example, if the managed bean is named `MapSampleBean` and the method is named `setCustomPointStyle`, then the reference becomes `#{mapSampleBean.CustomPointStyle}`.

---

37.2.6 How to Create a Geographic Map with a Color Theme

You can create a geographic map with a color theme to display areas of the map in colors. For example, a color theme might identify the states with warehouses, styled with a range of color to represent stock levels in each state.

To create a geographic map with a color theme, you first configure the base map and then bind a color theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel. You can also layer a color theme on a base map that has already been configured and bound to another theme.
For example, the geographic map in Figure 37–10 has a color theme that identifies the states with warehouses styled to represent stock levels for each state.

Figure 37–10 Geographic Map with Color Theme

Before you begin:
It may be helpful to have an understanding of databound geographic maps. For more information, see Section 37.2, “Creating Databound Geographic Maps.”

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

■ Create an application module that contains instances of the view objects that you want in your data model for the geographic map with color theme, as described in Section 13.2, "Creating and Modifying an Application Module."

For example, the data source for the geographic map with color theme shown in Figure 37–10 comes from a view object created for the Summit ADF DVT sample application.

■ Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

To create a geographic map with a databound color theme:
1. From the Data Controls panel, select a collection.
Figure 37–11 shows an example where you could select the WorldProductInventory1 collection in the Data Controls panel to create a color map theme that shows product inventory levels by the color of regions, in this example, US States.

Figure 37–11  Data Collection for Product Inventory Levels

2. Drag the collection onto a JSF page which already contains a geographic map component and, from the context menu, choose Geographic Map > Map and Color Theme.

3. If you have not yet configured a map on the page, complete the Create Geographic Map dialog. For more information, see Section 37.2.1, “How to Configure a Geographic Base Map.” Otherwise, do one of the following:
   - Use the dropdown list to select the map configuration you wish to use
   - Click OK to accept the available map configuration
   - Click New to configure a new base map
   - Click Edit to modify the available map configuration

4. If you are layering a color theme on a base map that has already been configured and bound to another theme, in the Create dialog select Color Theme.

5. In the Create Color Map Theme dialog, in the Theme Id field, enter a unique identifier for the map theme in the Id field.

6. In the Base Map Theme section, identify the base map color theme to use for the geographic map by doing the following:
   a. In the Name field, select the name of the base map theme.
   b. For Location, select the location column in the data collection that should be matched to the location column in the base map theme that you selected.
c. Optionally, click View Sample Theme Data to display the Sample Theme Data dialog, in which you can examine the first several rows of the actual data so that you can identify the appropriate location column.

For example, if you want to view the data for a region that consists of states in the United States map, you might select MAP_STATES_NAME as shown in Figure 37–12.

**Note:** It is possible for an administrator of Oracle Spatial to disable the display of sample data. If this button is not available, then consult the administrator for guidance.

![Sample Theme Data for Regions or States](image)

7. In the Appearance section, specify the look of the color theme as follows:

   a. In Data Bucket Count, enter the number of groups for the data in this geographic map. Each group is coded with a color. After specifying this number, you can provide colors for the minimum value and the maximum value. The colors for the other values are chosen automatically using an RGB algorithm.

   b. In Minimum Value Color, select the color for the minimum value.

   c. In Maximum Value Color, select the color for the maximum value.

**Note:** If you want to specify an exact color for each data bucket, see Section 37.2.8, "What You May Need to Know About Customizing Colors in a Map Color Theme".

8. In the Data section, provide the following information about the data in the collection:

   a. For Location, select the column in the data collection that should match the values in the location column that you selected from the base map theme.

   b. For Location Label, select the column in the data collection that contains the labels associated with the values in the location column. These labels are shown in the information window that is displayed when you click or hover over a color.

   c. For Data Label, enter the label to use for describing the data in the information window and the tooltip that is displayed when you click or hover over a color. For example, the information window might include a label
before the data value, such as **Product Popularity**. You can also enter a text resource to use for the data label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime for a dynamic label. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

9. Use **Enable Row Selection** only if you want to enable master-detail relationships. This is useful when the data collection for the map theme is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page.

**Figure 37–13** shows the Create Color Map Theme dialog for the product popularity by state color theme.

**Figure 37–13   Create Color Map Theme for Product Popularity By State**

37.2.7 What Happens When You Add a Color Theme to a Geographic Map

Dropping a color theme from the Data Controls panel to an existing geographic map has the following effect:

- Creates the bindings for the color theme and adds the bindings to the page definition file
- Adds the necessary color theme child tags within the geographic map tag to the JSF page

**Example 37–3** shows the row set bindings that were generated for the color theme of the geographic map.

**Example 37–3   Color Theme Binding XML**

```xml
<bindings>
  <mapTheme IterBinding="WorldProductInventory1Iterator"
    id="WorldProductInventory1"
    xmlns="http://xmlns.oracle.com/adfm/dvt">
    <mapThemeDataMap convert="false" mapThemeType="color">
      <item type="location" value="State" label="State"/>
    </mapThemeDataMap>
    <item type="dataValue" value="ReorderPoint"/>
    <item type="dataLabel" value="Reorder Point"/>
  </mapTheme>
</bindings>
```
Creating Databound Geographic Maps

Example 37–4 shows the XML code generated on the JSF page for a color theme that represents product popularity in different states on the United States map.

Example 37–4  Color Theme XML Code on the JSF Page

```xml
<dvt:map id="map" startingX="-102.39" mapServerConfigId="mapConfig1"
    baseMapName="ELOCATION_MERCATOR.WORLD_MAP"
    mapZoom="3" inlineStyle="width:600px; height:375px;" startingY="40.27"
    summary="Geographic map with color theme">
    <dvt:mapColorTheme id="mapColorTheme" themeName="MAP_STATES_ABBRV"
        value="#{bindings.WorldProductInventory1.geoMapModel}"
        bucketCount="5" minColor="#ff0000"
        maxColor="#00ff00" locationColumn="STATE_ABRV"/>
</dvt:map>
```

37.2.8 What You May Need to Know About Customizing Colors in a Map Color Theme

While you are data-binding a map color theme, you can specify only a minimum color and a maximum color for the data buckets. The map uses an algorithm to determine the colors of the buckets between the minimum and maximum. However, after the data-binding is finished, you have the option of specifying the exact color to be used for each data bucket.

In the Properties window, for the `dvt:mapColorTheme` tag you can use the `colorList` attribute to specify the color for each bucket. You can either bind a color array to this attribute or you can specify a string of colors using a semicolon separator.

For example, if the value of this attributes is set to: `#ff0000;#00ff00;#0000ff`, then the color of the first bucket is red, the second bucket is green, and the third bucket is blue.

37.2.9 How to Create a Geographic Map with a Pie or Bar Graph Theme

You can create a geographic map with a pie or bar graph theme to display specific locations in a map, identified by latitude and longitude or address. For example, a point theme might identify the locations of warehouses in a map. If you customize the style of the point that is displayed, you could choose to use a different image for the warehouse product count (high, acceptable, low) in a set of warehouses to differentiate them from each other.

To create a geographic map with a pie or bar graph theme, you first configure the base map and then bind a pie or bar graph theme of the map to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel. You can also layer a pie or bar graph theme on a base map that has already been configured and bound to another theme.

For example, the geographic map in Figure 37–14 has a point theme that identifies the location of warehouses and their product count levels in the United States.
For example, the geographic map in Figure 37–14 has a point theme that identifies the location of warehouses and their product count levels in the United States.
Before you begin:
It may be helpful to have an understanding of databound geographic maps. For more information, see Section 37.2, "Creating Databound Geographic Maps."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the geographic map with a pie or bar graph theme, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for the pie graph theme shown in Figure 37–14 and the bar graph theme shown in Figure 37–15 comes from a view object created for the Summit ADF DVT sample application.

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

To create a geographic map with databound pie or bar graph theme:

1. From the Data Controls panel, select a collection.

   Figure 37–16 shows an example where you could select the WorldProductInventory1 collection to create a pie or bar graph bar theme in
an existing geographic map component to represent the popular product categories within a state.

Figure 37–16  Data Collection for Inventory Levels by Product

2. Drag the collection onto a JSF page and, from the context menu, choose Geographic Map > Map and Pie (or Bar) Graph Theme.

3. If you have not yet configured a map on the page, complete the Create Geographic Map dialog. For more information, see Section 37.2.1, “How to Configure a Geographic Base Map.” Otherwise, do one of the following:
   - Use the dropdown list to select the map configuration you wish to use
   - Click OK to accept the available map configuration
   - Click New to configure a new base map
   - Click Edit to modify the available map configuration

4. If you are layering a pie graph theme on a base map that has already been configured and bound to another theme, in the Create dialog select Pie Graph Theme.

5. In the Create Pie Graph Theme dialog, do the following to identify the new theme and the base map theme elements that you want to work with:
   a. For Theme Id, enter a unique identifier for the pie graph theme that you are creating.
   b. In the Base Map Theme section, select the name of the base map and the region in which you want to place the pie graphs.

6. In the Appearance section, under Data, do the following:
   a. For Location, select the location column in the data collection that should be matched to the location column in the base map theme that you selected.
If needed, click **View Sample Theme Data** to examine the first several rows of the actual data so that you can identify the appropriate location column.

b. For **Location Label**, select the column in the data collection that contains labels for the locations in the data collection.

c. In the grid for the **Pie Slices Attributes** (for pie graph) or **Series Attributes** (for bar graph), enter each attribute that contains values that you want represented in the pie or bar graph that you are creating.

d. Beside each pie slice or series attribute, enter text that should be used as a label for the data value in the attribute. You can enter the text directly, select **No Label** to suppress the label as in the case of using a single data value, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime.

7. Select **Enable Row Selection** only if you want to enable the selection of rows in a related component. You select this component when the page contains a component that is linked to a data collection that is related to the geographic map that you are creating.

8. Click **OK**.

**Figure 37–17** shows the completed Create Pie Graph Map Theme dialog for the inventory levels by product.

**Figure 37–17  Create Pie Graph Map Theme for Inventory Levels by Product**

![Create Pie Graph Map Theme](image)

**Figure 37–17** shows the completed Create Bar Graph Map Theme dialog for the inventory levels by product.
37.2.10 What Happens When You Add a Pie or Bar Graph Theme to a Geographic Map

Dropping a pie graph theme from the Data Controls panel to an existing geographic map has the following effect:

- Creates the bindings for the pie graph theme and adds the bindings to the page definition file
- Adds the necessary pie graph theme code to the JSF page within the map XML

Example 37–5 shows the row set bindings that were generated for the pie graph theme of the geographic map.

**Example 37–5 Pie Graph Theme Binding XML**

```xml
<mapTheme IterBinding="PopularCategoriesByState1Iterator" id="PopularCategoriesByState1" xmlns="http://xmlns.oracle.com/adfm/dvt">
    <mapThemeDataMap mapThemeType="pieChart">
        <item type='location' value='StateProvince' label='StateProvince'/>
        <data>
            <item value='AudioVideo'
                  label='${adfBundle['view.ViewControllerBundle'].AUDIO_VIDEO}'/>
            <item value='CellPhones'
                  label='${adfBundle['view.ViewControllerBundle'].CELL_PHONES}'/>
            <item value='Games'
                  label='${adfBundle['view.ViewControllerBundle'].GAMES}'/>
        </data>
    </mapThemeDataMap>
</mapTheme>
```

Example 37–6 shows the XML code generated on the JSF page for the pie graph theme of the geographic map.
Creating Databound Thematic Maps

37.3 Creating Databound Thematic Maps

A thematic map represents business data as patterns in stylized areas or associated markers and does not require a connection to a remote Oracle MapViewer service. Thematic maps focus on data without the geographic details in a geographic map.

The thematic map is packaged with prebuilt base maps including a USA base map, a world base map, and base maps for continents and regions of the world including EMEA and APAC. Each base map includes several sets of regions and one fixed set of cities. A set of regions or cities is referred to as a layer. Each layer can be bound to a data collection and stylized to represent the data with color and pattern fills, or a data marker, or both. At runtime, only one map layer and its associated data can be displayed at a time, unless the thematic map has been enabled for drilling.

The data displayed in a thematic map is based on data collections. Using ADF data controls, JDeveloper makes data binding a declarative task. You drag and drop a collection from the Data Controls panel onto the JSF page and use a Component Gallery to select the base map and map layers on which to display the data. You can then use a Layer Browser and binding dialogs to bind data collection attributes to the data layers in the thematic map.

Stamping is used to associate map layers with a row of data in a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image. When you use stamping, child components are not created for every area, marker, or image in a thematic map. Rather, the content of the component is repeatedly rendered, or stamped, once per data attribute, such as the rows in a data collection.

Figure 37–19 shows a thematic map using a USA base map with a states map layer to display customer and warehouse locations, and the product inventory levels for states with warehouses in the Summit ADF DVT sample application. The example illustrates thematic map default features including a data bound legend and labels associated with the styled points and areas when you use the Data Controls panel and thematic map binding dialogs.

Example 37–6   Pie Graph Theme Code on the JSF Page

```xml
<dvt:mapPieGraphTheme id="mapPieGraphTheme1"
  themeName="MAP_STATES_NAME"
  shortLabel="#{viewControllerBundle.POPULAR_CATEGORIES}"
  pieRadius="10"
  styleName="comet"
  value="#{bindings.PopularCategoriesByState1.geoMapModel}"
  locationColumn="POLYGON_ID"/>
</dvt:mapPieGraphTheme>
```
37.3.1 How to Create a Thematic Map Using ADF Data Controls

The `thematicMap` component uses a model to access the data in the underlying list. The specific model class is `oracle.adf.view.rich.model.CollectionModel`. You can also use other model instances, for example, `java.util.List`, `java.util.Array`, and `javax.faces.model.DataModel`. The data layer will automatically convert the instance into a `CollectionModel`.

Before you begin:
It may be helpful to have an understanding of databound thematic maps. For more information, see Section 37.3, "Creating Databound Thematic Maps."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, “Additional Functionality for Data Visualization Components.”

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."
- Create a JSF page as described in the “How to Create JSF Pages” section of Developing Web User Interfaces with Oracle ADF Faces.

To create a thematic map using the Data Controls panel:

1. From the Data Controls panel, select a data collection.

   Figure 37–20 shows the data collection for warehouse locations and product inventory levels.
2. Drag the collection onto a JSF page and, from the context menu, choose **Thematic Map**.

3. In the Component Gallery, select the map layer associated with the base map you want to configure for displaying data. In the example, a states map layer in the US base map is selected. **Figure 37–21** shows the Component Gallery with the USA states map layer selected.

**Figure 37–21  Thematic Map Component Gallery**

By default, the Create Data Layer dialog opens for adding an area or point data layer to the selected map layer. In the thematic map displayed in **Figure 37–19**, an area data layer is configured style USA states by warehouse product levels.

4. In the Create Data Layer dialog, enter the following:
- **Layer Id**: Enter a unique name for the data layer you are defining. By default, a unique, consecutively numbered id is entered, d11, d12, and so on.

- **Area**: Select to add an area data layer to the map layer.

- **AreaLayer**: References the map layer to which you are adding a data layer. In the example, a USA States map layer.

- **Location**: Select the attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. For more information, see Section 37.3.5, "What You May Need to Know About Base Map Location Ids."

- **Set current row for master-detail**: Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see Section 37.3.6, "What You May Need to Know About Configuring Master-Detail Relationships."

Figure 37–22 shows the completed Create Data Layer dialog.

**Figure 37–22  Create Area Data Layer Dialog**

An area data layer representing the areaDataLayer component, and an area, representing the area component is added in the Layer Browser hierarchy. Figure 37–23 shows the expanded Layer Browser after adding an area data layer and area to the map layer.

**Figure 37–23  Thematic Map Layer Browser**

5. In the Layer Browser, expand the area data layer, select the area to be stylized, and click the **Edit** icon.
In the Configure Area dialog, Attribute Groups page, enter the following:

- **Grouping Rules**: Use this table to specify the styling of categorical groups of data in a data collection. Use the **Add** icon to add a row to the table for configuring rules for a categorical group and use the **Delete** icon to remove any row selected in the table. Each grouping rule is represented as an `attributeGroups` component, and assigned a unique, consecutively numbered Id, `ag1`, `ag2`, and so on.

  For each row added to the table, enter the following:
  
  - **Group by Value**: Enter or use the dropdown list to select the attribute representing the column in the data set by which you wish to group the data values. For example, `ProductCount` represents the warehouse product inventory levels by state.
  
  - **Area Properties**: Use the dropdown list to select the property to use for styling that area. Areas can be styled using **color**, **pattern**, **opacity**, or any combination of these valid values. Choose **Select multiple attributes** from the dropdown list for a dialog to specify any combination of values.

    The default style values that are generated for each property are defined using CSS style properties in the ADF skin. Each `attributeGroups` type has a default ramp defined in the skin, and these can be customized by setting the index-based properties to the desired values. For more information, see Section 37.3.4.4, "What You May Need to Know About Default Style Values for Attribute Groups."

    - **Legend Label**: Enter text or use the dropdown list to select the attribute representing the text to use for the categorical group in the thematic map legend. You can also select **Expression Builder** from the dropdown list to create an EL expression to specify the legend text. For more information, see Section 37.3.9, "Creating Databound Legends."

    - **Value-Specific Rules**: Click to open the **Match Rules** and **Exception Rules** tables used to specify a finer detail for one or more data values in categorical groups in a data set. For example, use a match rule to style every state with a warehouse with a low product inventory level with a #DD1E2F color, instead of a predefined range of colors.

**Note**: You configure an area with a default stamp across all areas in the thematic map layer, or you can use a child `attributeGroups` tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the `area` tag, and by an `attributeGroups` tag, the `attributeGroups` style type will take precedence. For more information, see Section 37.3.4, "Styling Areas, Markers, and Images to Display Data."
Creating Databound Thematic Maps

**Match Rules**: Use to specify the style rule matched to one or more data values in a group of data in a data collection. Use the **Add** icon to add a row to the table for configuring a match rule for a categorical group and use the **Delete** icon to remove any row selected in the table. Each match rule is represented as an `attributeMatchRule` component, and assigned a unique, consecutively numbered `Id`, `amr1`, `amr2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

```xml
<dvt:attributeMatchRule id="amr1" group="Mountain Dew">
  <f:attribute name="color" value="#FFFF00"/>
</dvt:attributeMatchRule>
```

For each row added to the table, enter the following:

- **Group Value**: Enter the exact value for a **Group By Value** attribute that will trigger this Match Rule to execute. In the example, warehouse product inventory level data collection attribute, values include low, med, and high.

- **Property**: Use the dropdown list to select the property to use for styling that data value. Areas can be styled using **color**, **pattern**, or **opacity** values. The property selected here must match one of the property types listed in the **Area Properties** for the attribute **Grouping Rules**.

- **Property Value**: Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, `smallChecker`, `largeDiamond`, `smallDiagonalRight`, `largeCrosshatch`. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from 0.0 for transparent to 1.0 for opaque.

**Exception Rules**: Use to specify one or more exception to the style rules for categorical groups in the data set. Use the **Add** icon to add a row to the table for configuring an exception rule and use the **Delete** icon to remove any row selected in the table. Each exception rule is represented as an `attributeExceptionRule` component, and assigned a unique, consecutively numbered `Id`, `aer1`, `aer2`, and so on. The property and property value is defined in a child `f:attribute` tag.

For each row added to the table, enter the following:

- **Condition**: Enter an EL expression, or use the dropdown list to open an Expression Builder dialog to create an EL expression that replaces the style property value with another when certain conditions are met. For example:

  ```el
  #(row.Sales gt 100000)
  ```

- **Property**: Use the dropdown list to select the property to use for styling that data value. Areas can be styled using **color**, **pattern**, or **opacity**
values. The property selected here must match one of the property types listed in the **Area Properties** for the attribute **Grouping Rules**.

- **Property Value**: Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

Valid values for **color** are RGB hexadecimal colors.

Valid values for **pattern** include a choice of twelve prebuilt patterns, for example, **smallChecker**, **largeDiamond**, **smallDiagonalRight**, **largeCrosshatch**. If fill color is specified, the pattern displays in that color on the default white background.

Valid values for **opacity** range from 0.0 for transparent to 1.0 for opaque.

- **Legend Label**: Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

---

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```
#{viewController.ResourceBundle[row.label]}
```

---

- **Messages**: Review and clear as necessary any alerts related to the configuration of the area.

**Figure 37–24** shows the completed Configure Area dialog. The warning in the message pane alerts the user that the default area color specified in the Default Stamp page of the dialog will be overwritten by the color specified in the Grouping Rules and any value-specific overrides specified in the Attribute Groups page.
7. Use the Layer Browser to add a global point data layer representing warehouse locations using the same data collection you used to create the thematic map. For detailed instructions, see Section 37.3.3, "How to Add Data Layers to Thematic Maps."

8. Use the Layer Browser to add a global point data layer representing customer addresses using a different data collection than the one you used to create the thematic map. For detailed instructions, see Section 37.3.3, "How to Add Data Layers to Thematic Maps." Figure 37–25 shows the data collection for customer locations.

9. Use the Layer Browser to add and style a marker representing the customer locations in the global point data layer. For detail instructions, see Section 37.3.4, "Styling Areas, Markers, and Images to Display Data."
Figure 37–26 shows the expanded Layer Browser for the thematic map in Figure 37–20.

**Figure 37–26  Thematic Map Layer Browser**

10. Add and configure a data bound legend and labels associated with the styled points and areas. For detailed instructions, see Section 37.3.9, "Creating Databound Legends.”

### 37.3.2 What Happens When You Use Data Controls to Create a Thematic Map

When you use ADF data controls to create a thematic map, JDeveloper:

- Defines the bindings for the thematic map in the page definition file of the JSF page, and
- Inserts code in the JSF page for the DVT thematic map components.

Example 37–7 shows the bindings defined in the page definition file of the JSF page for the example thematic map in Figure 37–19.

**Example 37–7  XML Bindings for a Thematic Map**

```
<bindings>
  <tree IterBinding="WorldProductInventory1Iterator"
     id="WorldProductInventory1">
    <nodeDefinition DefName="model.WorldProductInventory"
                   Name="WorldProductInventory10">
      <AttrNames>
        <Item Value='Address'/>
        <Item Value='AmountInStock'/>
        <Item Value='Category'/>
        <Item Value='CategoryId'/>
        <Item Value='City'/>
        <Item Value='Country'/>
        <Item Value='CountryCode'/>
        <Item Value='CountryId'/>
        <Item Value='Id'/>
        <Item Value='Id1'/>
        <Item Value='Id2'/>
        <Item Value='Id3'/>
        <Item Value='Id4'/>
        <Item Value='Latitude'/>
        <Item Value='Longitude'/>
        <Item Value='ProdName'/>
        <Item Value='ProductId'/>
        <Item Value='RegName'/>
        <Item Value='RegionId'/>
        <Item Value='ReorderPoint'/>
      </AttrNames>
  </tree>
</bindings>
```
Example 37–8 shows the code inserted in the JSF page for the example thematic map in Figure 37–19.

**Example 37–8  ** Code on the JSF Page for a Thematic Map

```
<dvt:thematicMap id="tm1" basemap="usa" animationOnDisplay="alphaFade"
  summary="#{viewcontrollerBundle.THEMATIC_MAP_DISPLAYING_WAREHOUSE_PRODUCT_INVENTORY_LEVELS}"
  idForLayer="states" id="al1"
  value="#{bindings.SWarehouseView1.collectionModel.map}
  var="row"
  name="#{row.State}"
  id="al2"
  shortDesc="#{row.ProductCount} units"
  id="ag1" type="color" value="#{row.ProductCount le 5 ? 'low' : (row.ProductCount le 8 ? 'med' : 'high')}
  <dvt:attributeMatchRule id="amr1" group="low">
  </dvt:attributeMatchRule>
</dvt:thematicMap>
```
Once you have created a data bound thematic map you can add additional map layers representing available regions in the geographical hierarchy of the base map, and associate area or point data layers using the same data collection you used to create the thematic map. The Layer Browser represents the logical structure of the map layers, area and point data layers, and stylized areas and markers. Use the Layer Browser to:

- Add additional map layers in the base map geographical hierarchy to the thematic map.
Define a custom map layer in the geographical hierarchy of the base map, using lower level regions to aggregate the regions in the custom layer. For more information, see Section 37.3.7, "How to Define a Custom Map Layer."

Add, edit, or delete area or point (global or map layer specific) data layers. For more information, see Section 37.3.3, "How to Add Data Layers to Thematic Maps."

Add, edit, or delete stylized areas or markers. For more information, see Section 37.3.4, "Styling Areas, Markers, and Images to Display Data."

After creating a thematic map using data controls, you can customize the default map labels, legend display, and add interactivity and animation effects. For more information, see in Developing Web User Interfaces with Oracle ADF Faces.

37.3.3 How to Add Data Layers to Thematic Maps

You use data layers to associate map layers with a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image. When a map layer is displayed at runtime, the data appears as stylized areas, markers, or images.

Map layers can display data using an area data layer and/or one or more point data layers. Area data layers can be styled using areas, markers, or images. Point data layers can be styled using markers or images.

When a point data layer is associated with the base map as a direct child of thematicMap instead of as a child of a specific map layer, the data displays at all times and is called a global point layer.

Before you begin:
It may be helpful to have an understanding of databound thematic maps. For more information, see Section 37.3, "Creating Databound Thematic Maps."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

Create a data bound thematic map to your JSF page, as described in Section 37.3.1, "How to Create a Thematic Map Using ADF Data Controls."

To add an area data layer to a map layer:
1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, select the map layer to which you wish to bind a row in the data collection. If the Layer Browser is not open in the Visual Editor, right-click inside the map and choose Open Layer Browser.
3. From the Add icon dropdown list, choose Add Data Layer.
4. In the Create Data Layer dialog, enter the following:
Creating Databound Thematic Maps

- **Layer Id**: Enter a unique name for the data layer you are defining. By default, a unique, consecutively numbered id is entered, d11, d12, and so on.

- **Bind Data Now**: Select and click **Browse** to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your data layer.

---

**Note:** Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your area data layer and areas. You can also use the Expression Builder dialog in each remaining field.

---

- **Area**: Select to add an area data layer to the map layer.

- **AreaLayer**: References the map layer to which you are adding a data layer.

- **Location**: Select attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are IDs of the regions from the base map for which the data is being displayed. For more information, see Section 37.3.5, "What You May Need to Know About Base Map Location IDs."

- **Set current row for master-detail**: Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see Section 37.3.6, "What You May Need to Know About Configuring Master-Detail Relationships."

Figure 37–27 shows the completed Create Area Data Layer dialog.

---

**Figure 37–27  Create Area Data Layer Dialog**

![Create Area Data Layer Dialog](image)

By default, an area data layer representing the `areaDataLayer` component, and an area, representing the `area` component is added in the Layer Browser hierarchy. **Example 37–9** shows the code added to the JSF page when you add an area data layer to a map layer.
Example 37–9  Area Data Layer Code in JSF Page

```xml
<dvt:thematicMap id="tml" basemap="usa">
  <dvt:areaLayer layer="counties" id="all">
    <dvt:areaDataLayer id="dl2" value="#{bindings.TmapStatesView11.collectionModel}" var="row">
      <dvt:areaLocation name="#{row.Name}" id="al2">
        <dvt:area id="a1"/>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  ...
</dvt:thematicMap>
```

To add a point data layer to a map layer:

1. Select the thematic map in the Visual Editor.
2. In the Layer Browser, select the map layer to which you wish to bind a data layer. If the Layer Browser is not open in the Visual Editor, right-click inside the map and choose Open Layer Browser.
3. From the Add icon dropdown list, choose Add Data Layer.

---

**Note:** If you wish to create a global point layer that displays at all times on the thematic map, choose Create Global Point Layer.

---

4. In the Create Data Layer dialog, enter the following:
   - **Layer Id:** Enter a unique ID for the data layer you are defining. By default, a unique, consecutively numbered id is entered, dl1, dl2, and so on.
   - **Bind Data Now:** Select and click Browse to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your data layer.

---

**Note:** Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your point data layer and markers. You can also use the Expression Builder dialog in each remaining field.

---

- **Points:** Select to add a point data layer to the map layer.
- **AreaLayer:** Use the dropdown list to select the map layer to which you are associating a data layer. If you select All, the point data layer will be configured as a global point layer and display at all times. If you select an available map layer, the point data layer will only display with that map layer is displayed.
- **Data Type:** Choose one of the following:
  - **City:** Select to use a pointName data type representing the named points, such as cities, in the data collection that map to named points in the base map.
Creating Databound Thematic Maps

- **Coordinates**: Select to use a `pointXY` data type representing the columns in the data collection that join `pointX` and `pointY` to define the point locations.

- **Location**: Available if a City Data Type is specified. Use the dropdown list to select the attribute that represents the column in the data model that determines the location of the data for the points in the data layer. The locations are IDs of the points from the base map for which the data is being displayed. For more information, see Section 37.3.5, "What You May Need to Know About Base Map Location Ids."

- **Longitude**: Available if a Coordinates Data Type is specified. Use the dropdown list to select the attribute in the data collection that represents the longitude, or `pointX` of the marker.

- **Latitude**: Available if a Coordinates Data Type is specified. Use the dropdown list to select the attribute in the data collection that represents the latitude, or `pointY` of the markers.

- **Set current row for master-detail**: Select if you want to enable master-detail relationships. This is useful when the data collection for the thematic map is a master in a master-detail relationship with a detail view that is displayed in another UI component on the page. For more information, see Section 37.3.6, "What You May Need to Know About Configuring Master-Detail Relationships."

Figure 37–28 shows the completed Create Point Data Layer dialog for a `pointName` data type.

**Figure 37–28  Create Point Data Layer Dialog**

![Create Point Data Layer Dialog](image)

By default, a point data layer representing the `pointDataLayer` component, and a marker, representing the `marker` component is added in the Layer Browser hierarchy. Example 37–10 shows the code added to the JSF page when you add a point data layer to a map layer.

**Example 37–10  Point Data Layer Code in JSF Page**

```xml
<dvt:thematicMap id='tm1' basemap='usa'>
  <dvt:areaLayer layer='states' id='al1'>
    <dvt:pointDataLayer id='dl1'>
      <!-- Code for point data layer goes here -->
    </dvt:pointDataLayer>
  </dvt:areaLayer>
</dvt:thematicMap>
```
Creating Databound Thematic Maps

Creating Databound Geographic and Thematic Map Components 37-41

Example 37–11 shows the code added to the JSF page when you add a global point data layer to a thematic map.

Example 37–11  Global Point Data Layer Code in JSF Page

After adding the area or point data layer to the thematic map, you style the data using areas, markers, or images. For more information, see Section 37.3.4, "Styling Areas, Markers, and Images to Display Data."

37.3.4 Styling Areas, Markers, and Images to Display Data

An area data layer is used to associate map layers with a data collection. Using stamping, each row of data in the data model can be identified by a style, for example a color or pattern; a marker, for example a circle or square; or an image.

A point data layer is used to associate a set of points on a map with a data collection. The data point can be specified by a named point in a map layer, for example, cities in the US map, or by longitude and latitude. Using stamping, each row of data in the data model can be identified by a marker, for example a circle or square, or an image.

37.3.4.1 How to Style Areas to Display Data

You configure an area with a default stamp across all areas in the thematic map areaLayer, or you can use a child attributeGroups tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the area tag, and by an attributeGroups tag, the attributeGroups style type will take precedence.

By default, when you add an area data layer, a configurable area is added to the Layer Browser. You can use the Layer Browser to add additional areas or markers to an area data layer, or markers to a point data layer. The Layer Browser reflects the logical structure of the map layers, area or point data layers, and areas or markers configured in the thematic map.

For example, you can style the states in the states layer of the usa base map with an attribute group to display states with warehouses using the color red as illustrated in Figure 37–29.
Before you begin:
It may be helpful to have an understanding of databound thematic maps. For more information, see Section 37.3, "Creating Databound Thematic Maps."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

■ Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

■ Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

■ Create a data bound thematic map to your JSF page, as described in Section 37.3.1, "How to Create a Thematic Map Using ADF Data Controls."

To style areas using a default stamp:
1. In the Layer Browser, select the area at the area location inside the map layer you are configuring.
2. Click the Edit icon.
3. In the Configure Area dialog, Default Stamp page, enter the following:
   ■ Location: By default, the attribute that represents the column in the data model that determines the location of the data for the areas in the data layer. The locations are Ids of the regions from the base map for which the data is being displayed. This read-only field displays the EL expression that maps the stamped area to a region in the base map. For more information, see Section 37.3.5, "What You May Need to Know About Base Map Location Ids."

   ■ Color: Optionally, from the dropdown list select the fill color for the area. Valid values are RGB hexadecimal. Choose Custom Color from the dropdown list to open a Color Picker dialog

   ■ Pattern: Optionally, from the dropdown list select one of twelve prebuilt patterns to style the area, for example, smallChecker, largeDiamond,
smallDiagonalRight, largeCrosshatch. If fill color is specified, the pattern displays in that color on the default white background.

- **Opacity**: Optionally, specify the opacity of the fill color of the area. Valid values range from 0.0 for transparent to 1.0 for opaque.

- **Include in Legend**: Select and use the search icon to open a Select Text Resource dialog to select or create an application text resource to use for the legend text. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. If you need help, press F1 or click Help.

---

**Note**: the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```
#{viewController.ResourceBundle[row.label]}
```

---

- **Messages**: Review and clear as necessary any alerts related to the configuration of the area.

Figure 37–30 shows the Configure Area dialog for the Default Stamp page.

**Figure 37–30  Configure Area Dialog Default Stamp Page**

![Configure Area Dialog Default Stamp Page](image)

Example 37–12 shows the code inserted in the JSF page for the configured area.

**Example 37–12  Sample Code for Area Default Stamp Configuration**

```xml
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="states" id="al1">
```

---

Note: the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```
#{viewController.ResourceBundle[row.label]}
```

---

**Example 37–12**: Sample Code for Area Default Stamp Configuration

```xml
<dvt:thematicMap id="tm1" basemap="usa">
  <dvt:areaLayer layer="states" id="al1">
```

---

Creating Databound Geographic and Thematic Map Components  37-43
Creating Databound Thematic Maps

37.3.4.2 How to Style Markers to Display Data

You configure a marker with a default stamp across all markers in the thematic map layer, or you can use a child attributeGroups tag to generate the style attribute type automatically based on categorical groups in the data set. If the same style attribute is set in both the marker tag, and by an attributeGroups tag, the attributeGroups style type will take precedence.

By default, when you add a point data layer, a configurable marker element is added to the Layer Browser. You can use the Layer Browser to add additional areas or markers to an area data layer, or markers to a point data layer. The Layer Browser reflects the logical structure of the map layers, area or point data layers, and areas or markers configured in the thematic map.

For example, using the default stamp, you can identify all the predefined cities in the states layer of the USA base map with a red circle as illustrated in Figure 37–31. In the example, markers are styled on a point data layer. Styling markers on an area data layer is similar.

Figure 37–31  Thematic Map with Marker Default Stamp Configured
Before you begin:

It may be helpful to have an understanding of databound thematic maps. For more information, see Section 37.3, "Creating Databound Thematic Maps."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 37.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."
- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.
- Create a data bound thematic map to your JSF page, as described in Section 37.3.1, "How to Create a Thematic Map Using ADF Data Controls."

To style markers using a default stamp:

1. In the Layer Browser, select the marker at the point location inside the map layer you are configuring.
2. Click the Edit icon.
3. In the Configure Marker dialog, Default Stamp page, enter the following:
   - **Location**: By default, the attribute that represents the column in the data model that determines the location of the data for the markers in the data layer. The locations are Ids of the points from the base map for which the data is being displayed. This read-only field displays the EL expression that maps the stamped marker to a point in the base map. For more information, see Section 37.3.5, "What You May Need to Know About Base Map Location Ids."
   - **Color**: Optionally, from the dropdown list select the fill color for the marker. Valid values are RGB hexadecimal. Choose Custom Color from the dropdown list to open a Color Picker dialog.
   - **Pattern**: Optionally, from the dropdown list select one of twelve prebuilt patterns to style the marker, for example, smallChecker, largeDiamond, smallDiagonalRight, largeCrosshatch. If fill color is specified, the pattern displays in that color on the default white background.
   - **Opacity**: Optionally, specify the opacity of the fill color of the marker. Valid values range from 0.0 for transparent to 1.0 for opaque.
   - **Shape**: Optionally, select the shape of the marker. Valid values are circle (default), square, plus, diamond, triangleUp, triangleDown, and human.

Optionally, use the Custom Shape field to specify the shapePath value to a Scalable Vector Graphics (SVG) file to use for the marker. Enter the path or use the Search icon to open the Select SVG File dialog and navigate to the file location. This option is only available if the default shape is selected in the Shape field.

Shapes can also be specified using CSS style properties. Predefined marker shapes can be overwritten, and the paths to SVG files for custom markers can also be defined without using the shapePath attribute. For more information, see Section 37.3.4.3, "What You May Need to Know About Styling Markers."
- **Size**: Optionally, enter a percentage by which to scale the marker from its default size for *ScaleX* (horizontal), and *ScaleY* (vertical). The percentages are then scaled to a float. For example, you can double the marker width by setting *ScaleX* to 200, written to the tag as `2.0`, and halve the height by setting *ScaleY* to 50, written to the tag as `0.5`.

- **Include in Legend**: Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click Help.

**Note**: the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```java
#{viewController.ResourceBundle[row.label]}
```

- **Messages**: Review and clear any messages related to the configuration of the marker.

Figure 37–32 shows the Configure Marker dialog, Default Stamp page.

**Figure 37–32 Configure Marker Dialog Default Stamp Page**

![Configure Marker Dialog Default Stamp Page](image)

Example 37–13 shows the code inserted in the JSF page for the configured marker.

**Example 37–13 Sample Code for Marker Default Stamp Configuration**

```html
<dvt:thematicMap id="tm1" basemap="usa">
```

```
```
If you wish to style markers using categorical groups of data in the data collection, use the Attribute Groups page of the Configure Marker dialog. You can configure markers for a point data layer or an area data layer.

**To style markers using categorical groups of data:**
1. In the Layer Browser, select the marker at the marker location inside the map layer you are configuring.
2. Click the Edit icon.
3. In the Configure Marker dialog, Attribute Groups page, enter the following:
   - **Grouping Rules**: Use this table to specify the styling of categorical groups of data in a data collection. Use the Add icon to add a row to the table for configuring rules for a categorical group and use the Delete icon to remove any row selected in the table. Each grouping rule is represented as an attributeGroups component, and assigned a unique, consecutively numbered Id, ag1, ag2, and so on.
   
   For each row added to the table, enter the following:
   - **Group by Value**: Enter or use the dropdown list to select the attribute representing the column in the data set by which you wish to group the data values.

   **Note**: The selected attribute should consist of discrete values that can be categorized. For example, a range of numeric values between 40 and 45, are not automatically grouped.

   - **Marker Properties**: Use the dropdown list to select the property to use for styling that marker. Markers can be styled using color, pattern, opacity, scaleX, scaleY, or any combination of these valid values. Choose Select multiple attributes from the dropdown list for a dialog to specify any combination of values.

   The default style values that are generated for each property are defined using CSS style properties in the ADF skin. Each attributeGroups type has a default ramp defined in the skin, and these can be customized by setting the index-based properties to the desired values. For more information, see Section 37.3.4.4, "What You May Need to Know About Default Style Values for Attribute Groups."

   - **Legend Label**: Enter text or use the dropdown list to select the attribute representing the text to use for the categorical group in the thematic map.
Creating Databound Thematic Maps

legend. You can also select **Expression Builder** from the dropdown list to create an EL expression to specify the legend text. For more information, see Section 37.3.9, "Creating Databound Legends."

- **Value-Specific Rules**: Click to open the **Match Rules** and **Exception Rules** tables used to specify a finer detail for one or more data values for categorical groups in a data set.

---

**Note**: Any match or exception rule specified in these tables will override the settings defined in the **Grouping Rules** table.

---

- **Match Rules**: Use to specify the style rule matched to one or more data values in a group of data in a data collection. Use the **Add** icon to add a row to the table for configuring a match rule for a categorical group and use the **Delete** icon to remove any row selected in the table. Each match rule is represented as a `attributeMatchRule` component, and assigned a unique, consecutively numbered Id, `amr1`, `amr2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

  <dvt:attributeMatchRule id="amr1" group="Mountain Dew">
    <f:attribute name="color" value="#ffff00"/>
  </dvt:attributeMatchRule>

  For each row added to the table, enter the following:
  - **Group Value**: Enter the exact value for the **Group by Value** attribute that will trigger the Match Rule to execute.
  - **Property**: Use the dropdown list to select the property to use for styling that data value. Markers can be styled using `color`, `pattern`, `opacity`, `scaleX`, `scaleY`, or any combination of these valid values. The property selected here must match one of the property types listed in the **Marker Properties** for the attribute **Grouping Rules**.
  - **Property Value**: Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp.

  Valid values for `color` are RGB hexadecimal colors.

  Valid values for `pattern` include a choice of twelve prebuilt patterns, for example, `smallChecker`, `largeDiamond`, `smallDiagonalRight`, `largeCrosshatch`. If fill color is specified, the pattern displays in that color on the default white background.

  Valid values for `opacity` range from 0.0 for transparent to 1.0 for opaque.

  Valid values for `scaleX` and `scaleY` are percentages that are then scaled to a float.

- **Exception Rules**: Use to specify one or more exceptions to the style rules for categorical groups in the data set. Use the **Add** icon to add a row to the table for configuring an exception rule and use the **Delete** icon to remove any row selected in the table. Each exception rule is represented as an `attributeExceptionRule` component, and assigned a unique, consecutively numbered Id, `aer1`, `aer2`, and so on. The property and property value is defined in a child `f:attribute` tag. For example:

  <dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}">
    <f:attribute name="color" value="#ffff00"/>
  </dvt:attributeExceptionRule>
For each row added to the table, enter the following:

- **Condition**: Enter an EL expression, or use the dropdown list to open an Expression Builder dialog to create an EL expression that replaces the style property value with another when certain conditions are met. For example:

  ```
  #{row.Sales gt 100000}
  ```

- **Property**: Use the dropdown list to select the property to use for styling that data value. Markers can be styled using `color`, `pattern`, `opacity`, `scaleX`, or `scaleY`. The property selected here must match one of the property types listed in the **Marker Properties** for the attribute **Grouping Rules**.

- **Property Value**: Enter or use the dropdown list to assign a value to the property. If the value provided by the match override is also in the prebuilt ramp returned by the **Grouping Rules**, then that value will only be used by the overrides and will be skipped in the prebuilt ramp. Valid values for `color` are RGB hexadecimal colors.

  Valid values for `pattern` include a choice of twelve prebuilt patterns, for example, `smallChecker`, `largeDiamond`, `smallDiagonalRight`, `largeCrosshatch`. If fill color is specified, the pattern displays in that color on the default white background.

  Valid values for `opacity` range from 0.0 for transparent to 1.0 for opaque.

  Valid values for `scaleX` and `scaleY` are percentages that are then scaled to a float.

- **Legend Label**: Enter a text resource to use for the legend label. The text resource can be a translatable string from a resource bundle or an EL expression executed at runtime. Use the dropdown list to open a Select Text Resource or Expression Builder dialog. If you need help, press F1 or click **Help**.

---

**Note:** the text resource option is only available for a fixed area. For row-varying areas, use an EL expression to retrieve a row-varying key to look up the text resource in a resource bundle, for example:

```ruby
#{viewController ResourceBundle[row.label]}
```

---

- **Messages**: Review and clear as necessary any alerts related to the configuration of the marker.

For example, you can use markers in an area data layer to display categorical groups of data using colors as illustrated in **Figure 37-33**.
Example 37–14 shows the sample code for marker attribute groups by color.

**Example 37–14  Sample Code for Marker Attribute Groups by Color**

```xml
<dvt:thematicMap basemap="usa" id="tm1">
    <dvt:areaLayer layer="states" id="al1" labelDisplay="off">
        <dvt:areaDataLayer id="dl1" var="row" value="#{stateData.colorModel}">
            <dvt:areaLocation id="al2" name="#{row.name}">
                <dvt:marker id="m1" scaleX="3.0" scaleY="3.0" shape="circle">
                    <dvt:attributeGroups id="ag1" type="color" value="#{row.category}"
                                        label="#{row.category}"/>
                </dvt:marker>
            </dvt:areaLocation>
        </dvt:areaDataLayer>
    </dvt:areaLayer>
    <dvt:legend id="l1">
        <f:facet name="separator"/>
        <dvt:legendSection id="ls1" label="Category" source="ag1"/>
    </dvt:legend>
</dvt:thematicMap>
```

You can also use markers to display categorical groups of data using multiple attributes such as color and shape, and display an exception to the grouping rules when certain conditions are met. Figure 37–34 shows a thematic map with categorical groups using color and shape with an exception for the state of Texas.
Creating Databound Thematic Maps

**Figure 37–34  Multiple Marker Attribute Groups with Exception Rule**

Example 37–15 shows sample code for multiple marker attribute groups with exception rule.

**Example 37–15  Sample Code for Multiple Marker Attribute Groups with Exception Rule**

```xml
<dvt:thematicMap basemap="usa" id="tm2">
  <dvt:areaLayer layer="states" id="al1" labelDisplay="off">
    <dvt:areaDataLayer id="dl1" var="row" value="#{stateData.colorModel}">
      <dvt:areaLocation id="al2" name="#{row.name}">
        <dvt:marker id="m1"
            scaleX="3.0"
            scaleY="3.0"
            shape="circle">
          <dvt:attributeGroups id="ag1" type="shape color" value="#{row.category}" label="#{row.category}">
            <dvt:attributeExceptionRule id="aer1" condition="#{row.name=='TX'}" label="Texas">
              <f:attribute name="color" value="#ff00ff"/>
            </dvt:exceptionRule>
          </dvt:attributeGroups>
        </dvt:marker>
      </dvt:areaLocation>
    </dvt:areaDataLayer>
  </dvt:areaLayer>
  <dvt:legend id="l1">
    <f:facet name="separator"/>
    <dvt:legendSection id="ls1" label="Category" source="ag1"/>
  </dvt:legend>
</dvt:thematicMap>
```

37.3.4.3 What You May Need to Know About Styling Markers

Thematic maps support a predefined set of seven shapes (circle, square, and so on) that can be specified using the `shape` attribute in the `marker` component. For custom markers, the `shapePath` attribute can be used to specify the path of an SVG file that will get displayed in place of a predefined shape.

Marker shapes can be also specified through CSS style properties in an ADF skin. Using thematic map style properties, predefined marker shapes can be overwritten, and the paths to SVG files for custom markers can be defined without using the
Creating Databound Thematic Maps

shapePath attribute. When using style properties, the shape attribute in the marker
cOMPONENT is used for defining both predefined and custom shapes.

A predefined shape will be overwritten if a global or component-specific style
property for that shape is specified in the ADF skin. For example, you can overwrite
the predefined circle shape by specifying the newCircle.svg file in the thematic
map component style property as follows:

af|dvt-thematicMap::shape-circle{
    -tr-path: url(/resources/path/newCircle.svg);
}

In the JSF page, the marker component shape attribute is set as follows:

<dvt:marker id="m1" shape="circle"/>

To specify a custom shape in the marker component shape attribute, you must use a
prefix of custom in the shape style property name. For example, if the custom shape is
named customName, then the ADF skin file should define either a global
.APDVTShapeCustomName:alias style property, or the thematic map specific
af|dvt-thematicMap::shape-customName with the -tr-path property
pointing to the SVG file as follows:

af|dvt-thematicMap::shape-customName{
    -tr-path: url(/resource/path/newCShape.svg);
}

In the JSF page, the marker component shape attribute is set as follows:

<dvt:marker id="m1" shape='customName'/>

For information about using ADF skins and style properties, see the "Customizing the
Appearance Using Styles and Skins" chapter in Developing Web User Interfaces with
Oracle ADF Faces.

37.3.4.4 What You May Need to Know About Default Style Values for Attribute
Groups

The attributeGroups component is used to generate stylistic property values such
as colors or shapes based on categorical grouping of the data in a data collection.
Based on the attribute representing the column in the data model to group by, the
attributeGroups component can generate style values for each unique value, or
group, in the data.

The type of stylistic properties to generate values for is specified by the type attribute
of the attributeGroups component. Supported types for area components are
color, pattern, and opacity. Supported types for marker components are color,
shape, pattern, opacity, scaleX, and scaleY. These types can be combined in a
space-delimited list to generate multiple stylistic properties for each unique data
value.

The default style values that are generated are defined using CSS style properties in
the ADF skin. Each attributeGroups type has a default ramp defined in the ADF
skin that can be customized by setting the index-based selectors to the desired values.
Example 37–16 show sample code for using CSS style properties to specify attribute
groups using CSS style properties.

Example 37–16  Attribute Groups CSS Style Properties

af|dvt-attributeGroups::shape1{
    -tr-shape: square;
Creating Databound Thematic Maps

af|dvt-attributeGroups::shape2{
   -tr-shape: square;
}
...
af|dvt-attributeGroups::color1{
   -tr-fill-color: #003366;
}

The default ramps for each attribute groups type are displayed in Table 37–2.

<table>
<thead>
<tr>
<th>Type</th>
<th>Default Ramps</th>
</tr>
</thead>
<tbody>
<tr>
<td>color</td>
<td>#003366 (blue), #CC3300 (red), #666699 (lavender), #006666 (emerald), #FF9900 (orange yellow), #993366 (purple), #99CC33 (lime green), #624390 (violet), #669933 (green), #FFCC33 (yellow), #006699 (turquoise blue), and #EBEA79 (pale yellow).</td>
</tr>
<tr>
<td>shape</td>
<td>square, circle, diamond, plus, triangleDown, triangleUp, and human</td>
</tr>
<tr>
<td>pattern</td>
<td>smallDiagonalLeft, smallDiagonalRight, smallTriangle, smallChecker, smallChecker, smallCrosshatch, smallDiamond, largeDiagonalLeft, largeTriangle, largeChecker, largeCrosshatch, largeDiamond</td>
</tr>
<tr>
<td>opacity</td>
<td>0.25, 0.50, 0.75, 1.0</td>
</tr>
<tr>
<td>scaleX and scaleY</td>
<td>1.0, 2.0, 3.0, 4.0, 5.0</td>
</tr>
</tbody>
</table>

For information about using ADF skins and style properties, see the "Customizing the Appearance Using Styles and Skins" chapter in Developing Web User Interfaces with Oracle ADF Faces.

37.3.4.5 How to Style Images to Display Data

You can use images to style data displayed in a thematic map. Using stamping, each row of data in the data model can be identified by an image. Images can be associated with either an area or point data layer.

For example, in an area data layer you can use a house image to identify prime locations on the states map layer of a US base map as illustrated in Figure 37–35.
Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in Developing Web User Interfaces with Oracle ADF Faces.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see Section 37.3.1, "How to Create a Thematic Map Using ADF Data Controls."

To use an image to display data:

1. In the Layer Browser, select the area or point data layer where you are configuring an image to display data.

2. In the Structure window, right-click the area or point data layer child areaLocation or pointLocation component and select insert inside dvt:areaLocation or insert inside dvt:pointLocation > Image.

3. In the Insert Image dialog, enter the following:
   - **Source**: Enter the URI specifying the location of the image source. You can use the dropdown menu to choose Edit and open an Edit Property: Source dialog or the Expression Builder to specify the location of the image source.
   - **ShortDesc**: Enter the short description of the image used as the alt text for screen reader users.

Example 37–17 shows a code sample for using images to display data.

**Example 37–17  Code Sample for Image Configuration**

```xml
<dvt:thematicMap id="thematicMap" imageFormat="flash" basemap="usa" summary="Thematic map showing the important real estate markets">
  <dvt:legend label="Legend">
    <dvt:legendSection source="areaLayer:dataLayer:img1"/>
  </dvt:legend>
</dvt:thematicMap>
```
Creating Databound Thematic Maps

37.3.4.6 What You May Need to Know About SVG Files

Scalable Vector Graphics (SVG) is the supported file format for creating custom shapes for thematic map markers.

SVG features that are not supported by custom shapes include:

- Image tags within the SVG file. Everything must be declared using SVG’s vector shapes.
- Pattern fills
- Gradients on strokes

37.3.5 What You May Need to Know About Base Map Location Ids

Each base map provided for the thematic map component has two or more prebuilt map layers that represent a set of regions. For example, the world base map includes a map layer for continents and another layer for countries. The regions in the lower level map layers are aggregated to make up the next level in the geographical hierarchy. The map layer is specified in the layer attribute of the areaLayer component.

When you are binding your data collection to a thematic map, you must provide a column in the data model that specifies the location of the area or point data using the map location Ids of the regions from the base map for which the data is being displayed. Area locations are specified in the name attribute of the areaLocation component, and point locations are specified in the pointName attribute for the pointLocation component when its type attribute is set to pointName.

For the United States base map, the locations Ids are determined by the following naming rules:

- country layer: USA
- states layer: Use the two-letter postal abbreviation. For example, the location Id for Massachusetts is MA, and the location Id for Texas is TX.
- counties layer: Use the states layer location Id, followed by an underscore, and then the name of the county, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for Middlesex county in Massachusetts is MA_MIDDLESEX, and the location Id for Red River county in Texas is TX_RED_RIVER.
- cities layer: Use the states layer location Id, followed by an underscore, and then the name of the city, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for the id for Boston,
Massachusetts is MA_BOSTON, and the location Id for San Antonio, Texas is TX_SAN_ANTONIO.

For all other base maps, location Ids are determined by the following naming rules:

- **continents** layer: AF (Africa), AS (Asia), AU (Australia), EU (Europe), NA (North America), and SA (South America) for the world, africa, asia, australia, europe, northAmerica, and southAmerica base maps.

- **worldRegions** layers: APAC (Asia-Pacific), EMEA (Europe and the Middle East), LAT (Latin America), NA (United States and Canada) for the worldRegions, apac, emea, latinAmerica, and usaAndCanada base maps.

- **countries** layer: Use the ISO 3166-1 alpha-3 country codes. For example, the location Id for Canada is CAN, and the location Id for China is CHN.

- **cities** layer: Use the three-letter countries location ID, followed by an underscore, and then the name of the city, all in capital letters with underscores replacing characters that are not letters. For example, the location Id for Toronto, Canada is CAN_TORONTO, and the location Id for Los Angeles, United States is USA_LOS_ANGELES.

You can download a comma-separated value (CSV) file for each of the prebuilt map layers with a complete listing of all the thematic map base map location Ids. Find these links in the tag documentation for the areaLocation component, name attribute. To access tag documentation for the data visualization components, select the component in the Structure window and click the help button in the Properties window.

### 37.3.6 What You May Need to Know About Configuring Master-Detail Relationships

You can configure a thematic map to display its associated data in another UI component on the page such as a table. In this configuration the data collection for the thematic map is a master in a master-detail relationship with a detail view in another UI component. Figure 37–36 shows a thematic map displaying unemployment rates by state. Users can select one or multiple states to display the data detail view in the table.

*Figure 37–36  Thematic Map Master and Detail Table View*

The following requirements must be met to achieve this master-detail processing declaratively:
You must use the same data collection to provide data for both views as follows:

- Bind the thematic map areaDataLayer or pointDataLayer to the data collection whose attributes represent the data to be styled by areas or markers in the thematic map layer.
- Bind the other ADF component (such as a table) to same data collection.

Select Set the current row for master-detail in the Create Data Layer dialog to automatically set a value for the selectionListener attribute of the thematic map areaLayer component and use the processSelection method that is already part of the thematic map binding.

For example, if the value attribute of the thematic map area data layer component is value="#{stateData.employmentData}", then the selectionListener attribute is set to:

```
selectionListener="#{stateData.employmentData.processSelection}".
```

Ensure that the selectionMode attribute on the areaDataLayer or pointDataLayer component is set to single or multiple, depending on the requirements for the thematic map.

### 37.3.7 How to Define a Custom Map Layer

You can define a custom map layer from your own regional data and insert it into the natural geographical hierarchy of a thematic map. The custom layer is created by extending a predefined map layer and aggregating the lower level regions to form the new regions in the custom layer. After defining a custom map layer, it is used in the same way as any other map layer.

For example, you could define geographical regions for the NorthEast, Midwest, West and South in the United States in a US Regions custom map layer as illustrated in Figure 37–37. In the figure, the US Regions custom layer is extended from the states layer in the US base map. The new areas in the layer are aggregated from the states in the states layer. The label for the South US Region lists the states in that region. The MidWest US Region is drilled down to display the sales categories in the lower level counties region. For more information about drilling, see Section 37.3.8, "How to Configure Drilling in Thematic Maps."
Creating Databound Thematic Maps

Figure 37–37  US Regions Custom Map Layer

The customAreaLayer component uses a model to access the data in the underlying list. The specific model class is oracle.adf.view.rich.model.CollectionModel. You can also use other model instances, for example, java.util.List, java.util.Array, and javax.faces.model.DataModel. The customAreaLayer will automatically convert the instance into a CollectionModel.

Before you begin:

It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in Developing Web User Interfaces with Oracle ADF Faces.

You should already have an ADF data control or ADF managed bean that defines the aggregated areas in the predefined base map you are extending.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see Section 37.3.1, "How to Create a Thematic Map Using ADF Data Controls."

How to add and configure a custom map layer:

1. Select the thematic map in the Visual Editor.

2. In the Layer Browser, from the Add icon dropdown list, choose Add Custom Layer. If the Layer Browser is not open in the Visual Editor, right-click in the map and choose Open Layer Browser.

3. In the Create Custom Layer dialog, enter the following:

   - **Bind Data Now**: Select and click Browse to open the Picker dialog > Data Controls Definitions page. Select the data collection in the ADF data controls you are using to data bind your custom layer and areas.
Note: Alternatively, you can use the Expression Builder page to select an ADF managed bean you are using to data bind your custom layer and areas. You can also use the Expression Builder dialog in each remaining field.

- **Layer Id:** Enter a unique identifier for the `customAreaLayer` component. For example, if you divide the US into aggregate regions (Northeast, Midwest, West, and South), then you might define them with corresponding Ids (NE, MW, W, and S).

- **Extends:** Use the search icon to display the built-in map layers that can be used to aggregate areas for the custom layer. Select the map layer that the custom layer will extend.

- **Area List:** Use the dropdown list to select the data collection attribute representing the list of lower level map regions that are used to aggregate the areas in the custom map layer. The comma separated list of values aggregate the regions in the map layer defined in the in the `Extends` attribute.

- **Area Id:** Use the dropdown list to select the data collection attribute representing the unique identifier of lower level map regions that are used to aggregate the areas in the custom map layer. By default, a unique identifier, `ca1, ca2`, and so on, is used in the for the `customArea` component.

- **Area Label:** Use the dropdown list to select the data collection attribute representing the names of lower level map regions that are used to aggregate the areas in the custom map layer. At runtime the label will display the comma separated list of the aggregated regions.

Figure 37–38 shows the completed Create Custom Layer dialog.

**Figure 37–38 Create Custom Layer Dialog**

![Create Custom Layer Dialog](image)

Figure 37–39 shows the Layer Browser after defining a custom layer. In the layer structure, the custom layer `cal1` is referenced in the map layer `al1`, where you add area or point data layers to display data. For more information, see Section 37.3.3, "How to Add Data Layers to Thematic Maps."
Figure 37–39 Custom Map Layer in Layer Browser

Example 37–18 shows the code inserted in the JSF page

Example 37–18 Custom Map Layer Code

```xml
<dvt:thematicMap>
  ...
  <dvt:areaLayer layer="states" id="all"/>
  <dvt:areaLayer layer="call" id="al3"/>
  <dvt:customAreaLayer id="call"
    value="#{bindings.TmapStatesView.collectionModel}"
    var="row"
    extendsLayer="states">
    <dvt:customArea areaId="#{row.RowID}" areaList="#{row.RowID}"
      label="#{row.RowID}" id="ca1"/>
  </dvt:customAreaLayer>
  ...
</dvt:thematicMap>
```

After configuring and adding a custom layer to the map layer hierarchy, you can then use the map layer in the same way as any other map layer. For example, to create the thematic map illustrated in Figure 37–37, you will need to do the following:

- Configure the thematic map to support drilling. For more information, see Section 37.3.8, "How to Configure Drilling in Thematic Maps."

**Note:** If drilling is enabled for the thematic map, drilling between a custom layer and the map layer used to aggregate the custom layer is available without configuring data display for either layer.

- Add and configure an area data layer for the county data view. For more information, see Section 37.3.3, "How to Add Data Layers to Thematic Maps."

- Add and style area components to display the related data for each map layer. For more information, see Section 37.3.4, "Styling Areas, Markers, and Images to Display Data."

- Configure the thematic map legend. For more information, see Section 37.3.9, "Creating Databound Legends."

Example 37–19 shows sample code for using a custom layer in a thematic map.

Example 37–19 Sample Code for Thematic Map with Custom Layer

```xml
<dvt:thematicMap id="thematicMap" imageFormat="flash" basemap="usa" drilling="on"
  maintainDrill='true'
  controlPanelBehavior='initExpanded' summary="US Custom Regions">
  <dvt:customAreaLayer id="crl1" value="#{tmapRegions.collectionModel}" var="row"
    varStatus="rowStatus">
```
37.3.8 How to Configure Drilling in Thematic Maps

A thematic map with related data views in different map layers can be configured for drilling between the higher and lower level data views. For example, a thematic map can display data for sales category by USA state drilled down to USA county data as illustrated in Figure 37–37. When a state or county is selected, drilling up or down is initiated through a context menu choice or the Control Panel.

The following requirements must be met to achieve thematic map area drilling declaratively:

- For each map layer (areaLayer) in the drilling hierarchy, you must bind its child areaDataLayer with a data control that defines the related data for that map layer.
Each areaDataLayer in the map layer drill hierarchy must have its selectionMode attribute set to single or multiple.

You must configure the area in the lower level map layer drill hierarchy to display data using the same default stamp or categorical attribute style used in the higher level map layer area component.

The thematicMap component drilling attribute must be set to on.

**Note:** If drilling is enabled for the thematic map, drilling between a custom layer and the map layer used to aggregate the custom layer is available.

**Before you begin:**
It may be helpful to have an understanding of how thematic map attributes and thematic map child tags can affect functionality. For more information, see the "Configuring Thematic Maps" section in Developing Web User Interfaces with Oracle ADF Faces.

You should already have a thematic map on your page. If you do not, follow the instructions in this chapter to create a thematic map. For more information, see Section 37.3.1, "How to Create a Thematic Map Using ADF Data Controls."

You should already have data controls that define the data model for each of the map layers in the drill hierarchy.

**To configure a thematic map area for drilling:**

1. In the Structure window, select the dvt:thematicMap component.

2. In the Properties window, expand the Behavior section. Use this section to set the following attributes:
   - **Drilling:** Use to enable drilling the area data view between thematic map layers. From the dropdown list select on to enable drilling. The default value is off.
   - **MaintainDrill:** Optionally, use to specify an optional true value for maintaining the drilled state of a previously drilled area when a new area is drilled. The default value is false.
   - **DrillBehavior:** Optionally, use to specify an optional zoomToFit effect on the area being drilled. The default value is none.

3. In the Layer Browser, select each Area Layer component in the desired drilling hierarchy and do the following:
   - Click the Add icon and choose Add Data Layer to open the Create Data Layer dialog. Complete the dialog to add an area data layer and bind the data layer to the data control for that map layer. If you need help, press F1 or click Help.

   **Note:** If the Area Data Layer is already present, click the Edit icon to confirm binding to the data control.

4. In the Properties window, expand the Behavior section and set the SelectionMode attribute to single or multiple.

   In the Layer Browser, select each Area Data Layer component in the desired drilling hierarchy and do the following:

- Click the Add icon and choose Add Area to open the Configure Area dialog. Complete the dialog to define a default stamp or use attribute groups to style the area for that map layer. If you need help, press F1 or click Help.

**Note:** If the Area is already present, click the Edit icon to confirm the styling of the area.

**Figure 37–20** shows sample code for drilling enabled for USA states and counties map layers with an area styled to display data about sales categories.

**Example 37–20  Sample Code for Configuring Drilling**

```xml
<dvt:thematicMap id="thematicMap"
    baseMap="usa"
    drillings="on"
    maintainDrill="true"
    drillBehavior="zoomToFit"
    animationOnDisplay="none"
    >
    <dvt:areaLayer id="al1" layer="states">
        <dvt:areaDataLayer id="adl1"
            selectionMode="single"
            contentDeliver="immediate"
            value="#{row.state}"
            var="row"
            varStatus="rowStatus">
            <dvt:areaLocation id="areaLocS" name="#{row.stname}"
                >
                <dvt:area id="a1" fillColor="#{row.state}"/>
            </dvt:areaLocation>
        </dvt:areaDataLayer>
    </dvt:areaLayer>
    <dvt:areaLayer id="al2" layer="counties">
        <dvt:areaDataLayer id="adl2"
            selectionMode="single"
            contentDeliver="immediate"
            value="#{row.county}"
            var="row"
            varStatus="rowStatus">
            <dvt:areaLocation id="areaLocC" name="#{row.coname}"
                >
                <dvt:area id="a2" fillColor="#{row.county}"/>
            </dvt:areaLocation>
        </dvt:areaDataLayer>
    </dvt:areaLayer>
    ...  
</dvt:thematicMap>
```

### 37.3.9 Creating Databound Legends

Legends provide an explanatory table of the thematic map’s styled data in symbol and label pairs. Thematic map legend components (legend) support symbols for color, shape, custom shape, fill pattern, opacity, images and size. One or more child legend item components (legendSection) are sourced from thematic map area, marker, attributeGroups, or af:image components stamped to style the data displayed in the map. The legend section structure supports control over content ordering and appearance. You can wrap legend items into a disclosable section using a showLegendSection component. **Figure 37–40** shows a legend with a disclosable section for map areas and a marker.
Figure 37–40  Legend with Disclosable Section and Marker

Legend items sourced from the attributeGroups component automatically split area or marker attribute types into different sections. You can specify a separator facet to draw separators between legend sections. Figure 37–41 shows a legend with attribute groups for color, shape, fill pattern, opacity, and size with separators between each section.

Figure 37–41  Legend with Attribute Groups

Legends can be displayed in both Flash (default) and PNG image formats and both formats support locales with right-to-left display. When rendered in a PNG format, for example when printing the thematic map, disclosable sections in the legend are not supported, and legend items display as disclosed.

When you create a thematic map using the Data Controls panel and the thematic map binding dialogs, the legend data bindings are created for you. If you configure an area or marker as a default stamp across all areas in the thematic map, you can assign a static text resource to a fixed area or marker for the legend.

For default stamps displaying row-varying data, you can use an EL expression to assign the legend text and optionally, a managed bean to retrieve a row-varying key to look up the text resource in a resource bundle. Example 37–21 shows a code sample to generate legend entries for area and marker stamps. The code illustrates a disclosable section for a row-varying area and a fixed marker with an assigned text resource.
Creating Databound Thematic Maps

Example 37–21  Code Sample for Legend Area and Marker Stamps

```xml
<dvt:thematicMap id="tm1" basemap="usa" ...>
  <dvt:legend id="l1" label="Legend">
    <f:facet name="separator">
      <af:separator/>
    </f:facet>
    <dvt:legendSection id="ls1" source="all:adl1:areaStamp" />
    <dvt:legendSection id="ls2" source="all:adl1:fixedMarker" />
    <dvt:legendSection id="ls3" source="all:adl1:attributeGroupColor" />
    <dvt:legendSection id="ls4" source="all:adl1:attributeGroupShape" />
    <dvt:legendSection id="ls5" source="all:adl1:attributeGroupPattern" />
    <dvt:legendSection id="ls6" source="all:adl1:attributeGroupOpacity" />
  </dvt:legend>
</dvt:thematicMap>
```

If you configure an area or marker to use an attributes group to specify the styling of categorical groups of data in a data collection, you can use an EL expression to assign the legend text and optionally, a managed bean to retrieve a row-varying key to look up the text resource in a resource bundle.

If you specify a match rule for the attributes group, the legend text is specified in the group attribute. If you specify an exception rule, you can specify a text resource from the application resource bundle. Example 37–22 shows sample code for a legend with attribute groups, including both a match rule and an exception rule, and specifying a separator between legend sections.

Example 37–22  Sample Code for Legend with Attribute Groups

```xml
<dvt:thematicMap id="tm1" basemap="usa" ...>
  <dvt:legend id="l1" label="Legend">
    <f:facet name="separator">
      <af:separator/>
    </f:facet>
    <dvt:legendSection id="ls1" source="all:adl1:attributeGroupColor" />
    <dvt:legendSection id="ls2" source="all:adl1:attributeGroupShape" />
    <dvt:legendSection id="ls3" source="all:adl1:attributeGroupPattern" />
    <dvt:legendSection id="ls4" source="all:adl1:attributeGroupOpacity" />
  </dvt:legend>
</dvt:thematicMap>
```

Creating Databound Geographic and Thematic Map Components
You configure thematic map legend areas or markers in a custom region in the same way as any other map layer. shows sample code for a custom map layer legend.

**Example 37–23  Sample Code for Legend for Custom Map Layer**

```xml
<dvt:thematicMap>
  <dvt:legend>
    <dvt:legendSection label="Sales Regions" source="customAreaStamp"/>
    ... 
    <dvt:customAreaLayer id="crl1">
      ... 
    </dvt:customAreaLayer>
    <dvt:areaLayer layer="crl1">
      <dvt:areaDataLayer var="row">
        <dvt:areaLocation name="#{row.name}" id="al1">
          <dvt:area id="customAreaStamp" fillColor="#{row.color}">
            <f:attribute name="legendLabel" value="#{row.name}"/>
          </dvt:area>
        </dvt:areaLocation>
      </dvt:areaDataLayer>
    </dvt:areaLayer>
  </dvt:legend>
</dvt:thematicMap>
```

You can customize the appearance of thematic map legends using ADF skins. For more information, see the "Customizing the Appearance Using Styles and Skins" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
Creating Databound Gantt Chart and Timeline Components

This chapter describes how to create Gantt charts and timelines from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization projectGantt, resourceUtilizationGantt, schedulingGantt, and timeline components to create Gantt charts and timelines that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.

If you are designing your page using simple UI-first development, then you can add the Gantt chart or timeline to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the Gantt chart and timeline components, see the "Using Gantt Chart Components" and "Using Timeline Components" chapters in Developing Web User Interfaces with Oracle ADF Faces.

This chapter includes the following sections:

- Section 38.1, "About ADF Data Visualization Components"
- Section 38.2, "Creating Databound Gantt Charts"
- Section 38.3, "Creating Databound Timelines"

38.1 About ADF Data Visualization Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the component is dictated by the data that is displayed.

There are three types of ADF Gantt chart components; a project Gantt chart used for project management, a scheduling Gantt chart used for resource scheduling, and a resource utilization Gantt chart used for displaying resource metrics. All Gantt charts display two regions combined with a splitter. The list region displays a list of tasks or resources, and the chart region displays task progress, resource utilization, or resource progress graphed over time.

The ADF timeline is an interactive data visualization tool that allows users to view events in chronological order and easily navigate forwards and backwards within a defined time range. Events are represented as timeline items using simple ADF components to display information such as text and images, or supply actions such as links. A dual timeline can be configured to display two series of events to allow a side-by-side comparison of related information.
The prefix dvt: occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

### 38.1.1 Data Visualization Components Use Cases and Examples

For detailed descriptions of each data visualization use cases and examples, see the following:

- Gantt chart components: "Gantt Chart Component Use Cases and Examples" section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Timeline components: "Timeline Use Cases and Examples" section in *Developing Web User Interfaces with Oracle ADF Faces*.

### 38.1.2 End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the following:

- Gantt chart components: "End User and Presentation Features" section in *Developing Web User Interfaces with Oracle ADF Faces*.
- Timeline components: "End User and Presentation Features" section in *Developing Web User Interfaces with Oracle ADF Faces*.

### 38.1.3 Additional Functionality for Data Visualization Components

You may find it helpful to understand other Oracle ADF features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the "Rerendering Partial Page Content" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the "Allowing User Customization on JSF Pages" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Accessibility: By default, data visualization components are accessible. You can make your application pages available to screen readers. For more information, see the "Developing Accessible ADF Faces Pages" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (styleClass or inlineStyle). For more information, see the "Customizing the Appearance Using Styles and Skins" chapter in *Developing Web User Interfaces with Oracle ADF Faces*. 

---

**About ADF Data Visualization Components**

Developing Fusion Web Applications with Oracle Application Development Framework
■ Placeholder data controls: If you know the data visualization components on your
page will eventually use ADF data binding, but you need to develop the pages
before the data controls are ready, then you should consider using placeholder
data controls, rather than manually binding the components. Using placeholder
data controls will provide the same declarative development experience as using
developed data controls. For more information, see Chapter 19, "Designing a Page
Using Placeholder Data Controls."

38.2 Creating Databound Gantt Charts

A Gantt chart is a type of bar graph displayed on the horizontal axis. It is used in
planning and tracking projects to show tasks or resources in a time frame with a
distinct beginning and end.

When you create a Gantt chart, you can choose from the following types:

■ Project
A project Gantt chart lists tasks vertically and shows the duration of each task as a
bar on a horizontal time line.

■ Resource Utilization
A resource utilization Gantt chart shows graphically whether resources are over or
under allocated. It shows resources vertically while showing their allocation and,
optionally, capacity on the horizontal time axis.

■ Scheduling
A scheduling Gantt chart is based on manual scheduling boards and shows
resources vertically with corresponding activities on the horizontal time axis.
Examples of resources include people, machines, or rooms.

38.2.1 How to Create a Databound Project Gantt Chart

For a project Gantt chart, you must specify values for tasks. Optionally, you can
specify values for split tasks, subtasks, recurring tasks, and dependencies between
tasks, if your data collection has accessors for this additional information.

The project Gantt chart is displayed with default values for overall start time and end
time and for the major and minor time axis values. In a project Gantt chart, the setting
for the major time axis defaults to weeks and the setting for the minor time axis
defaults to days.

Figure 38–1 shows a project Gantt chart in which each task is an order to be filled. The
list region on the left side of the splitter shows columns with the name of the person
responsible for the order and columns for the order date and ship date. In the chart
region on the right side of the splitter, the Gantt chart displays a horizontal bar from
the order date to the ship date for each order.
To create a project Gantt chart using a data control, bind the project Gantt chart component to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

Tip: You can also create a project Gantt chart by dragging a project Gantt chart component from the Components window and completing the Create Project Gantt dialog. This approach allows you to design the Gantt chart user interface before binding the component to data.

Before you begin:
It may be helpful to have an understanding of databound Gantt charts. For more information, see Section 38.2, "Creating Databound Gantt Charts."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 38.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for the project Gantt chart in Figure 38–1 comes from a view object representing shipping orders including their shipping and delivery dates, in the Summit sample application for ADF DVT components.

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

To create a project Gantt chart using the Data Controls panel:

1. From the Data Controls panel, select a data collection. Select a row set collection that produces a flat list of tasks, or a basic tree collection that produces a hierarchical list of tasks.

Figure 38–2 shows an example where you could select the OrderEmployee1 collection in the Data Controls panel to create a project Gantt chart that displays the progress of order shipping.
2. Drag the collection onto a JSF page and, from the context menu, choose **Gantt > Project**.

3. In the Create Project Gantt dialog, in the **Tasks** page, select the columns in the data collection that correspond to the following attributes:
   - **Task Id**: The unique Id for the tasks represented in the Gantt chart.
   - **Start Time**: The starting time of the task.
   - **End Time**: The ending time of the task.
   - **Task Type**: The type used to specify the appearance of the task bar when it is rendered in the Gantt chart. If you do not bind the type to a column in your data collection, then all tasks default to **Normal**. Task types include:
     - **Normal**: The basic task type, a plain horizontal bar that shows the start time, end time, and duration of the task.
     - **Summary**: Shows start time and end time for a group of tasks, typically subtasks. A summary task cannot be moved or extended. However, your application should recalculate the summary task times when the dates of any subtask changes.
     - **Milestone**: Shows a specific date in the Gantt chart. There is only one date associated with a milestone task. A milestone task cannot be extended but it can be moved.

4. Click **Show More** to select additional columns in the data collection that correspond to the following attributes for the specified task type:
   - **Actual Start** and **Actual End**: When these attributes are specified, instead of drawing one bar, two bars are drawn. One bar indicates the base start and end date, the other bar indicates the actual start and end date. This is applicable to normal and milestone task types.
   - **% Complete**: When specified, an additional inner bar is drawn to indicate the percentage complete for the task.
   - **Completed Through**: Allows you to specify a date rather than a percentage. When specified, an additional inner bar is drawn to indicate the percentage complete based on the date that the attribute references.
   - **Critical**: Changes the color of the bar to red to mark it as critical. This is applicable to normal, summary, and milestone task types.
   - **Edits Allowed**: Boolean value to specify if the task start date, end date, or duration is supported in the chart region.
   - **Is Container**: Boolean value to specify if the node definition is a container.
5. If the data collection has an accessor for subtasks, use the Subtasks page to select the Subtasks Accessor from the dropdown list, and then the columns in the data collection that correspond to the following attributes:

- **Subtask ID**: The unique Id for the list of subtasks in the data collection.
- **Start Time**: The starting time of the subtask.
- **End Time**: The ending time of the subtask.
- **Subtask Type**: The type used to specify the appearance of the subtask bar when it is rendered in the Gantt chart. If you do not bind the type to a column in your data collection, then all tasks default to Normal. Task types include:
  - **Normal**: The basic task type, a plain horizontal bar that shows the start time, end time, and duration of the task.
  - **Summary**: Shows start time and end time for a group of tasks, typically subtasks. A summary task cannot be moved or extended. However, your application should recalculate the summary task times when the dates of any subtask changes.
  - **Milestone**: Shows a specific date in the Gantt chart. There is only one date associated with a milestone task. A milestone task cannot be extended but it can be moved.

If you do not bind subtasks, then the Gantt chart cannot render a hierarchy view of tasks. If you bind subtasks, you can drill from tasks to subtasks in the hierarchy view of the Gantt chart.

6. If the data collection has an accessor for dependent tasks, use the Dependent Tasks page to select the Dependent Task accessor from the dropdown list, and then the columns in the data collection that correspond to the following attributes:

- **Dependency Type**: Specifies the type of the dependency. Valid values are start-start, start-finish, finish-finish, finish-start, start-before, start-together, finish-after, and finish-together.
- **From Task Id**: Specifies the first task in the dependent relationship.
- **To Task Id**: Specifies the last task in the dependent relationship.

7. If the data collection has an accessor for split tasks, use the Split Tasks page to select the Split Task accessor from the dropdown list, and then the columns in the data collection that correspond to the following attributes:

- **Split Task Id**: The unique Id for a task split into two horizontal bars, usually linked by a line. The time between the bars represents idle time due to traveling or down time.
- **Start Time**: The starting time of the split task.
- **End Time**: The ending time of the split task.

8. If the data collection has an accessor for recurring tasks, use the Recurring Tasks page to select the Recurring Tasks accessor from the dropdown list, and then the columns in the data collection that correspond to the following attributes:

- **Recurring Task Id**: A unique Id for a task repeated in a Gantt chart, each instance with its own start and end date. Individual recurring tasks can optionally contain a subtype. All other properties of the individual recurring tasks come from the task which they are part of. However, if an individual recurring task has a subtype, this subtype overrides the task type.
■ **Type**: Specifies the type of the recurring task.

■ **Start Time**: The starting time of the recurring task.

■ **End Time**: The ending time of the recurring task.

9. In the **Appearance** page, specify the attributes that correspond to the **Label** of the task bar, and up to three icons to associate with the task bar.

10. In the **Table Columns** section, specify the columns to display for each row in the list region of the Gantt chart. Use the **New** icon to add new rows, the **Delete** icon to remove rows, and the arrow icons to arrange the rows in the sequence that you want the columns to appear in the Gantt chart list.

   For each row, specify the following:

   ■ **Display Label**: Select the values for the headers of the columns in the Gantt chart list. If you select `<default>`, the text for the header is automatically retrieved from the data binding.

   ■ **Value Binding**: Select the columns in the data collection to use for the columns in the Gantt chart list. The available values are the same as those for the tasks group.

   ■ **Component to Use**: Select the type of component to display in the cell of the Gantt chart list. You can specify that a cell is editable by using an ADF input component. The default is the ADF Output Text component.

11. Click **OK**.

   Figure 38–3 shows the dialog used to create the project Gantt chart in Figure 38–1 from the data collection for shipping orders.
12. In the Structure window, right-click the dvt:projectGantt component and select **Go to Properties**.

13. In the Properties window, expand the **Common** section, and specify the dates (yyyy-mm-dd) for the **StartTime** and **EndTime** attributes representing the start and end dates respectively for the time period of the Gantt chart data.

The dates that you specify determine the initial view that appears in the project Gantt chart at runtime.

14. If you want to include a legend in the Gantt chart, right-click the project Gantt chart node in the Structure window and choose **Insert Inside Project Gantt > Legend**.

The legend shows information about each symbol and color coded bar used to represent different task types. It also shows detailed information about the task selected in the Gantt chart.

After creating the project Gantt chart, use the Properties window to specify values for additional attributes. For detailed information about Gantt chart use cases, end user and presentation features, tag structure, and adding special features to Gantt charts, see the "Using Gantt Chart Components" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

### 38.2.2 What Happens When You Create a Project Gantt Chart from a Data Control

Dragging and dropping a view object from the Data Controls panel to create a project Gantt chart has the following effect:

- Creates the bindings for the Gantt chart and adds the bindings to the page definition file
Adding the necessary code for the UI components to the JSF page.

Example 38–1 displays the row set bindings generated for the project Gantt chart in Figure 38–1 to display shipped orders. This code example shows the node defined for tasks with attributes for task Id, start date, and end dates. There are also nodes defined for subtasks, dependent tasks, split tasks, and recurring tasks with no defined attributes.

Example 38–1  Bindings for a Project Gantt Chart

```xml
<bindings>
  <gantt IterBinding="OrderEmployee1Iterator" id="OrderEmployee1"
    xmlns="http://xmlns.oracle.com/adfm/dvt">
    <ganttDataMap>
      <nodeDefinition DefName="model.OrderEmployee" type="Tasks">
        <AttrNames>
          <Item Value="TaskId" type="taskId"/>
          <Item Value="StartDate" type="startTime"/>
          <Item Value="EndDate" type="endTime"/>
        </AttrNames>
      </nodeDefinition>
      <nodeDefinition type="subTasks">
        <AttrNames/>
      </nodeDefinition>
      <nodeDefinition type="Dependents">
        <AttrNames/>
      </nodeDefinition>
      <nodeDefinition type="SplitTasks">
        <AttrNames/>
      </nodeDefinition>
      <nodeDefinition type="RecurringTasks">
        <AttrNames/>
      </nodeDefinition>
    </ganttDataMap>
  </gantt>
</bindings>
```

Example 38–2 shows the code generated on the JSF page for the project Gantt chart. This tag code contains settings for the overall start and end time for the project Gantt chart. It also shows the default time axis settings for the major axis in weeks and the minor axis in days. Finally, it lists the specifications for each column that appears in the list region of the Gantt chart.

Example 38–2  Code on the JSF Page for a Project Gantt Chart

```xml
<dvt:projectGantt id="gantt1" value="#{bindings.OrderEmployee1.projectGanttModel}"
dataChangeListener="#{bindings.OrderEmployee1.projectGanttModel .processDataChanged}" var="row"
  startTime="2012-03-31" endTime="2012-06-30">
  <f:facet name="major">
    <dvt:timeAxis scale="weeks" id="ta1"/>
  </f:facet>
  <f:facet name="minor">
    <dvt:timeAxis scale="days" id="ta2"/>
  </f:facet>
  <f:facet name="nodeStamp">
    <af:column
      sortProperty="#{bindings.OrderEmployee1hints.FirstName.name}"
```
### 38.2.3 How to Create a Databound Resource Utilization Gantt Chart

For a resource utilization Gantt chart, you must supply identification for resources, identification for time, and start and end times for resource usage. Optionally, you can provide data values for subresources.

The resource utilization Gantt chart is displayed with default values for the major and minor time axis values. In a resource utilization Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 38–4 shows a resource utilization Gantt chart that lists each resource and an associated calendar that can display when the resource is in use.

**Figure 38–4  Resource Utilization Gantt Chart**

To create a resource utilization Gantt chart using a data control, you bind the resource utilization component to a data collection. JDeveloper allows you to do this.
declaratively by dragging a collection from the Data Controls panel and dropping it on a JSF page.

**Tip:** You can also create a resource utilization Gantt chart by dragging a resource utilization Gantt chart component from the Components window and completing the Create Resource Utilization Gantt dialog. This approach gives you the option of designing the Gantt chart user interface before binding the component to data.

**Before you begin:**
It may be helpful to have an understanding of databound Gantt charts. For more information, see Section 38.2, "Creating Databound Gantt Charts."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 38.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for the Gantt chart in Figure 38–4 comes from view objects in the Summit ADF DVT sample application. Use the `SalesRepViewObj1` view object representing the sales personnel with a view link to the `SOrdView2` view object that includes the time bucket accessor and attributes for order and ship dates.

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

**To create a resource utilization Gantt chart using the Data Controls panel:**

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection or a basic tree collection.

   Figure 38–5 shows an example where you could select the `SalesRepViewObj1` collection in the Data Controls panel to create a resource utilization Gantt chart to display the usage of a resource.

   **Figure 38–5  Data Collection for Resource Utilization Gantt Chart**

2. Drag the collection onto a JSF page and, from the context menu, choose Gantt > Resource Utilization.
3. In the Create Resource Utilization Gantt dialog, select the columns in the data collection that correspond to the following attributes:

- **Resource Id**: The unique identifier of the resource, for example Id representing the sales representatives in the view object.

- **Is Container**: Boolean. Specify whether or not the node definition is a container.

4. In the **Time Buckets** page, select a value from the **Bucket Accessor** dropdown list that contains the time buckets assigned to the resource, and select a value from the **Bucket Date** dropdown list that corresponds to a unit of time.

For example, the SOrdView2 view object includes attributes representing the date ordered and date shipped for each order assigned to a sales representative. Figure 38–6 shows the view object used for the bucket accessor.

![Figure 38–6 Resource Utilization Gantt Chart Bucket Accessor](image)

5. In the **Bucket Metrics** list, specify attributes that appear as bars within the time bucket. Use the **New** icon to add new rows, the **Delete** icon to remove rows, and the arrow icons to arrange the rows in the sequence that you want the metrics to appear in the Gantt chart region.

Each attribute that you specify in the **Bucket Metrics** list must be of type Number as the value of the attribute is used to calculate the height of the bar.

6. In the **Table Columns** section, specify the columns to display for each row in the list region of the Gantt chart. Use the **New** icon to add new rows, the **Delete** icon to remove rows, and the arrow icons to arrange the rows in the sequence that you want the columns to appear in the Gantt chart list.

---

**Note:** The first row that you specify in the **Table Columns** section designates the nodestamp column for the list region. If you specify a subresource accessor, this row displays the parent in a hierarchical relationship that can be expanded or collapsed.

---

For each row, specify the following:

- **Display Label**: Select the values for the headers of the columns in the Gantt chart list. If you select <default>, the text for the header is automatically retrieved from the data binding.

- **Value Binding**: Select the columns in the data collection to use for the columns in the Gantt chart list. The available values are the same as those for the tasks group.
- **Component to Use**: Select the type of component to display in the cell of the Gantt chart list. You can specify that a cell is editable by using an ADF input component. The default is the ADF Output Text component.

7. If the data collection has an accessor for subresources, use the **Subresources** page to select a **Subresources accessor** from the dropdown list, and then select a unique identifier for the subresource from the **Resource Id** dropdown list.

8. In the **Appearance** page, specify the attributes that correspond to the **Label** of the task bar.

9. Click **OK**.

   *Figure 38–7 shows the dialog used to create a resource utilization Gantt chart from the data collection for resources available for a project.*

10. In the Structure window, right-click the `dvt:resourceUtilizationGantt` component and select **Go to Properties**.

11. In the Properties window, expand the **Common** section, and specify the dates (yyyy-mm-dd) for the **StartTime** and **EndTime** attributes representing the start and end dates respectively for the time period of the Gantt chart data.

   The dates that you specify determine the initial view that appears in the resource utilization Gantt chart at runtime.

12. If you want to include a legend in the Gantt chart, right-click the resource utilization Gantt chart node in the Structure window and choose **Insert Inside Resource Utilization Gantt > Legend**.

   The legend shows information about each symbol and color coded bar used to represent different tasks. It also shows detailed information about the task selected in the Gantt chart.
After creating the resource utilization Gantt chart, use the Properties window to specify values for additional attributes. For detailed information about Gantt chart use cases, end user and presentation features, tag structure, and adding special features to Gantt charts, see the "Using Gantt Chart Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.

### 38.2.4 What Happens When You Create a Resource Utilization Gantt Chart

Dragging and dropping a view object from the Data Controls panel onto a JSF page to create a resource utilization Gantt chart has the following effects:

- Creates bindings for the resource utilization Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

Example 38–3 shows the row set bindings that were generated for the resource utilization Gantt chart illustrated in Figure 38–7.

**Example 38–3 Binding XML for a Resource Utilization Gantt Chart**

Example 38–4 shows the code generated on the JSF page for the resource utilization Gantt chart. This tag code contains settings for the overall start and end time for the resource utilization Gantt chart. These settings have to be edited manually. The code also shows the time axis settings for the major time axis (in weeks) and the minor time axis (in days). Finally, it lists the specifications for each column to appear in the list region of the resource utilization Gantt chart.

**Example 38–4 Code on the JSF Page for a Resource Utilization Gantt Chart**
Creating Databound Gantt Charts

38.2.5 How to Create a Databound Scheduling Gantt Chart

For a scheduling Gantt chart, you must supply identification for resources, identification for tasks, and start and end times for tasks. Optionally, you can provide data values for subresources, recurring tasks, split tasks, and dependencies between tasks.

The scheduling Gantt chart is displayed with default values for overall start and end time and for the major and minor time axis values. In a scheduling Gantt chart, the setting for the major time axis defaults to weeks and the setting for the minor time axis defaults to days.

Figure 38–8 shows a scheduling Gantt chart that lists each resource and all the orders for which that resource is responsible. In contrast to a project Gantt chart, the scheduling Gantt chart shows all the tasks for a given resource on the same line, while the project Gantt chart lists each task on a separate line.
To create a scheduling Gantt chart using a data control, you bind the `schedulingGantt` tag to a data collection. JDeveloper allows you to do this declaratively by dragging and dropping a collection from the Data Controls panel.

**Before you begin:**

It may be helpful to have an understanding of databound Gantt charts. For more information, see Section 38.2, "Creating Databound Gantt Charts."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 38.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for the Gantt chart in Figure 38–8 comes from view objects in the Summit ADF DVT sample application. Use the `SalesRepViewObj1` view object representing the sales personnel with a view link to the `SOrdView2` view object that includes the tasks accessor and attributes for order and ship dates.

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

**To create a scheduling Gantt chart using the Data Controls panel:**

1. From the Data Controls panel, select a data collection. For a Gantt chart, you can select a row set collection or a basic tree collection.

  Figure 38–9 shows an example where you could select the `SalesRepViewObj1` data collection to create a scheduling Gantt chart that displays the orders each sales representative is responsible for managing.
Creating Databound Gantt Charts

Creating Databound Gantt Chart and Timeline Components

Figure 38–9  Data Collection for Scheduling Gantt Chart

2. Drag the collection onto a JSF page and, from the context menu, choose Gantt > Scheduling.

3. In the Create Scheduling Gantt dialog, select the columns in the data collection that correspond to the following attributes:
   - **Resource Id**: The unique Id for the resource represented in the scheduling Gantt chart.
   - **Working Start Time**: The work start date of the scheduling Gantt chart.
   - **Working End Time**: The work end date of the scheduling Gantt chart.
   - **Working Days of Week**: Specifies a list of the working days of the week.
   - **Is Container**: Boolean. Specify whether or not the node definition is a container.

4. In the Tasks page, select the Task Accessor from the dropdown list, and then select the columns in the data collection that correspond to the following attributes:
   - **Task Id**: The unique Id for the task associated with a resource in the Gantt chart.
   - **Task Type**: The type used to specify the appearance of the task bar when it is rendered in the Gantt chart. If you do not bind the type to a column in your data collection, then all tasks default to Scheduled.
   - **Start Time**: The starting time of the task.
   - **End Time**: The ending time of the task.
   - **Startup Time**: The time to start up the task before beginning.
   - **Shutdown Time**: The time to shut down the task after completion.

For example, the SOrdView2 view object includes attributes representing the date ordered and date shipped for each order assigned to a sales representative. Figure 38–10 shows the view object used for the task accessor.
5. If the data collection has an accessor for dependent tasks, use the **Dependent Tasks** page to select the **Dependent Task** accessor, and then select the columns in the data collection that correspond to the following attributes:

   - **Dependency Type**: Specifies the type of the dependency. Valid values are `start-start`, `start-finish`, `finish-finish`, `finish-start`, `start-before`, `start-together`, `finish-after`, and `finish-together`.
   - **From Task Id**: Specifies the first task in the dependent relationship.
   - **To Task Id**: Specifies the last task in the dependent relationship.

   Dependent tasks are linked by their associations with the finish and start times between them.

6. If the data collection has an accessor for split tasks, use the **Split Tasks** page to select the **Split Tasks** accessor, and then select the columns in the data collection that correspond to the following attributes:

   - **Split Task Id**: The unique Id for a task split into two horizontal bars, usually linked by a line. The time between the bars represents idle time due to traveling or down time.
   - **Start Time**: The starting time of the split task.
   - **End Time**: The ending time of the split task.

7. If the data collection has an accessor for recurring tasks, use the **Recurring Tasks** page to select the **Recurring Tasks** accessor from the dropdown list, and then select the columns in the data collection that correspond to the following attributes:

   - **Recurring Task Id**: A unique Id for a task repeated in a Gantt chart, each instance with its own start and end date. Individual recurring tasks can optionally contain a subtype. All other properties of the individual recurring tasks come from the task which they are part of. However, if an individual recurring task has a subtype, this subtype overrides the task type.
   - **Type**: Specifies the type of the recurring task.
   - **Start Time**: The starting time of the recurring task.
   - **End Time**: The ending time of the recurring task.

8. If the data collection has an accessor for subresources, use the **Subresources** page to select the **Subresources Accessor** from the dropdown list, and then select the
column in the data collection that corresponds to the **Subresource Id**, the unique Id for the list of subresources in the data collection.

If you do not bind subresources, then the Gantt chart cannot render a hierarchy view of resources. If you bind subresources, then you can drill from resources to subresources in the hierarchy view of the Gantt chart.

9. In the **Appearance** page, specify the attributes that correspond to the **Label** of the task bar, and up to three icons to associate with the task bar.

10. In the **Table Columns** section, specify the columns that will appear in the list region of the Gantt chart on the left side of the splitter. Specify one row of information for each column that is to appear. Use the **New** icon to add new rows. Use the arrow icon to arrange the rows in the exact sequence that you want the columns to appear in the Gantt chart list. For each row, you provide the following specifications:

   - **Display Label**: Select the values for the headers of the columns in the Gantt chart list. If you select `<default>`, then the text for the header is automatically retrieved from the data binding.
   - **Value Binding**: Select the columns in the data collection to use for the column in the Gantt chart list. The available values are the same as those for the tasks group.
   - **Component to Use**: Select the type of component to display in the cell of the Gantt chart list. The default is the **ADF Output Text** component.

11. Click **OK**.

   Figure 38–11 shows the dialog used to create the scheduling Gantt chart from the data collection for sales representatives responsible for shipping orders.

### Figure 38–11 Create Scheduling Gantt Dialog

![Create Scheduling Gantt Dialog]

12. In the Structure window, right-click the `dvt:schedulingGantt` component and select **Go to Properties**.
13. In the Properties window, expand the **Common** section, and specify the dates (yyyy-mm-dd) for the **StartTime** and **EndTime** attributes representing the start and end dates respectively for the time period of the Gantt chart data.

The dates that you specify determine the initial view that appears in the scheduling Gantt chart at runtime.

14. If you want to include a legend in the Gantt chart, right-click the scheduling Gantt chart node in the Structure window and choose **Insert Inside Scheduling Gantt > Legend**.

The legend shows information about each symbol and color coded bar used to represent different tasks. It also shows detailed information about the task selected in the Gantt chart.

### 38.2.6 What Happens When You Create a Scheduling Gantt Chart

Dropping a scheduling Gantt chart from the Data Controls panel has the following effect:

- Creates the bindings for the Gantt chart and adds the bindings to the page definition file
- Adds the necessary code for the UI components to the JSF page

**Example 38–5** shows the row set bindings that were generated for the scheduling Gantt chart that displays resources and orders shipped.

#### Example 38–5  Binding XML for a Scheduling Gantt Chart

```xml
<bindings>
  <gantt IterBinding="SalesRepViewObj1Iterator" id="SalesRepViewObj1"
         xmlns="http://xmlns.oracle.com/adfm/dvt">
    <ganttDataMap>
      <nodeDefinition DefName="model.SalesRepViewObj" type="Resources">
        <AttrNames>
          <Item Value="Id" type="resourceId"/>
        </AttrNames>
        <Accessors>
          <Item Value="SOrdView" type="tasks"/>
        </Accessors>
      </nodeDefinition>
      <nodeDefinition type="Tasks" DefName="model.SOrdView">
        <AttrNames>
          <Item Value="Id" type="taskId"/>
          <Item Value="DateOrdered" type="startTime"/>
          <Item Value="DateShipped" type="endTime"/>
        </AttrNames>
      </nodeDefinition>
      <nodeDefinition type="Dependents">
        <AttrNames/></nodeDefinition>
      <nodeDefinition type="SplitTasks">
        <AttrNames/></nodeDefinition>
      <nodeDefinition type="RecurringTasks">
        <AttrNames/></nodeDefinition>
      <nodeDefinition type="Subresources">
        <AttrNames/></nodeDefinition>
    </ganttDataMap>
  </gantt>
</bindings>
```
Creating Databound Gantt Charts

Example 38–6 shows the code generated on the JSF page for the scheduling Gantt chart. This tag code contains settings for the overall start and end time for the scheduling Gantt chart. It also shows the time axis settings for the major time axis in weeks and the minor time axis in days. Finally, it lists the specifications for each column that appears in the list region of the Gantt chart.

Example 38–6  Code on the JSF Page for a Scheduling Gantt Chart

```xml
<dvt:schedulingGantt id="gantt1"
    value="#{bindings.SalesRepViewObj1.schedulingGanttModel}"
    dataChangeListener="#{bindings.SalesRepViewObj1.schedulingGanttModel.processDataChanged}"
    var="row" startTime="2012-04-15" endTime="2013-05-15"
    summary="#{viewcontrollerBundle.SCHEDULING_GANTT_CHART}"
    
    <f:facet name="major">
        <dvt:timeAxis scale="weeks" id="ta1"/>
    </f:facet>
    
    <f:facet name="minor">
        <dvt:timeAxis scale="days" id="ta2"/>
    </f:facet>
    
    <f:facet name="nodeStamp">
        <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.FirstName.name}"
            sortable="false"
            headerText="#{bindings.SalesRepViewObj1.hints.FirstName.label}"
            id="c1">
            <af:outputText value="#{row.FirstName}"
                shortDesc="#{bindings.SalesRepViewObj1.hints.FirstName.tooltip}"
                id="ot1"/>
        </af:column>
    </f:facet>
    
    <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.LastName.name}"
        sortable="false"
        headerText="#{bindings.SalesRepViewObj1.hints.LastName.label}"
        id="c2">
        <af:outputText value="#{row.LastName}"
            shortDesc="#{bindings.SalesRepViewObj1.hints.LastName.tooltip}"
            id="ot2"/>
    </af:column>
    
    <af:column sortProperty="#{bindings.SalesRepViewObj1.hints.Email.name}"
        sortable="false"
        headerText="#{bindings.SalesRepViewObj1.hints.Email.label}" id="c3">
        <af:outputText value="#{row.Email}"
            shortDesc="#{bindings.SalesRepViewObj1.hints.Email.tooltip}"
            id="ot3"/>
    </af:column>
    </dvt:schedulingGantt>
```

38.2.7 What You May Need to Know About Data Change Event Handling

When you use ADF data controls to data bind project and scheduling Gantt charts, a data change listener is automatically provided for data change events that require an update to row attributes, for example:

- DURATION_CHANGE: End time of a task; resize task bar
Creating Databound Gantt Charts

- **PROGRESS_CHANGE**: Progress of task; resize progress bar
- **TIME_CHANGE**: Start and end time of a task; move the task bar

At design time, the data change listener provides a built-in `processDataChange` method for project and scheduling Gantt bindings as illustrated in Example 38–7.

**Example 38–7  Sample Code for Default dataChangeListener**

```xml
dvt:projectGantt id='gantt1'
  dataChangeListener='#{bindings.GanttProjectView1.
    projectGanttModel.processDataChanged}''
  value='#{bindings.GanttProjectView1.projectGanttModel}'
  ...
</dvt:projectGantt>
```

Data change events requiring row insertion or deletion are not supported, for example:

- **TASK_SPLITTED**: Split a task
- **TASK_MERGED**: Merge task with another task
- **LINK**: Link two tasks together
- **UNLINK**: Unlink two tasks linked together
- **COPY**: Copy one or more tasks or resources
- **CREATE**: Create a new task
- **CREATE_Resource**: Create a new resource
- **CUT**: Cut one or more tasks or resources
- **PASTE**: Paste tasks or resources
- **UPDATE**: Update a task
- **UPDATE_Resource**: Update a resource
- **TASKS_PROPERTIES_UPDATE**: Task properties dialog event
- **INDENT**: Indent a task or resource
- **OUTDENT**: Outdent a task or resource
- **DELETE**: Delete one or more tasks or resources

If you wish to configure your application to handle events that do not have a default implementation, specify a method in a backing bean and delegate to the built-in `processDataChange` method. For example, Example 38–8 shows a `dataChangeListener` configured to use a `handleDataChange` method to handle a `TASK_PROPERTIES_UPDATE` event using the backing bean shown in Example 38–9.

**Example 38–8  Sample Code for Custom dataChangeListener Method**

```xml
dvt:projectGantt id='gantt1'
  dataChangeListener='#{backingBeanScope.backing_
    projectGantt.handleDataChange}''
  value='#{bindings.GanttProjectView1.projectGanttModel}'
  ...
</dvt:projectGantt>
```
### Example 38–9  Sample Code for Backing Bean

```java
public void handleDataChange(DataChangeEvent evt)
{
    // handle events not supported by built-in "processDataChange" method
    int _type = evt.getActionType();
    if (_type == DataChangeEvent.TASK_PROPERTIES_UPDATE)
    {
        // handle event.
    }
    else // delegate to built-in "processDataChange" method.
    {
        String expression =
            "#{bindings.GanttProjectView1.projectGanttModel.processDataChanged}";
        ExpressionFactory elFactory = app.getExpressionFactory();
        ELContext elContext = facesContext.getELContext();
        MethodExpression methodExp = elFactory.createMethodExpression(elContext,
            expression, null, new Class[]{DataChangeEvent.class});
        methodExp.invoke(elContext, new Object[]{evt});
    }
}
```

---

**Note:** The project and scheduling Gantt chart’s default implementation of a dataChangeListener for ADF data controls will not perform commit or rollback changes to the database. You must configure your application to handle those operations.

### 38.3 Creating Databound Timelines

A timeline is an interactive data visualization tool that allows users to view date-based events in chronological order and easily navigate forwards and backwards within a defined time range. A dual timeline can be used for a side-by-side comparison of events. For example, you can use a timeline to display the hire dates of employees, or use a dual timeline to compare multiple human resource events between two employees.

A timeline is composed of the display of events as timeline items along a time axis, a movable overview window that corresponds to the period of viewable time in the timeline, and an overview time axis that displays the total time increment for the timeline. A horizontal zoom control is available to change the viewable time range. Timeline items corresponding to events display associated information or actions and are connected to the date of the event in the time axis. Timelines items are represented by a marker in the overview panel. No more that two series of events are supported by the timeline component.

**Figure 38–12** shows a timeline displaying the chronological order of the hire dates of employees in the Summit ADF DVT sample application. In this example, timeline items representing each event display information about the employee using an image and text with labels. When selection is configured, the timeline item, line feeler, and the event marker in the overview panel are highlighted.
Creating Databound Timelines

Figure 38–12  Timeline of Employee Hire Dates

Figure 38–12 shows a timeline of employee hire dates. The time axis is displayed horizontally across the width of the timeline.

Figure 38–13 Dual Timeline Events Between Employees

Figure 38–13 shows a dual timeline comparing multiple human resource events between two employees. The time axis is positioned between the two series of events and the overview panel displays at the bottom of the timeline.

The content of timeline items, marker display, and time axis are configurable. For detailed information about timeline use cases, end user and presentation features, tag structure, and adding special features to timelines, see the “Using Timeline Components” chapter in Developing Web User Interfaces with Oracle ADF Faces.

38.3.1 How to Create a Timeline Using ADF Data Controls

The data displayed in a timeline is based on data collections. The timeline component uses a model to access the data in the underlying list. The specific model class is oracle.adf.view.rich.model.CollectionModel. You can also use other model instances, for example, java.util.List, java.util.Array, and
javax.faces.model.DataModel. The data layer will automatically convert the instance into a CollectionModel.

Stamping is used to associate information about a timeline event with a row of data in a data collection. Using stamping, each row of data in the data model can be displayed for an event. When you use stamping, child components are not created for every item in the timeline. Rather, the content of the component is repeatedly rendered, or stamped, once per data attribute.

Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a data collection from the Data Controls panel that generates one (up to two) series of events onto the JSF page.

**Before you begin:**

It may be helpful to have an understanding of databound timelines. For more information, see Section 38.3, "Creating Databound Timelines."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 38.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

  For example, the data source for the timeline in Figure 38–12 comes from a single table in the Summit ADF DVT sample application. Use the SEmp table to create a view object representing the employees including their hire dates.

- Create a JSF page as described in the “How to Create JSF Pages” section of Developing Web User Interfaces with Oracle ADF Faces.

**To create a timeline using the Data Controls panel:**

1. From the Data Controls panel, select a collection.

   Figure 38–14 shows an example where you could select the SEmpView1 collection in the Data Controls panel to create a timeline that displays the hire dates of employees.
2. Drag the collection onto the JSF page, and from the context menu choose **Timeline**.

3. In the Configure Timeline Series Data page of the Create Timeline wizard, configure the timeline data model for at least one (at most two for a dual timeline), by setting the following values:

   a. **Series Value**: Use the dropdown list to select the data collection to use in the timeline. By default, the data collection you inserted from the Data Controls panel is displayed. JDeveloper automatically lists any collection from the application module that includes at least one qualifying date-based attribute from which to choose.

   b. **Item Date Value**: Use the dropdown list to select the date-based attribute to use for the timeline items stamped in the timeline. JDeveloper automatically lists all qualifying attributes in the collection referenced in the **Series Value** from which to choose.

   c. **Group**: Optionally use the dropdown list to select the attribute to use to group timeline items when the item date values are identical. JDeveloper automatically lists all data collection attributes from which to choose.

      You can also choose **Expression Builder** and create an EL Expression to specify grouping of attributes at runtime. If you need help press **F1** or click **Help**.

4. For each timeline series that you configured as a data model, select the series, and set the following values for the timeline item display attributes:

   a. **Image**: Optionally, enter the relative path to the image file to stamp in the timeline item, or use the **Search** icon to open the Select Image File dialog to navigate to the image source.

      You can also choose **Expression Builder** to configure an EL Expression that evaluates at runtime to locate the image file.

   b. **Component**: From the dropdown list, select the ADF Faces component to use to display the attribute text in the timeline item. You can choose from **outputText**, which displays unformatted text, and **outputFormatted**, which displays text and can include a limited range of formatting options. You can also choose to associate a label with either output text option in the **Label** value.

   c. **Value**: From the dropdown list select the attribute value to display in the timeline item. JDeveloper automatically lists all attributes in the data collection for the selected timeline series.

   d. **Label**: This option is available if you specify an ADF Faces component with a label in the **Component** value for the display attribute. You can use the default **Use Attribute Name** text, specify a text resource from a resource bundle, or use the EL Expression builder to evaluate the label text at runtime. The label displays in the timeline item at runtime.

   **Note**: if you need to change the size of the image in the timeline item, specify the **InlineStyle** attribute of the af:image component in source code or declaratively in the Property window. For example, in the Summit ADF DVT sample, specify

   ```html
   inlineStyle="width:85px;height:100px;".
   ```
For example, to specify the timeline series and display attributes for the Summit ADF DVT sample in Figure 38–12, complete the Configure Timeline Series Data page of the Create Timeline wizard as shown in Figure 38–15.

Figure 38–15  Configure Timeline Series Data Page of Create Timeline Wizard

5. Select Next to advance to the next page of the wizard or Cancel to end the creation of the timeline.

6. In the Configure Event Marker page of the Create Timeline Wizard, for each timeline series that you configured as a data model, select the series, and set the following optional values for the event marker:
   a. Color: Specify the fill color for the event marker. You can use the dropdown list to select available colors, or click the icon to display a color picker dialog. By default, no color is specified.
   b. Opacity: Specify the opacity of the fill color of the marker. Valid values range from 0 percent for transparent, to 100 percent for opaque.
   c. Standard Shape: Specify the shape of the overview marker for each selected timeline series value. From the dropdown list, select one of seven prebuilt shapes to style the overview marker shape. Valid values are circle (default), diamond, human, plus, square, triangleDown, and triangleUp.
   d. ScaleX/ScaleY: Enter the horizontal (scaleX) and vertical (scaleY) scale factor to modify the overview marker from its default size. Valid values are numerical percentages. JDeveloper will automatically resize a marker to fit within the timeline overview area if the marker is too large.

For example, to specify the timeline overview series markers for the Summit ADF DVT sample in Figure 38–12, complete the Configure Event Marker page of the Create Timeline wizard as shown in Figure 38–16.
7. Select **Back** to return to the last page of the wizard, **Next** to advance to the next page of the wizard, or **Cancel** to end the creation of the timeline.

8. In the Configure Time Range and Scale of the Create Timeline Wizard, configure the time axis and overview axis by setting the following values:

   a. **Start Time**: Enter the starting date to use for the time range of the timeline using the format `yyyy-mm-dd`. Select a start date that will include events in the data collection you wish to display on the timeline. From the dropdown list you can select **Current Date**. You can also click the Calendar icon to display a date picker dialog. The default value is set for three months before the current date.

   b. **End Time**: Enter the ending date to use for the timeline time range using the format `yyyy-mm-dd`. Select an end date that will include events in the data collection you wish to display on the timeline. From the dropdown list you can select **Current Date**. You can also click the Calendar icon to display a date picker dialog. The default value is twelve months after the default Start Time value.

   c. **Axis Scale**: Use the dropdown list to select the time scale to use for the timeline time axis. The time axis shows the user the current time increment for the timeline.

      You must use a smaller time scale than the **Overview Scale**. For example, you cannot set the axis scale to **years** if the overview scale is set to **months**. You can also specify a custom axis scale.

      Valid values are twoyears, years, halfyears, quarters (default), twomonths, months, twoweeks, weeks, days, sixhours, threehours, hours, halfhours, and quarterhours. You can also specify a custom axis scale.
scale. For more information, see "How to Add a Custom Time Scale to a Timeline" in *Developing Web User Interfaces with Oracle ADF Faces*.

d. **Overview Scale**: Use the dropdown list to select the time scale to use for the timeline overview axis. The overview axis shows the user the total time increment covered by the timeline.

Valid values are *twoyears*, *years* (default), *halfyears*, *quarters*, *twomonths*, *months*, *toweeeks*, *weeks*, *days*, *sixhours*, *threethours*, *hours*, *halfhours*, and *quarterhours*. You can also specify a custom axis scale. For more information, see "How to Add a Custom Time Scale to a Timeline" in *Developing Web User Interfaces with Oracle ADF Faces*.

For example, to specify the timeline axis and overview time range for the Summit DVT ADF sample in *Figure 38–12*, complete the Configure Time Range and Scale page in the Create Timeline wizard as show in *Figure 38–17*.

**Figure 38–17 Configure Time Range and Scale Page of Create Timeline Wizard**

9. Select **Back** to return to the last page of the wizard, **Finish** to complete the definition of the data binding, or **Cancel** to end the creation of the timeline.

### 38.3.2 What Happens When You Use Data Controls to Create a Timeline

When you use ADF data controls to create a timeline, JDeveloper:

- Defines the bindings for the timeline in the page definition file of the JSF page, and
- Inserts code in the JSF page for the DVT timeline components.

**Example 38–10** shows the bindings defined in the page definition file of the JSF page for the Summit ADF DVT sample timeline in *Figure 38–12*. 
Example 38–10  XML Bindings in Page Definition File

```xml
<bindings>
  <tree IterBinding="SEmpView1Iterator" id="SEmpView1" ChangeEventPolicy="ppr">
    <nodeDefinition DefName="model.SEmpView" Name="SEmpView1">
      <AttrNames>
        <Item Value="DeptId"/>
        <Item Value="FirstName"/>
        <Item Value="Id"/>
        <Item Value="LastName"/>
        <Item Value="StartDate"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
```

Example 38–11 shows the code inserted in the JSF page for the example timeline in Figure 38–12.

Example 38–11  Sample Code for Timeline Component

```xml
<dvt:timeline id="tl1" startTime="2010-01-01" endTime="2012-12-31" itemSelection="multiple">
  <dvt:timelineSeries id="ts1" var="evt" value="#{bindings.SEmpView1.collectionModel}">
    <dvt:timelineItem value="#{evt.StartDate}" id="ti1" group="#{evt.DeptId}">
      <af:panelGroupLayout id="pg1" layout="horizontal">
        <af:image id="img1" source="/images/#{evt.Id}.png" inlineStyle="width:85px;height:100px;"/>
        <af:spacer width="3" id="s1"/>
        <af:panelGroupLayout id="pg2" layout="vertical">
          <af:panelLabelAndMessage id="plam1" label="#{viewcontrollerBundle.EMPLOYEE_ID}">
            <af:outputText id="ot1" value="#{evt.Id}" noWrap="true">
              <af:convertNumber groupingUsed="false" pattern="#{bindings.SEmpView1.hints.Id.format}"/>
            </af:outputText>
          </af:panelLabelAndMessage>
          <af:panelLabelAndMessage id="plam2" label="#{viewcontrollerBundle.FIRST_NAME}">
            <af:outputText id="ot2" value="#{evt.FirstName}" noWrap="true"/>
          </af:panelLabelAndMessage>
          <af:panelLabelAndMessage id="plam3" label="#{viewcontrollerBundle.LAST_NAME}">
            <af:outputText id="ot3" value="#{evt.LastName}" noWrap="true"/>
          </af:panelLabelAndMessage>
          <af:panelLabelAndMessage id="plam4" label="#{viewcontrollerBundle.DEPARTMENT_ID}">
            <af:outputText id="ot4" value="#{evt.DeptId}" noWrap="true">
              <af:convertNumber groupingUsed="false" pattern="#{bindings.SEmpView1.hints.DeptId.format}"/>
            </af:outputText>
          </af:panelLabelAndMessage>
        </af:panelGroupLayout>
      </af:panelGroupLayout>
      <f:facet name="overviewItem">
        <dvt:marker id="m1" fillColor="#ff0000"/>
      </f:facet>
    </dvt:timelineItem>
  </dvt:timelineSeries>
  <dvt:timeAxis id="ta1" scale="months"/>
</dvt:timeline>
```
38.3.3 What You May Need to Know About Using Data Controls to Create a Dual Timeline

When you use the Data Controls panel to create a dual timeline, you can configure the same or different data collections to configure the two timeline series and specify the timeline item display attributes and overview marker for each one. JDeveloper automatically lists any data collection from the application module that includes at least one qualifying date-based attribute from which to choose in the Create Timeline wizard.

Example 38–12 show the sample code for the dual timeline displayed in Figure 38–13.

Example 38–12   Sample Code for a Dual Timeline

```xml
<dvt:timeline id="tl1" startTime="2000-01-01" endTime="2011-12-31"
inlineStyle="width:1024px;height:500px" itemSelection="single"
currentTime='2010-04-01'>
<dvt:timelineSeries id="ts1" var="evt" value="#{timeline.firstModel}"
contentDelivery="lazy">
<dvt:timelineItem id="ti1" value="#{evt.date}" group="#{evt.group}"
><af:panelGroupLayout id="pg1" layout="horizontal">
<af:image id="img1" inlineStyle="width:30px;height:30px"
source="/resources/images/timeline/#{evt.type}.png"/>
<af:spacer width="3"/>
<af:panelGroupLayout id="pg2" layout="vertical">
<af:outputText id="ot1" inlineStyle="color:#084B8A"
value="#{evt.description}" noWrap="true"/>
<af:outputText id="ot2" value="#{evt.date}" inlineStyle="color:#6e6e6e" noWrap="true">
<af:convertDateTime dateStyle="medium"/>
</af:outputText>
</af:panelGroupLayout>
<af:image id="img1" inlineStyle="width:30px;height:30px"
source="/resources/images/timeline/#{evt.type}.png"/>
<af:panelGroupLayout id="pg2" layout="vertical">
<af:outputText id="ot1" inlineStyle="color:#084B8A"
value="#{evt.description}" noWrap="true"/>
<af:outputText id="ot2" value="#{evt.date}" inlineStyle="color:#6e6e6e" noWrap="true">
<af:convertDateTime dateStyle="medium"/>
</af:outputText>
</af:panelGroupLayout>

<dvt:marker id="m1" shape="circle" fillColor="#ff0000"/>
</f:facet>
</dvt:timelineItem>
</dvt:timelineSeries>
</dvt:timeline>
```
For information about the data requirements, tag structure, and options for customizing the look and behavior of the component, see the "Using Timeline Components" chapter in the Developing Web User Interfaces with Oracle ADF Faces.
Creating Databound Hierarchy Viewer, Treemap, and Sunburst Components

This chapter describes how to create a hierarchy viewer, treemap, or sunburst from data modeled with ADF Business Components, using ADF data controls and ADF Faces components in a Fusion web application. Specifically, it describes how you can use ADF Data Visualization hierarchyViewer, treemap, and sunburst components to create hierarchy viewers, treemaps, and sunbursts that visually represent business data. It describes how to use ADF data controls to create these components with data-first development.

If you are designing your page using simple UI-first development, then you can add the hierarchy viewer, treemap, or sunburst to your page and configure the data bindings later. For information about the data requirements, tag structure, and options for customizing the look and behavior of the hierarchy viewer, treemap, and sunburst components, see the "Using Hierarchy Viewer Components" and "Using Treemap and Sunburst Components" chapters in Developing Web User Interfaces with Oracle ADF Faces.

This chapter includes the following sections:

- Section 39.1, "About ADF Data Visualization Components"
- Section 39.2, "Creating Databound Hierarchy Viewers"
- Section 39.3, "Creating Databound Treemaps and Sunbursts"

39.1 About ADF Data Visualization Components

ADF Data Visualization components provide extensive graphical and tabular capabilities for visually displaying and analyzing business data. Each component needs to be bound to data before it can be rendered since the appearance of the components is dictated by the data that is displayed.

The ADF hierarchy viewer component produces an interactive graphic that displays hierarchical data as a set of linked shapes. The shapes and links correspond to the elements and relationships in the data. For example, a hierarchy viewer component might be used to generate an organizational chart based on employee data. At runtime, end users can pan and zoom the graphic and expand, select, and navigate the management hierarchy that the graphic displays.

Use treemaps and sunbursts to display quantitative hierarchical data across two dimensions, represented visually by size and color. Treemaps and sunbursts use a shape called a node to reference the data in the hierarchy. For example, you can use a treemap or sunburst to display quarterly regional sales and to identify sales trends, using the size of the node to indicate each region's sales volume and the node's color to
indicate whether that region’s sales increased or decreased over the quarter. The appearance and content of the nodes are configurable at each level of the hierarchy. The prefix \texttt{dvt:} occurs at the beginning of each data visualization component name indicating that the component belongs to the ADF Data Visualization Tools (DVT) tag library.

### 39.1.1 End User and Presentation Features

Visually compelling data visualization components enable end users to understand and analyze complex business data. The components are rich in features that provide out-of-the-box interactivity support. For detailed descriptions of the end user and presentation features for each component, see the following:

- Hierarchy Viewer components: "End User and Presentation Features" section in \textit{Developing Web User Interfaces with Oracle ADF Faces}.
- Treemap and Sunburst components: "End User and Presentation Features of Treemaps and Sunbursts" section in \textit{Developing Web User Interfaces with Oracle ADF Faces}.

### 39.1.2 Data Visualization Components Use Cases and Examples

For detailed descriptions of each data visualization use case and example, see the following:

- Hierarchy Viewer components: "Hierarchy Viewer Use Cases and Examples" section in \textit{Developing Web User Interfaces with Oracle ADF Faces}.
- Treemap and Sunburst components: "Treemap and Sunburst Use Cases and Examples" section in \textit{Developing Web User Interfaces with Oracle ADF Faces}.

### 39.1.3 Additional Functionality for Data Visualization Components

You may find it helpful to understand other Oracle ADF features before you data bind your data visualization components. Additionally, once you have added a data visualization component to your page, you may find that you need to add functionality such as validation and accessibility. Following are links to other functionality that data visualization components use:

- Partial page rendering: You may want a data visualization component to refresh to show new data based on an action taken on another component on the page. For more information, see the "Rerendering Partial Page Content" chapter in \textit{Developing Web User Interfaces with Oracle ADF Faces}.
- Personalization: Users can change the way the data visualization components display at runtime, those values will not be retained once the user leaves the page unless you configure your application to allow user customization. For more information, see the "Allowing User Customization on JSF Pages" chapter in \textit{Developing Web User Interfaces with Oracle ADF Faces}.
- Accessibility: You can make your data visualization components accessible. For more information, see the "Developing Accessible ADF Faces Pages" chapter in \textit{Developing Web User Interfaces with Oracle ADF Faces}.
- Skins and styles: You can customize the appearance of data visualization components using an ADF skin that you apply to the application or by applying CSS style properties directly using a style-related property (\texttt{styleClass} or \texttt{inlineStyle}). For more information, see the "Customizing the Appearance..."
Using Styles and Skins” chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

- Placeholder data controls: If you know the data visualization components on your page will eventually use ADF data binding, but you need to develop the pages before the data controls are ready, then you should consider using placeholder data controls, rather than manually binding the components. Using placeholder data controls will provide the same declarative development experience as using developed data controls. For more information, see Chapter 19, "Designing a Page Using Placeholder Data Controls."

### 39.2 Creating Databound Hierarchy Viewers

A hierarchy viewer is an ADF Data Visualization component that visually displays data where parent-child relationships exist within the data. This component is useful where you want to display organization charts, network diagrams, social networks, or similar visual displays.

Hierarchy viewers use a shape called a *node* to reference the data in a hierarchy. The shape and content of the nodes are configurable, as well as the visual layout of the nodes. Nodes can display multiple views in a panel card.

Figure 39–1 shows a runtime view of a hierarchy viewer component that renders an organization chart.

![Figure 39–1](image)

Each hierarchy viewer component (**dvt:hierarchyViewer**) that you create can include:

- One or more node elements (**dvt:node**)
- One or more link elements (**dvt:link**)

[Diagram of hierarchy viewer rendering an organization chart]
The optional panel card element (dvt:panelCard) can be used in conjunction with the hierarchy viewer component. The panel card provides a method to switch dynamically between multiple sets of content referenced by a node element using animation by, for example, horizontally sliding the content or flipping a node over.

For detailed information about hierarchy viewer end user and presentation features, use cases, tag structure, and adding special features to hierarchy viewers, see the "Using Hierarchy Viewer Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.

### 39.2.1 How to Create a Hierarchy Viewer Using ADF Data Controls

Hierarchy viewers are based on data collections where a master-detail relationship exists between one or more detail collections and a master data collection. Using data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop a data collection from the Data Controls panel that generates one or more root nodes onto a JSF page.

**Before you begin:**

It may be helpful to have an understanding of databound hierarchy viewers. For more information, see Section 39.2, "Creating Databound Hierarchy Viewers."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 39.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model for the hierarchy viewer, as described in Section 13.2, "Creating and Modifying an Application Module."

For example, the data source for the hierarchy viewer in Figure 39–1 comes from a single table representing the employees in the Summit sample application for ADF DVT components. To set up a hierarchical relationship in the Summit ADF DVT sample application between the managers and employees using the SEmp table and to establish the highest level employee as the root of the hierarchy, do the following:

1. Create an entity object based on the SEmp table.

   Figure 39–2 shows the SEmp entity object based on the SEmp table. Each row in the table includes both the employee’s ID and the employee’s manager ID. For help with creating entity objects, see Section 4.2, "Creating Entity Objects and Associations."
2. Create an association between SEmp.Id and SEmp.ManagerID to establish the relationship between the employee and manager.

Figure 39–3 shows the SEmpManagerIdFkAssoc association in the Summit ADF DVT sample application. In this example, the association is automatically created when you create the SEmp entity object. For additional information about associations, see Section 4.2, "Creating Entity Objects and Associations."

3. To establish the hierarchy between the managers and employees, create a view link between the managers and employees based on the SEmpManagerIdFkAssoc association.

Figure 39–4 shows the SEmpManagerIDFKLink view link in the Summit ADF DVT sample application. For additional information about establishing the master-detail relationship using view links, see Section 6.2.1, "How to Create a Master-Detail Hierarchy Based on Entity Associations."
Creating Databound Hierarchy Viewers

4. To use the SEmpManagerDFKLink, create a new view object that ties the managers with the employees as shown in Figure 39–5.

Figure 39–5  Managers-Employees View Object in the Summit ADF DVT Sample Application

5. Create a view object that retrieves the root value from the data collection.

For example, in the Summit ADF DVT sample application, Carmen Velasquez is the highest level manager and has an employee ID of 1. To create a view object based on the Summit ADF DVT sample application, create a view object that retrieves the employee whose ID is 1.

Figure 39–6 shows the RootEmployeeViewObject for the Summit ADF DVT sample application. The query retrieves the employee whose ID is 1 and stores it in the rootEmpno bind variable. For more information about working with view objects and bind variables, see Section 5.10, "Working with Bind Variables."
6. To establish the hierarchy between the root employee and the lower-level managers and employees, add a view link between the `RootEmployeeViewObj` and the managers-employees view object created in Step 4.

7. In the Data Controls panel, click **Refresh** to update the data controls.

   - Create a JSF page as described in the "How to Create JSF Pages" section of *Developing Web User Interfaces with Oracle ADF Faces*.

**To create a hierarchy viewer using the Data Controls panel:**
1. From the Data Controls panel, select a collection.
Figure 39–8 shows an example where you could select the RootEmployeeViewObj2 collection in the Data Controls panel to create a hierarchy viewer representing the personnel data in an organizational chart.

**Figure 39–8  Data Collection for Personnel Organizational Chart**

2. Drag the collection onto a JSF page and, from the context menu, choose **Hierarchy Viewer**.

3. From the Component Gallery, select the layout of the hierarchy viewer you want to create. **Figure 39–9** shows the Component Gallery with the vertical top down layout selected.
4. In the Create Hierarchy Viewer dialog, enter the following:

- **Hierarchy**: Select the collections you want to include as nodes in the runtime diagram. By default, the root collection is selected. You can also choose to configure ancestors or descendants in the hierarchy.

- **Node**: For each collection that you select in the Hierarchy list, configure the attributes in the Title Area, and the title and attributes in each panel card, using one or more of the zoom levels available to you. By default, the node for the 100% zoom level follows an algorithm that:
  - Assigns the first three attributes in the data collection to the **Title Area**.
  - Assigns the next two attributes to the first panel card.
  - Assigns the following two attributes to the second panel card, and so on until all attributes are assigned to a panel card.

Select the panel card title or node attributes to configure one or more of the following for that element:

- **Text**: Available for panel card titles. Not available for the **Title Area** element. Enter text for the panel card title in the hierarchy, or choose **Select Text Resource** from the dropdown list to open a dialog to select or add a text resource to use for the title. The text resource is a translatable string from an application resource bundle. If you need help, press F1 or click **Help**.

- **Panel Card Data Source**: Available for panel cards. The data source indicates which data collection will be used for the panel card attributes.
By default, the collection associated with the current hierarchy level will be used for attribute selection.

Figure 39–10 shows a Create Hierarchy Viewer dialog for a hierarchy viewer using data collections based on the Summit ADF schema. In this example, the Panel Card Data Source is the default SEmpView collection.

**Figure 39–10  Hierarchy Viewer Configured With Default Panel Card Data Source**

To use an alternative child accessor for the panel card attributes, select an alternative child accessor from the dropdown list as shown in Figure 39–11. For additional information, see Section 39.2.3, "How to Configure an Alternate View Object for a Databound Panel Card."
Creating Databound Hierarchy Viewers

Creating Databound Hierarchy Viewer, Treemap, and Sunburst Components

Figure 39–11  Create Hierarchy Viewer Dialog Showing Alternate Panel Card Data Source

- **Attribute**: Available for attribute and image elements. From the dropdown list, select the attribute in the data collection that represents the value you wish to display in the hierarchy viewer node.

- **Label**: Available for attributes. From the dropdown list, select the attribute in the data collection that represents the label you wish to display for that element in the hierarchy viewer node. You can use the default **Use Attribute Name** to render the value as a string using the label from the UIHints for that attribute in the underlying ViewObject, select **No Label** to render no label for the attribute, or choose **Select Text Resource** to open a Select Text Resource dialog to select or add a text resource to use for the label. The text resource is a translatable string from an application resource bundle.

- **Component**: Available for attributes. Select the type of component to use to display the data in the node. Valid values are: **ADF Output Text w/ Label**, **ADF Output Text**, **ADF Output Formatted Text w/ Label**, and **ADF Output Formatted Text**. For more information about using these components, see the “Using Output Components” chapter in Developing Web User Interfaces with Oracle ADF Faces.

Click the **New** icon to add a new panel card, attribute, or image to the node, relative to your selection in the node. After selecting an existing element, use the arrow icons (**Up**, **Down**, **Top**, **Bottom**) to reorder the element, or use the **Delete** icon to delete the selected element.

Use the 75%, 50%, and 25% pages to specify the expanded display of the hierarchy at each page level. Select **Add Zoom Level** to enable the zoom level.
for a page level. By default, the algorithms to assign node attributes and panel cards in the node are similar to the 100% zoom level.

---

**Note:** The hierarchy viewer component defines four zoom levels. You cannot modify these zoom levels or create new zoom levels. The default zoom level is 100%.

---

- **Sample:** A nonconfigurable display of the sample outline of the hierarchy viewer node. Areas such as Title Area and attributes are highlighted in the sample when selected in the node area.

5. Click OK.

Figure 39–12 shows the Create Hierarchy Viewer dialog that appears if you create a hierarchy viewer using data from a data collection named `RootEmployeeViewObj2`.

**Figure 39–12  Create Hierarchy Viewer Dialog**

![Create Hierarchy Viewer Dialog](image)

After completing the Create Hierarchy Viewer dialog, you can use the Properties window to specify settings for the hierarchy viewer attributes, and you can also use the child tags associated with the hierarchy viewer tag to customize the hierarchy viewer further. For detailed information about hierarchy viewer end user and presentation features, use cases, tag structure, and adding special features to hierarchy viewers, see the "Using Hierarchy Viewer Components" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

When editing the hierarchy viewer in the visual editor, the display approximates the runtime display and functionality. You can move between panel cards and work with
stamped elements within the panel cards and title area to rearrange attributes or bind new attributes imported from the Data Controls panel.

### 39.2.2 What Happens When You Create a Databound Hierarchy Viewer

Creating a hierarchy viewer from Data Controls panel has the following effect:

- Creates the bindings for the hierarchy viewer in the page definition file of the JSF page
- Adds the necessary tags to the JSF page for the hierarchy viewer component

**Example 39–1** displays bindings that JDeveloper generated for a hierarchy viewer component. The rules for populating the nodes of the master-detail tree are defined as a node definition. The example shows that two node definitions were generated. Each of these node definitions references a view object and associated attributes. The code example also references an accessor `SEmpView`.

**Example 39–1  Bindings for a Hierarchy Viewer**

```xml
<parameters/>
<executables>
  <variableIterator id="variables"/>
  <iterator Binds="RootEmployeeViewObj2" RangeSize="25"
            DataControl="AppModuleDataControl"
            id="RootEmployeeViewObj2Iterator"/>
</executables>
/bindings
<tree IterBinding="RootEmployeeViewObj2Iterator" id="RootEmployeeViewObj2">
  <nodeDefinition DefName="model.RootEmployeeViewObj"
                  Name="RootEmployeeViewObj20">
    <AttrNames>
      <Item Value="ManagerId"/>
      <Item Value="TitleId"/>
      <Item Value="Userid"/>
      <Item Value="Comments"/>
      <Item Value="DeptId"/>
      <Item Value="StartDate"/>
      <Item Value="Email"/>
      <Item Value="Salary"/>
      <Item Value="FirstName"/>
      <Item Value="Id"/>
      <Item Value="CommissionPct"/>
      <Item Value="LastName"/>
    </AttrNames>
    <Accessors>
      <Item Value="SEmpView">
        <Properties>
          <CustomProperties>
            <Property Name="hierarchyType" Value="children"/>
          </CustomProperties>
        </Properties>
      </Item>
    </Accessors>
  </nodeDefinition>
  <nodeDefinition DefName="model.SEmpView" Name="RootEmployeeViewObj21">
    <AttrNames>
      <Item Value="ManagerId"/>
      <Item Value="TitleId"/>
      <Item Value="Userid"/>
      <Item Value="Comments"/>
      <Item Value="DeptId"/>
      <Item Value="StartDate"/>
      <Item Value="Email"/>
      <Item Value="Salary"/>
      <Item Value="FirstName"/>
      <Item Value="Id"/>
      <Item Value="CommissionPct"/>
      <Item Value="LastName"/>
    </AttrNames>
    <Accessors>
      <Item Value="SEmpView">
        <Properties>
          <CustomProperties>
            <Property Name="hierarchyType" Value="children"/>
          </CustomProperties>
        </Properties>
      </Item>
    </Accessors>
  </nodeDefinition>
</tree>
```
Creating Databound Hierarchy Viewers

Example 39–2 shows the code generated on the JSF page that is associated with the page definition file in Example 39–1. For brevity, the details in the facet elements named zoom75, zoom50, and zoom25 and panel card showDetailItem components have been omitted. In addition, the details for the second node in the hierarchy viewer have also been omitted.

The example shows a hierarchy viewer component that references the RootEmployeeViewObj2 tree binding. It includes a node (dvt:node) component that in turn includes a panel card component (dvt:panelCard). The panel card component defines slide_horz as the effect to use when changing the display of content referenced by the node.

Once you create your hierarchy viewer, you can modify the layout of the component or add additional components, such as a panel card, using the Create Hierarchy dialog illustrated in Figure 39–12. To open the dialog, use the Edit icon in the Properties window for the hierarchyViewer component. You can also customize the layout of a hierarchy viewer component directly in the code, in the visual editor, or by setting values in the Properties window. You can add additional components, such as panel cards, using the Components window.

Example 39–2  Code on the JSF Page for a Hierarchy Viewer

```xml
<dvt:hierarchyViewer id="hv1" var="node"
    value="#{bindings.RootEmployeeViewObj2.treeModel}"
    selectionListener="#{bindings.RootEmployeeViewObj2.treeModel.makeCurrent}"
    detailWindow="none"
    layout="hier_vert_top"
    levelFetchSize="#{bindings.RootEmployeeViewObj2.rangeSize}"
    styleClass="AFStretchWidth"
    summary="Hierarchy Viewer Demo">
  <dvt:link linkType="orthogonalRounded" id="l1"/>
  <dvt:node type="model.RootEmployeeViewObj" width="233" height="233" id="n1">
    <f:facet name="zoom100">
      <af:panelGroupLayout styleClass="AFStretchWidth AFHVNnodeStretchHeight"
        layout="vertical" id="pgl1">
        <af:panelGroupLayout layout="horizontal" id="pgl2">
          <af:panelGroupLayout id="pgl7">
            <af:image source="/images/#{node.Id}.png" shortDesc="Employee Image"
              id="i1" styleClass="AFHVNnodeImageSize"/>
          </af:panelGroupLayout>
        </af:panelGroupLayout>
      </af:panelGroupLayout>
    </f:facet>
  </dvt:node>
</dvt:hierarchyViewer>
```
Creating Databound Hierarchy Viewers

Creating Databound Hierarchy Viewer, Treemap, and Sunburst Components

39-15

39.2.3 How to Configure an Alternate View Object for a Databound Panel Card

You can specify an alternate view object as the data source for a panel card when you create or edit a databound hierarchy viewer. For example, you may have a data collection that has a master-detail relationship between sales representatives and orders, but you want your panel card to display details about the customer who placed the order.
Figure 39–13 shows a portion of the runtime view of a hierarchy viewer configured to display the orders and order details for sales representatives using the Summit ADF schema. In this example, the hierarchy viewer is configured to use an alternate view object for the Customer Details panel card.

The alternate view object must be a child of the parent collection. You can establish this parent-child relationship by creating a view link between the parent and child collection.

Before you begin:
It may be helpful to have an understanding of databound hierarchy viewers. For more information, see Section 39.2, "Creating Databound Hierarchy Viewers."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 39.1.3, "Additional Functionality for Data Visualization Components."

Create an application module that contains instances of the entity and view objects that you want in your application, as described in Section 13.2, "Creating and Modifying an Application Module."

Create the data model for the hierarchy viewer. For example, the hierarchy viewer in Figure 39–13 uses a top level view object based on the $Emp entity in the Summit ADF DVT sample application. In this example, the view object retrieves all sales representatives in the Summit ADF employee database by retrieving all employee...
records with a TITLE_ID of 2. Figure 39–14 shows the SalesRepViewObj view object.

**Figure 39–14  Sales Representatives View Object Using the Summit ADF Schema**

For information about creating a view object, see Section 5.2.1, "How to Create an Entity-Based View Object."

The master-detail relationship between the Summit sales representatives and orders is established with a view link between SalesRepViewObj and OrdersViewObj. Figure 39–15 shows the relationship between the view objects.

**Figure 39–15  View Link Between Summit Sales Representatives and Orders**

For additional information about establishing the master-detail relationship using view links, see Section 6.2.1, "How to Create a Master-Detail Hierarchy Based on Entity Associations."
To configure an alternate view object for a databound panel card:

1. If you have not already done so, create the view object that will be the alternate data source for the panel card.

   For example, the hierarchy viewer in Figure 39–13 uses a view object based on the SCustomer entity object in the Summit ADF DVT sample application.

2. Create a view link between the parent collection and the alternate view object.

   Figure 39–16 shows the view link between the sales representatives and customers in the Summit ADF DVT sample application. For help with creating view links, see Section 6.2.1, “How to Create a Master-Detail Hierarchy Based on Entity Associations.”

3. If needed, create a view link to establish the hierarchy between the parent collection and the alternate child collection.

   For example, to establish the hierarchy between orders and customers in the Summit ADF DVT sample application, create a view link between the SOrdView and SCustomerView collections. Figure 39–17 shows the sample view link.
39.2.3.1 What Happens When You Use an Alternate View Object for a Hierarchy Viewer Panel Card

When you configure your hierarchy viewer to use an alternate view object for the panel card data source, JDeveloper adds the bindings for the hierarchy viewer and alternate source in the page definition file of the JSF page.

Example 39–3 shows the sample bindings for the hierarchy viewer displayed in Figure 39–13. The entries for the alternate source are highlighted. Note that the alternate data source is defined as one of the hierarchy viewer’s node definitions.

Example 39–3  Bindings For a Hierarchy Viewer Using an Alternate Panel Card Data Source

```
<bindings>
  <tree IterBinding="SalesRepViewObj1Iterator" id="SalesRepViewObj1">
    <nodeDefinition DefName="model.SalesRepViewObj" Name="SalesRepViewObj10">
      <AttrNames>
        <Item Value="ManagerId"/>
        <Item Value="TitleId"/>
        <Item Value="Userid"/>
        <Item Value="Comments"/>
        <Item Value="DeptId"/>
        <Item Value="StartDate"/>
        <Item Value="Email"/>
        <Item Value="Salary"/>
        <Item Value="FirstName"/>
        <Item Value="Id"/>
        <Item Value="CommissionPct"/>
        <Item Value="LastName"/>
      </AttrNames>
      <Accessors>
        <Item Value="SOrdView">
          <Properties>
            <CustomProperties>
              <Property Name="hierarchyType" Value="children"/>
            </CustomProperties>
          </Properties>
        </Item Value="SOrdView">

    <Item Value="QuantityShipped"/>
    <Item Value="ItemId"/>
    <Item Value="Quantity"/>
    <Item Value="Price"/>
    <Item Value="OrdId"/>
    <Item Value="ProductId"/>
  </AttrNames>
</nodeDefinition>
</tree>
</bindings>
```

### 39.2.4 How to Create a Databound Search in a Hierarchy Viewer

The search function in a hierarchy viewer is based on the searchable attributes or columns of the data collection that is the basis of the hierarchy viewer data model. Using a query results collection defined in data controls in Oracle ADF, JDeveloper makes this a declarative task. You drag and drop an `ExecuteWithParams` operation into an existing hierarchy viewer component on the page.

Figure 39–18 shows the Summit ADF employee hierarchy viewer configured to search for employees by last name. In this example, the user can enter an employee’s last name in the Search panel or specify a pattern match using % or _.
Before you begin:

It may be helpful to have an understanding of databound hierarchy viewers. For more information, see Section 39.2, "Creating Databound Hierarchy Viewers."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 39.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

1. Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."

2. Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

3. Create a databound hierarchy viewer component as described in Section 39.2.1, "How to Create a Hierarchy Viewer Using ADF Data Controls."

4. Verify the query that retrieves the root node in the hierarchy viewer.

   For example, Figure 39–6 shows retrieving the root node by the Id column and storing it in the rootEmpno bind variable.

5. Create a view object that performs the search.

   For example, Figure 39–19 shows the EmployeesSearchResults view object that performs the search based on the LastName column in the data collection with a default value of % for matching any value, and a comparison value of like to enable pattern matching.
To create a databound search with a hierarchy viewer:

1. From the Data Controls panel, select the collection that corresponds to the query results and expand the Operations node to display the `ExecuteWithParams` operation.

   Figure 39–20 shows the expanded `EmployeeSearchResults1` operations node in the Summit ADF DVT sample application.
2. Drag the **ExecuteWithParams** operation and drop it onto the hierarchy viewer in the visual editor or onto the component in the Structure window.

3. In the Create Hierarchy Viewer Search dialog, use the **Add** icon to specify the list of results to display in the Search Results panel, and specify the following for each result:
   a. **Display Label**: Select the values for the headers of the nodes in the hierarchy. If you select `<default>`, then the text for the header is automatically retrieved from the data binding.
   b. **Value Binding**: Select the columns in the data collection to use for nodes in the tree for the hierarchy viewer.
   c. **Component to Use**: Select the type of component to display in the node. The default is the ADF Output Text component.

After selecting an existing field, use the arrow icons (Up, Down, Top, Bottom) to reorder the results or use the **Delete** icon to delete that result.

4. In the **Operation** dropdown list, select the hierarchy root data collection to use when a search result is selected. Valid values include:
   - **removeRowWithKey**: Uses the row key as a String converted from the value specified by the input field to remove the data object in the bound data collection.
   - **setCurrentRowWithKey**: Sets the row key as a String converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection.
   - **setCurrentRowWithKeyValue**: Sets the current object on the iterator, given a key’s value.
   - **ExecuteWithParams**: Sets the values to the named bind variables passed as parameters.

5. In the **Parameter Mapping** table, use the dropdown list in the **Results Attribute** column to select the results collection attribute to map to the parameter displayed in the **Hierarchy Parameter** column.

**Figure 39–21** shows the Create Hierarchy Viewer Search dialog that appears if you create a hierarchy viewer using data from a data collection named **EmployeesSearchResults1**.
Figure 39–21  Create Hierarchy Viewer Search Dialog

Example 39–4 shows the code on the JSF page after you click OK and the \texttt{dvt:search} is added to the page as a child of the hierarchy viewer component.

Example 39–4  \texttt{dvt:search} Sample Code for Hierarchy Viewer

\begin{verbatim}
<dvt:search value="#{bindings.searchName.inputValue}" actionListener="#{bindings.ExecuteWithParams.execute}" id="s19">
    <f:facet name="end">
        <af:commandLink text="Advanced" id="cl1"/>
    </f:facet>
    <dvt:searchResults id="sr1" value="#{bindings.EmployeeSearchResults.collectionModel}"
        emptyText="#{bindings.EmployeeSearchResults.viewable ? 'No data to display.' : 'Access Denied.'}"
        fetchSize="#{bindings.EmployeeSearchResults.rangeSize}"
        resultListener="#{bindings.ExecuteWithParams1.execute}"
        var="resultRow">
        <af:setPropertyListener type="action" from="#{resultRow.Id}"
            to="#{bindings.rootEmpno.inputValue}"/>
        <f:facet name="content">
            <af:panelGroupLayout layout="horizontal" id="pgl27">
                <af:panelLabelAndMessage
                    label="#{bindings.ExecuteWithParams.hints.LastName.label}"
                    id="plam29">
                    <af:outputText value="#{resultRow.LastName}"
                        shortDesc="#{bindings.ExecuteWithParams.hints.LastName.tooltip}"
                        id="ot45"/>
                </af:panelLabelAndMessage>
                <af:panelLabelAndMessage
                    label="#{bindings.ExecuteWithParams.hints.FirstName.label}"
                    id="plam30">
                    <af:outputText value="#{resultRow.FirstName}"
                        shortDesc="#{bindings.ExecuteWithParams.hints.FirstName.tooltip}"
                        id="ot46"/>
                    <af:convertNumber groupingUsed="false"
                        id="conv47"/>
                </af:panelLabelAndMessage>
            </af:panelGroupLayout>
        </f:facet>
    </dvt:searchResults>
</dvt:search>
\end{verbatim}
At runtime, the search results are displayed in a table by **LastName** and **FirstName**. Figure 39–22 shows the search results panel if a user enters C% to search for all employees whose last names begin with C.

**Figure 39–22**  Hierarchy Viewer Search Results Panel

![Search Results Panel](image)

The user can choose one of the search results to display the associated hierarchy viewer node and any children if they exist. Figure 39–23 shows the hierarchy viewer node if the user chooses **Catchpole** from the search results list.

**Figure 39–23**  Hierarchy Viewer Showing Nodes After Search Selection

![Hierarchy Viewer](image)

### 39.3 Creating Databound Treemaps and Sunbursts

Treemaps and sunbursts are ADF Data Visualization components that display quantitative hierarchical data across two dimensions, represented visually by size and color. For example, you can use a treemap or sunburst to display quarterly regional...
sales and to identify sales trends, using the size of the node to indicate each region’s sales volume and the node’s color to indicate whether that region’s sales increased or decreased over the quarter.

Treemaps and sunbursts use a shape called a node to reference the data in the hierarchy. Treemaps display nodes as a set of nested rectangles. Each branch of the tree is given a rectangle, which is then tiled with smaller rectangles representing sub-branches.

Figure 39–24 shows a treemap displaying the products available at warehouses in the Summit ADF DVT sample application. In this example, the node size represents the amount in stock for each product, and node color represents inventory status.

Figure 39–24  Treemap Showing Product Availability and Inventory Levels

Sunbursts display the nodes in a radial rather than a rectangular layout, with the top of the hierarchy at the center and deeper levels farther away from the center. Figure 39–25 shows the same inventory data displayed in a sunburst.
The shape and content of the nodes are configurable, as well as the visual layout of the nodes. For detailed information about treemap and sunburst end user and representation features, use cases, tag structure, and adding special features, see the "Using Treemap and Sunburst Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.

39.3.1 How to Create Treemaps and Sunbursts Using ADF Data Controls

Treemaps and sunbursts are based on data collections where a master-detail relationship exists between one or more detail collections and a master data collection. Treemaps and sunbursts also require that the following attributes be set in JDeveloper:

- **value**: the size of the node
- **fillColor**: the color of the node
- **label**: a text identifier for the node

The values for the `value` and `label` attributes must be stored in the treemap’s or sunburst’s data model or in classes and managed beans if you are using UI-first development. You can specify the `fillColor` values in the data model, classes, and managed beans, or declaratively in the Properties window.
In order to configure a treemap or sunburst successfully, ensure that the data adheres to the following rules:

- Each child node can have only one parent node.
- There can be no skipped levels.

Using data controls in Oracle ADF, JDeveloper makes treemap and sunburst creation a declarative task. You drag and drop a data collection from the Data Controls panel that generates one or more nodes onto a JSF page.

**Before you begin:**

It may be helpful to have an understanding of databound treemaps and sunbursts. For more information, see Section 39.3, "Creating Databound Treemaps and Sunbursts."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 39.1.3, "Additional Functionality for Data Visualization Components."

You will need to complete these tasks:

- Create an application module that contains instances of the view objects that you want in your data model, as described in Section 13.2, "Creating and Modifying an Application Module."
  
  If you need help working with master-detail relationships, see Chapter 31, "Displaying Master-Detail Data."

- Create a JSF page as described in the "How to Create JSF Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

**To create a treemap or sunburst using the Data Controls panel:**

1. From the Data Controls panel, select a collection.

   Figure 39–26 shows the data collection for the treemap in Figure 39–24 and the sunburst in Figure 39–25.
In the Summit ADF DVT sample, the application uses a view link between the SCountriesView2 collection and the SWarehouseView2 collection to establish a hierarchy between the SRegionView1 and SWarehouseView2 data collections. Figure 39–27 shows the sample view link.

Table 39–1 shows the data collection and size, label, and color values used to create the treemap or sunburst.
2. Drag the collection onto a JSF page and, from the context menu, choose **Treemap** or **Sunburst**.

3. In the Create Treemap dialog or Create Sunburst dialog, in the **Hierarchy** section, select the collections you want to include as nodes in the runtime treemap or sunburst. By default, the root collection is selected.

4. For each collection that you select in the Hierarchy list, enter a value for the following.

   - **Value**: From the dropdown list, select the attribute in the data collection that represents the size value for the sunburst. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression. For help with the Expression Builder dialog, press **F1** or click **Help**.

     For example, to create a treemap or sunburst using the data collection in Figure 39–26, select **CountryCount** for the **SRegionView1** value to represent the size value for the first node.

   - **Label**: From the dropdown list, select the attribute in the data collection that represents the label you wish to display for the sunburst node label. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

     For example, select **Name** for the **SRegionView1** node label.

   - Optionally, in the **View Area** section, click **New** to configure an attribute group for the node. Use attribute groups if you want the node’s display to vary based on color or pattern. You can also specify the node’s fill color or pattern in the node’s **fillColor** and **fillPattern** properties after you create the treemap or sunburst.

     If you do not configure an attribute group to vary by color or specify a **fillColor** attribute on the node, the node will display in black. By default, no pattern will be displayed on the node.

     In the treemap and sunburst example, attribute groups are configured for each level in the hierarchy.

     To configure an attribute group, enter values for the following:

     - **Group by value**: From the dropdown list, select the attribute in the data collection to group by in the attribute group. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

       In the treemap and sunburst example, the colors used are based on the count metric for each level in the hierarchy. For example, select **CountryCount** as the **Group by value** for the **SRegionView1** collection, and the colors displayed on the **Regions** node will vary depending upon the number of countries in a given region.

---

Table 39–1 Sample Values for Treemap and Sunburst Inventory Example

<table>
<thead>
<tr>
<th>Collection</th>
<th>Size Value</th>
<th>Label Value</th>
<th>Color Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>SRegionView1</td>
<td>CountryCount</td>
<td>Name</td>
<td>Default</td>
</tr>
<tr>
<td>SCountriesView2</td>
<td>WarehouseCount</td>
<td>Country</td>
<td>Default</td>
</tr>
<tr>
<td>SWarehouseView2</td>
<td>ProductCount</td>
<td>City</td>
<td>Default</td>
</tr>
<tr>
<td>ProductInventoryView2</td>
<td>AmountInStock</td>
<td>Name</td>
<td>Varies by stock level</td>
</tr>
</tbody>
</table>
– **Area**: From the dropdown list, select **Color** if you want the attribute group to vary by color or select **Pattern** if you want the attribute group to vary by pattern. To vary the attribute group by both color and pattern, select **Select Multiple Attributes** and select both **Color** and **Pattern**. Click **OK**.

In the treemap and sunburst example, color is used for each level of the hierarchy.

– **Legend Label**: From the dropdown list, select the attribute in the data collection to display in the treemap’s legend. You can select one of the attributes provided or select **Expression Builder** to enter a JSF EL expression.

In the treemap and sunburst inventory example, this value is left blank.

Figure 39–28 shows the Create Treemap dialog completed for the first node in the Summit ADF DVT sample application. The entries for the Create Sunburst dialog are identical.

Figure 39–28  **Create Treemap Dialog for a Region Node**

![Create Treemap Dialog](image)

- Optionally, click **Value-Specific Rules** to expand the attribute group dialog to specify a match or exception rule. Use match rules to specify colors or patterns for simple true or false conditions or when you want to match a specific value. Use exception rules when you want to specify a color or pattern when the node’s grouped-by value meets a specific condition.

To specify a match rule, in the **Match Rules** section, click **New** and enter values for the following:

- **Group Value**: Enter the category value for the match. This can be a string that represents a category or you can set this to `true` or `false`. If you set
this to true or false, the **Group by value** field must contain an EL expression that evaluates to true or false as in the following example: 

```
#{row.AmountInStock gt row.ReorderPoint}.
```

- **Property**: From the dropdown list, select **Color** if you want the node to vary by color or select **Pattern** if you want the attribute node to vary by pattern.

- **Property Value**: From the dropdown list, select the color or pattern to display when the node’s value matches the **Group Value**. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.

Figure 39–29 shows the Create Treemap dialog for a data collection using match rules for the bottom level of the hierarchy. The Create Sunburst dialog entries are identical.

**Figure 39–29  Treemap Showing Match Rules for an Attribute Group**

In this example, the treemap nodes will display in green (RGB hexadecimal #008000) when the inventory levels are acceptable and in red (RGB hexadecimal #ff0000) when the inventory level is at or below the product’s reorder level. The attribute group’s **Label** field contains the details for the legend display. In this case, the field contains an expression that determines the legend label based on an item’s amount in stock:

```
#{(row.AmountInStock gt row.ReorderPoint) ? 'Stock Level OK' : 'Reorder Time'}.
```

**Figure 39–30** shows the runtime treemap.
To specify an exception rule, in the Exception Rules section, click New and enter values for the following:

- **Condition**: Enter a JSF EL expression that evaluates to true or false. You can enter the expression directly in the Condition field or select Expression Builder to enter the JSF EL expression.

In the Summit ADF DVT sample application, three exception rules are defined for the bottom level of the hierarchy. When the product’s inventory level is well above the reorder level, the treemap node in Figure 39–24 and the sunburst node in Figure 39–25 display in green. The treemap and sunburst node display in yellow when the inventory level is close to the reorder point and display in red when the inventory level is at or very near the reorder point.

Figure 39–31 shows the Create Sunburst dialog for the Summit ADF DVT sample data collection using exception rules for the bottom level of the hierarchy. The Create Treemap dialog entries are identical.
Creating Databound Treemaps and Sunbursts

Figure 39–31 Sunburst Showing Exception Rules Creation Dialog

- **Property**: From the dropdown list, select **Color** if you want the node to vary by color. Select **Pattern** if you want the node to vary by pattern.

- **Property Value**: From the dropdown list, select the color or pattern to display when the node's value meets the condition you specified in the **Condition** field. For color, you can select one of the provided values or select **Custom Color** to enter a custom color in the Select Custom Color dialog. For pattern, you must select one of the provided values.

- **Legend Label**: From the dropdown list, select **Select Text Resource** to select a text resource to be used for the legend label. You can also enter text in this field or select **Expression Builder** to enter a JSF EL expression.

5. Click **OK**.

### 39.3.2 What Happens When You Create a Databound Treemap or Sunburst

Creating a treemap or sunburst from Data Controls panel has the following effect:

- Creates the bindings for the sunburst or treemap in the page definition file of the JSF page

- Adds the necessary tags to the JSF page for the **treemap** or **sunburst** component

**Example 39–5** displays bindings that JDeveloper generated for a **treemap** or **sunburst** component using the data collection in **Figure 39–26**. Since both components use the same data model, the bindings in the page definition file are identical.
Example 39–5  Sample Bindings for a Treemap or Sunburst

<executables>
  <variableIterator id="variables"/>
  <iterator Binds="SRegionView1" RangeSize="-1" DataControl="AppModuleDataControl"
            id="SRegionView1Iterator"/>
</executables>

<bindings>
  <tree IterBinding="SRegionView1Iterator" id="SRegionView1">
    <nodeDefinition DefName="model.SRegionView" Name="SRegionView10">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Name"/>
        <Item Value="CountryCount"/>
      </AttrNames>
      <Accessors>
        <Item Value="SCountriesView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SCountriesView" Name="SRegionView11">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Country"/>
        <Item Value="RegionId"/>
        <Item Value="WarehouseCount"/>
      </AttrNames>
      <Accessors>
        <Item Value="SWarehouseView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.SWarehouseView" Name="SRegionView12">
      <AttrNames>
        <Item Value="Id"/>
        <Item Value="Address"/>
        <Item Value="City"/>
        <Item Value="State"/>
        <Item Value="CountryId"/>
        <Item Value="ZipCode"/>
        <Item Value="Phone"/>
        <Item Value="ManagerId"/>
        <Item Value="ProductCount"/>
      </AttrNames>
      <Accessors>
        <Item Value="ProductInventoryView"/>
      </Accessors>
    </nodeDefinition>
    <nodeDefinition DefName="model.ProductInventoryView" Name="SRegionView13">
      <AttrNames>
        <Item Value="ProductId"/>
        <Item Value="WarehouseId"/>
        <Item Value="AmountInStock"/>
        <Item Value="ReorderPoint"/>
        <Item Value="MaxInStock"/>
        <Item Value="OutOfStockExplanation"/>
        <Item Value="RestockDate"/>
        <Item Value="Id"/>
        <Item Value="Name"/>
        <Item Value="ShortDesc"/>
      </AttrNames>
    </nodeDefinition>
  </tree>
</bindings>
The rules for populating the nodes of the treemap or sunburst are defined in node definitions. The example shows that four node definitions were generated, one for each level of the hierarchy. Each of these node definitions references a view object and associated attributes. Each node definition also references an accessor for the next level of the hierarchy if the next level exists.

Once you create your treemap or sunburst, you can modify the value, label, and attribute group for each node using the Create Treemap or Create Sunburst dialog. To open the dialog, use the Edit icon in the Properties window for the treemap or sunburst component. You can also customize the values directly in the code or by setting values in the Properties window.

### 39.3.3 What Happens at Runtime: How Databound Sunbursts or Treemaps Are Initially Displayed

By default, a sunburst or treemap displays only the first two levels of the hierarchy and will not display a legend until you configure the legendSource attribute on the sunburst or treemap. Figure 39–32 shows the sunburst that is displayed at runtime if you create the sunburst using the data collection in Figure 39–26.

![Databound Sunburst Example Before Configuration](image)

After completing the Create Treemap or Create Sunburst dialog, you can use the Properties window to configure the treemap or sunburst level display and legendSource attribute. You can also specify settings for other treemap or sunburst attributes and use the child tags associated with the sunburst and treemap tags to customize the components further.

Example 39–6 shows the code on the JSF page code for the treemap in Figure 39–24. In this example, the databound treemap is configured to display all levels in the hierarchy, a legend, and a tooltip when the user hovers the mouse over a node.
Example 39–6  Sample Code on a JSF Page for a Treemap

```xml
<dvt:treemap id="t1" value="#{bindings.SRegionView1.treeModel}"
  var="row" displayLevelsChildren="3"
  legendSource="ag1" summary="Sample Treemap">
  <af:switcher facetName="#{row.hierTypeBinding.name}" id="s1">
    <f:facet name="SRegionView11">
      <dvt:treemapNode value="#{row.WarehouseCount}" label="#{row.Country}"
        id="tn1">
        <dvt:attributeGroups id="ag2" value="#{row.WarehouseCount}" type="color"/>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView10">
      <dvt:treemapNode value="#{row.CountryCount}" label="#{row.Name}" id="tn2">
        <dvt:attributeGroups id="ag3" value="#{row.CountryCount}" type="color"/>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView13">
      <dvt:treemapNode value="#{row.AmountInStock}" label="#{row.Name}" id="tn3"
        shortDesc="Amount in Stock:
                    #{{row.AmountInStock}}&lt;br/&gt;Reorder Point:
                    #{{row.ReorderPoint}}">
        <dvt:attributeGroups value="#{row.AmountInStock}" type="color" id="ag1">
          <dvt:attributeExceptionRule id="aer1"
            condition="#{{(row.AmountInStock - row.ReorderPoint) gt 50}}"
            label="Stock OK">
            <f:attribute name="color" value="#008800"/>
          </dvt:attributeExceptionRule>
          <dvt:attributeExceptionRule id="aer2"
            condition="#{{(row.AmountInStock - row.ReorderPoint) le 50) and
                        ((row.AmountInStock - row.ReorderPoint) gt 25)}}"
            label="Stock Level Getting Low">
            <f:attribute name="color" value="#FFFF33"/>
          </dvt:attributeExceptionRule>
          <dvt:attributeExceptionRule id="aer3"
            condition="#{{(row.AmountInStock - row.ReorderPoint) le 25}}"
            label="Reorder Time">
            <f:attribute name="color" value="#880000"/>
          </dvt:attributeExceptionRule>
        </dvt:attributeGroups>
      </dvt:treemapNode>
    </f:facet>
    <f:facet name="SRegionView12">
      <dvt:treemapNode value="#{row.ProductCount}" label="#{row.City}" id="tn4">
        <dvt:attributeGroups id="ag4" value="#{row.ProductCount}" type="color"/>
      </dvt:treemapNode>
    </f:facet>
  </af:switcher>
</dvt:treemap>
```

Example 39–7 shows the code on the JSF page code for the sunburst in Figure 39–25. In this example, the databound sunburst is configured to display all levels in the hierarchy, a legend, and a tooltip when the user hovers the mouse over a node. Note the similarities between the sunburst code in this example and the treemap code in the previous example.

Example 39–7  Sample Code on a JSF Page for a Sunburst

```xml
<dvt:sunburst id="t1" value="#{bindings.SRegionView1.treeModel}"
  var="row"
  displayLevelsChildren="3"
  legendSource="ag1" summary="Sample Sunburst">
```

Creating Databound Hierarchy Viewer, Treemap, and Sunburst Components

39-37
For information about configuring the sunburst or treemap level display, legendSource attribute, tooltips, additional attributes, or child tags, see the "Using Treemap and Sunburst Components" chapter in Developing Web User Interfaces with Oracle ADF Faces.
This chapter describes how to create, publish, and subscribe to contextual events to facilitate communications between ADF Faces regions in the Fusion web application. It describes how to declaratively create the events, as well as programmatically use managed beans and JavaScript.

This chapter includes the following sections:

- Section 40.1, "About Creating Contextual Events"
- Section 40.2, "Creating Contextual Events Declaratively"
- Section 40.3, "Creating Contextual Events Manually"
- Section 40.4, "Creating Contextual Events Using Managed Beans"
- Section 40.5, "Creating Contextual Events Using JavaScript"
- Section 40.6, "Creating the Event Map Manually"
- Section 40.7, "Registering a Custom Dispatcher"

### 40.1 About Creating Contextual Events

The contextual events framework provides the communications between regions within a page. The framework provides the page with the ability to map events that are produced and consumed by the various regions on the page. You can use JDeveloper to declaratively publish events using the page definition file. Similarly, you can declaratively subscribe to those events from the page definition file. You can pass parameters with the event and implement handlers to respond to an event. Other ways to create contextual events include using managed beans and using JavaScript. Note that contextual events do not require regions to be refreshed for the region to uptake parameters.

Contextual events are not the same as the business events that can be raised by ADF Business Components or the events raised by UI components. For a description of these types of events, see *Developing Web User Interfaces with Oracle ADF Faces*. Contextual events can be used, however, in association with UI events. In this case, an action listener that is invoked due to a UI event can, in turn, invoke a method action binding that then raises the event.

Often a page or a region within a page needs information from somewhere else on the page or from a different region. While you can pass parameters to obtain that information, doing so makes sense only when the parameters are well known and the inputs are EL-accessible to the page. Parameters are also useful when a task flow may need to be restarted if the parameter value changes.
However, suppose you have a task flow with multiple page fragments that contain various interesting values that could be used as input on one of the pages in the flow. If you were to use parameters to pass the value, the task flow would need to surface output parameters for the union of each of the interesting values on each and every fragment. Instead, for each fragment that contains the needed information, you can define a contextual event that will be raised when the page is submitted. The page or fragment that requires the information can then subscribe to the various events and receive the information through the event.

In the Summit sample application for ADF task flows, contextual events are used in the Inventory Control tab of the main page to display the inventory for a selected product. When the Inventory Control tab is selected by the user, it displays two regions side by side. One region contains the `showProducts.jsff` page fragment which contains a table of the products available. The other region contains the `showInventory.jsff` page fragment which contains a DVT chart showing the product inventory percentages for different warehouses. Figure 40–1 shows the Inventory Control tab displaying the products and inventory regions.

**Figure 40–1  Inventory Control Tab**

The products region contains the `show-products-task-flow` task flow which utilizes the `showProducts.jsff` page fragment. The inventory region contains the `product-inventory-task-flow` task flow which utilizes the `showInventory.jsff` page fragment.

The main page `index.jsff` is the parent page for both regions, which are located in a child of the `af:panelTabbed` layout component.

A contextual event is passed from the products region to the inventory region so that the `showInventory-task-flow` can display the DVT chart for the selected product. When you create a event for the producer component using the Properties window, a event is registered in the producer's page definition file. In the Summit ADF sample application, the `productSelected` event is registered in the `showProductsPageDef.xml` file, as shown in Example 40–1.
About Creating Contextual Events

Example 40–1  Contextual Event in the Producer Page Definition File

```xml
<tree IterBinding="ProductVO1Iterator" id="ProductVO1">
  <nodeDefinition DefName="oracle.summit.model.views.ProductVO"
                  Name="ProductVO10">
    <AttrNames>
      <Item Value="Id"/>
      <Item Value="Name"/>
      <Item Value="ShortDesc"/>
      <Item Value="LongtextId"/>
      <Item Value="ImageId"/>
      <Item Value="SuggestedWhlslPrice"/>
      <Item Value="WhlslUnits"/>
    </AttrNames>
    <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
      <event name="productSelected" eventType="Currency Change Event"
             customPayLoad="#{bindings.Id.inputValue}"/>
    </events>
  </nodeDefinition>
</tree>
```

When you use the overview editor for the page definition file to subscribe to events, an eventMap will be created to map events between producers and consumers.

In the Summit ADF sample application, the eventMap is create in the consumer’s page definition file, as shown in Example 40–2.

Example 40–2  Event Map in the showInventoryPageDef.xml File

```xml
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
  <event name="productSelected">
    <producer region="*">
      <consumer handler="populateInventoryForProduct" region="*">
        <parameters>
          <parameter name="productId" value="${payLoad}"/>
        </parameters>
      </consumer>
    </producer>
  </event>
</eventMap>
```

At runtime, when users enter the show-products-task-flow-definition and the showProducts.jsff page fragment, they are presented with a table of the products that are available. When the user selects a product from the list, a currency change event is invoked, resulting in the broadcast of the productSelected contextual event. In this example, a payLoad parameter containing the productId of the selected product is passed with the event.

This event is then consumed by the product-inventory task flow and its handler, the populateInventoryForProduct() method. This method uses the payLoad parameter to determine which product’s inventory information to be displayed in the DVT component.

You will need to create the code for the event handler. For the Summit ADF sample application, the populateInventoryForProduct() handler was added to the InventoryVOImpl.java file because the InventoryVO view object contains the inventory data, as shown in Example 40–3.
Events are configured in the page definition file for the page or region that will raise the event (the producer). In order to associate the producer with the consumer that will do something based on the event, you create an event map in the page definition file of the consuming page or the parent page. (The parent page is the page that contains both regions). If the consuming page is in a dynamic region, the event map should be in the page definition file of the consuming page and the producer’s attribute region set to “*”. The attribute region is set to “*” because at design time, the framework cannot determine the relative path to the producer.

You can raise a contextual event for an action binding, a method action binding, a value attribute binding, or a range binding (table, tree, or list binding). You also can conditionally fire an event and conditionally handle an event using EL expressions.

For action and method action bindings, the event is raised when the action or method is executed. The payLoad contains the method return value. You can also raise a contextual event from an ADF Faces event such as clicking a button or selecting from a menu. An eventBinding is created in the page definition to define the event.

For a value attribute binding, the event is triggered by the binding container and raised after the attribute is set successfully. The payLoad is an instance of DCBindingContainerValueChangeEvent, which provides access to the new and old value, the producer iterator, the binding container, and the source. If the payLoad property is changed to point to a custom data object, then the payLoad reference will return the object instead. Example 40–4 shows a value change event inside an attribute value binding associated with an input component. The event, valueChangeEvent, will be dispatched when the user changes the value of LAST_NAME in the page.

Example 40–4  Value Attribute Event in the Page Definition File
<attributeValues IterBinding="DeptView1Iterator" id="Dname"
 xmlns="http://xmlns.oracle.com/adfm/jcuimodel">
<events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
<event name="valueChangeEvent"/>
</events>
</AttrNames xmlns="http://xmlns.oracle.com/adfm/uimodel"
For an range binding (tree, table, list), the event is raised after the currency change has succeeded. The payload is an instance of
DCBindingContainerValueChangeEvent, which provides access to the new and old value, the producer iterator, the binding container, and the source. Example 40–2 shows the event map for a currency change event associated with a range binding.

Value attribute binding and range binding contextual events may also be triggered by navigational changes. For example, if you create an event inside a tree table binding, the event will be dispatched when the user selects a different node of the tree in the page.

You use the **Contextual Events** section under the **Behavior** section in the Properties window to create and publish contextual events. The Contextual Events panel will only appear when you select eligible components or regions in the page, as shown in **Figure 40–2**.
You subscribe to contextual events using the overview editor for page definition file’s **Contextual Events** tab **Subscriber** section, as shown **Figure 40–3**.
40.1.1 Contextual Events Use Cases and Examples

There are three kinds of communication patterns between a region and the parent page: parent to region, region to parent, and region to region. The contextual events framework is the most powerful communication implementation that works for all three of these scenarios. Also note that contextual events do not require a region to be refreshed in order to consume input parameters.

You should use contextual events to communicate between ADF regions. While it is possible to use ADF task flow parameters to communicate between regions, doing so may create direct dependencies between the regions. ADF task flow parameters may be fine for static regions, but using contextual events will allow you to implement independent communications between regions.

For example, a page may contain a region with a form for entering employee information. When the user updates the employee Id and presses the submit button, a value change contextual event is raised and the employee Id value is also passed as payLoad. On the same page, another region subscribes to and consumes the event and displays departmental information about the selected employee based on the payLoad information passed with the contextual event.

40.1.2 Additional Functionality for Contextual Events

You may find it helpful to understand other ADF features before you work with contextual events. Following are links to other functionality that may be of interest.

- You can also use ADF task flow parameters to communicate between ADF regions. For more information about using task flows and regions, see Chapter 23, "Using Task Flows as Regions."
40.2 Creating Contextual Events Declaratively

You create contextual events by first creating and publishing the event on the producer based on a method action, action, value attribute, or list binding. On the consumer, you subscribe to the event and create a handler to process the event.

Typically, you create a parent page with regions that contain task flows and view activities. You create contextual events in one region to be published for consumer event handlers in the other region. For more information about using task flows and regions, see Chapter 23, "Using Task Flows as Regions."

Note: You can also publish an action contextual event from code (for example, from within a managed bean). You can use getBindingContainer().getEventDispatcher which returns an instance of EventDispatcher. EventDispatcher has public APIs which you can use to programmatically raise contextual events.

40.2.1 How to Publish Contextual Events

You use the Properties window to create contextual events in the page where the contextual event will be produced. That is, the producer’s page is the page where the contextual event is generated. For instance, clicking a button on a page that would trigger a contextual event to be consumed by another component. The page that contains the button is the producer’s page.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Section 40.2, "Creating Contextual Events Declaratively."

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Section 40.1.2, "Additional Functionality for Contextual Events."

You will need to complete this task:

Decide on the type of component you want to use to raise the contextual event. If you plan to use a method action binding, you must have already created the method to be dropped onto the page.

To create a contextual event:

1. In the page where you want to publish the contextual event, drag and drop a component from the Data Controls panel to the page.

   This is the component that will trigger the event. It must have a method action, action, value attribute, or list binding event.

2. In the Properties window, expand the Behavior section.

3. In the Publish Events section, click the Add icon.

4. In the Publish Contextual Events dialog:
   a. Select Create New Event.
   b. Enter the name of the event.
   c. If your component is a table, tree, or tree table, a Node field appears for you to enter the node that will publish the event upon a change event.
d. Select **Pass Custom Value From** if you want to pass payload data to the consumer.

e. If you are passing payload data, select the type of data from the dropdown list. Normally, the parameter is \{payLoad\}

For instance, if you want to pass an attribute value from the producer page to the consumer page, you can select **Page Data** and select the attribute from the tree structure.

f. You can conditionally raise the event by entering an EL expression in the **Raise Condition** tab.

For instance, entering an expression such as \${bindings.LAST_{NAME}.inputValue == 'KING'}\) will cause the event to be raised only if the customer’s last name is KING.

g. Click **OK**.

The event is created on the page, but it is not ready for publishing until it is associated with the component binding.

**Figure 40–4  Publish a Contextual Event**

![Publish Contextual Event](image)

### 40.2.2 How to Subscribe to and Consume Contextual Events

You use the overview editor for page definition files to subscribe to contextual events. The overview editor displays the current region and its child regions. Only the regions that are shown can subscribe to contextual events.
Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Section 40.2, "Creating Contextual Events Declaratively."

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Section 40.1.2, "Additional Functionality for Contextual Events."

You will need to complete this task:

Create a contextual event in the page definition file, as described in Section 40.2.1, "How to Publish Contextual Events."

To subscribe and consume the event:
1. Create a handler to process the event and its payload data.
   
   In the Summit ADF sample application, the `PopulateInventoryForProduct` handler method was created in the `InventoryVO` view object by adding the code to the `InventoryVOImpl.java` file.
   
   The method appears in the `BackOfficeAppModuleDataControl` application module.

2. In the consuming page, add the components that will respond to the event.
   
   In the Summit ADF sample application, a DVT component is added to the page to display the inventory available in different warehouses.
   
   The DVT component will receive the data from the `PopulateInventoryForProduct` method.

3. In the Applications window, double-click the page definition file that will contain the event map.
   
   In the Summit ADF sample application, the `showInventoryPageDef.xml` page definition file will have the event map.

4. In the overview editor, click the Bindings and Executables tab and then click the Add icon for the Bindings section.

5. In the Insert Item dialog, select methodAction and click OK.

6. In the Create Action Binding dialog:
   
   a. Expand the data collection where you have created your handler.
   
   b. Select the handler.
   
   c. Click OK.

7. In the overview editor Contextual Events tab, click Subscribers and click the Add icon in the Event Subscribers section.

8. In the Subscribe to Contextual Event dialog:
   
   a. Enter the event name or click the Search icon to start the Select Contextual Event dialog.
      
      If you have started the Select Contextual Events dialog, select the event from the tree and click OK.
   
   b. Select the producer or <Any> from the Publisher dropdown list. A contextual event can have more than one producer.
Selecting `<Any>` will allow the consumer to subscribe to any producer producing the selected event. In the page definition file, the `producer` attribute will be set to the wildcard `"*"`. If your producer is in a dynamic region, you should set this field to `<Any>` so that the subscriber can consume from any producer.

c. Click the `Search` icon next to the `Handler` field.

d. In the Select Handler dialog, select the event handler from the tree and click `OK`.

e. If the handler requires parameters, click the `Parameters` tab, click `Add`, and enter name-value pair as parameters.

f. If you want to conditionally handle the event, select the `Handle` tab, and enter an EL Expression that determines the conditions under which the handler will process the event.

g. Click `OK`.

**Figure 40–5  Subscribe to a Contextual Event**

<table>
<thead>
<tr>
<th>Event: ProductSelected</th>
</tr>
</thead>
<tbody>
<tr>
<td>Type: <code>&lt;Any&gt;</code></td>
</tr>
<tr>
<td>Publisher: <code>&lt;Any&gt;</code></td>
</tr>
<tr>
<td>Handler: <code>populateInventoryForProduct</code></td>
</tr>
<tr>
<td>Parameters:</td>
</tr>
<tr>
<td>Name: <code>productId</code></td>
</tr>
<tr>
<td>Value: <code>@payload</code></td>
</tr>
</tbody>
</table>

**Note:** You can edit the event map by right-clicking the page definition in the Structure window and choosing `Edit Event Map`. You can also edit event attributes in the page definition file or in the Properties window.

### 40.2.3 What Happens When You Create Contextual Events

When you create an event for the producer, JDeveloper adds an `events` element to the page definition file. Each event name is added as a child. **Example 40–5** shows the `productSelected` event defined in the producer page definition file as a currency change event.
Creating Contextual Events Declaratively

**Example 40–5  Event Definition for the Producer**

```xml
<tree IterBinding="ProductVO1Iterator" id="ProductVO1">
  <nodeDefinition DefName="oracle.summit.model.views.ProductVO" Name="ProductVO10">
    <AttrNames>
      <Item Value="Id"/>
      <Item Value="Name"/>
      <Item Value="ShortDesc"/>
      <Item Value="LongtextId"/>
      <Item Value="ImageId"/>
      <Item Value="SuggestedWhlslPrice"/>
      <Item Value="WhlslUnits"/>
    </AttrNames>
    <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
      <event name="productSelected" eventType="Currency Change Event" customPayLoad="#{bindings.Id.inputValue}"/>
    </events>
  </nodeDefinition>
</tree>
```

In the consumer page definition file, a method action binding is created to respond to the event. **Example 40–6** shows the method action binding defined in the `showInventoryPageDef` page definition file.

**Example 40–6  Method Action Definition in the Page Definition File**

```xml
<methodAction id="populateInventoryForProduct" RequiresUpdateModel="true" Action="invokeMethod"
  MethodName="populateInventoryForProduct" IsViewObjectMethod="true"
  DataControl="BackOfficeAppModuleDataControl" InstanceName="data.BackOfficeAppModuleDataControl.InventoryVO1">
  <NamedData NDName="productId" NDType="java.lang.String"/>
</methodAction>
```

When the currency change occurs, the event is broadcasted to its consumers. The method action definition is defined in the consuming page definition file.

When you configure an event map, JDeveloper creates an event map entry in the corresponding page definition file. **Example 40–7** shows the event map on the `showInventoryPageDef` page definition file that maps the `productSelected` event from the `showproductstaskflowdefinition1` region to the `productinventorytaskflowdefinition1` region. It also maps the `populateInventoryForProduct` handler method bindings that is defined in the `showInventoryPageDef` page definition file. The handler processes the `payLoad` information (containing the `productID`) and passes it to the DVT component so it can query the warehouse inventory for that product.

**Example 40–7  Event Map in the Consuming Page Definition File**

```xml
<eventMap xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
  <event name="productSelected">
    <producer region=""/>
    <consumer handler="populateInventoryForProduct" region=""/>
    <parameters>
      <parameter name="productId" value="${payLoad}"/>
    </parameters>
    <consumer/>
    <producer/>
</eventMap>
```
40.2.4 How to Control Contextual Events Dispatch

You can control the dispatch of contextual events to child regions at the application level or at the page level.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Section 40.2, "Creating Contextual Events Declaratively."

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Section 40.1.2, "Additional Functionality for Contextual Events."

To disable event dispatch:
1. To disable event dispatch at the application level, set the `dynamicEventSubscriptions` property to `false` in the `adf-config.xml` file, as shown in Example 40–8.

   ```xml
   <?xml version="1.0" encoding="windows-1252" ?>
   <adf-config xmlns="http://xmlns.oracle.com/adf/config"
               xmlns:cef="http://xmlns.oracle.com/adfm/contextualEvent">
   <cef:DynamicRegionEventsConfig dynamicEventSubscriptions="false">
   </cef:DynamicRegionEventsConfig>
   </adf-config>
   ``

   You can disable the event dispatch to regions that have an event map with producers as wildcards.

   Example 40–8   Disabling Contextual Event Dispatch at the Application Level Using adf-config.xml

2. To disable event dispatch at the individual page level, set the `dynamicEventSubscriptions` property to `false` in the associated page definition file, as shown in Example 40–9.

   Contextual events will not be passed to the page and any of its children.

   Example 40–9   Disabling Contextual Event Dispatch for a Page Using the Page Definition File

40.2.5 What Happens at Runtime: Contextual Events

If both the event producer and the consumer are defined in the same page definition file, then after the corresponding page is invoked and the binding container is created, the event is raised when:

- The corresponding method or action binding is executed
- A value binding is set successfully
- A range binding currency is set successfully
For a method binding, the result of the method execution forms the payload of the event, and the event is queued. In the Invoke Application phase of the JSF lifecycle, all the queued events will be dispatched. The event dispatcher associated with the binding container checks the event map (also in the binding container, as it is part of the same page definition file) for a consumer interested in that event and delivers the event to the consumer.

When the producer and consumer are in different regions, the event is first dispatched to any consumer in the same container, and then the event propagation is delegated to the parent binding container. This process continues until the parent or the topmost binding container is reached. After the topmost binding container is reached, the event is again dispatched to child-binding containers that have regions with pages that have producer set to wildcard "* ".

### 40.3 Creating Contextual Events Manually

You create contextual events by first creating the event on the producer. You then determine the consumer of the event, and map the producer to the consumer.

#### 40.3.1 How to Create Contextual Events Manually

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Section 40.3, "Creating Contextual Events Manually."

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Section 40.1.2, "Additional Functionality for Contextual Events."

You will need to complete this task:

Create a contextual event that has a method binding, action binding, value attribute binding, or list binding on the producer page.

**To create a contextual event:**

1. In the Applications window, double-click the page definition file that contains the binding for the producer of the event.

   A producer must have an associated binding that will be used to raise the event. For example, if a method or operation will be the producer, the associated action binding or method action binding will contain the event.

2. In the Structure window, right-click the binding for the producer and choose **Insert inside binding name > events** or **Insert inside binding name > Contextual Events > events**.

3. In the Structure window, right-click the **events** element just created, and choose **Insert inside events > event**.

4. In the Insert event dialog, enter a name for the event in the **name** field, and click **Finish**.

   The event is now created. By default, any return of the associated method or operation will be taken as the payload for the event and stored in the EL-accessible variable `${data.payload}`. You now need to map the event to the consumer, and to configure any payload that needs to be passed to the consumer.
5. In the Applications window, double-click the page definition file that contains the binding for the consumer.

The binding container represented by this page provides access to the events from the current scope, including all contained binding containers (such as task flow regions). If regions or other nested containers need to be aware of the event, the event map should be in the page definition of the page in the consuming region.

6. In the Structure window, right-click the topmost node that represents the page definition, and choose **Edit Event Map**.

   **Note:** If the producer event comes from a page in an embedded dynamic region, you may not be able to edit the event map using the Event Map Editor. You can manually create the event map by editing the page definition file or use **insert inside** steps, as described in Section 40.3, "Creating Contextual Events Manually."

7. In the Event Map Editor, click the **Add** icon to add an event entry.

8. In the Add New EventMap Entry dialog, do the following:
   a. Use the **Producer** dropdown menu to choose the producer.
   b. Use the **Event Name** dropdown menu to choose the event.
   c. Use the **Consumer** dropdown menu to choose the consumer. This should be the actual method that will consume the event.
   d. If the consuming method or operation requires parameters, click the **Add** icon.

   In the **Param Name** field, enter the name of the parameter expected by the method. In the **Param Value** field, enter the value. If this is to be the payload from the event, you can access this value using the \{data.payload\} expression. If the payload contains many parameters and you don’t need them all, use the ellipses button to open the Expression Builder dialog. You can use this dialog to select specific parameters under the payload node.

   You can also click the **Parameters** ellipses button to launch the selection dialog.
   e. Click **OK**.

9. In the Event Map Editor, click **OK**.

### 40.4 Creating Contextual Events Using Managed Beans

You can publish an action contextual event from code such as from within a managed bean.

#### 40.4.1 How to Create Contextual Events Using Managed Beans

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Section 40.4, "Creating Contextual Events Using Managed Beans."

You may also find it helpful to understand functionality that can be used with contextual events. For more information, see Section 40.1.2, "Additional Functionality for Contextual Events."
To create contextual events using managed beans:

1. Create a method in a managed bean to generate the contextual event.

   Example 40–10 shows managed bean code that perform an action when a button is pressed. The `myActionPerformed` method is invoked and calls methods to generate the contextual event with "myString" as the payLoad:

   ```java
   BindingContainer bc = BindingContext.getCurrent().getCurrentBindingsEntry();
   JUCtrlActionBinding actionBnd = (JUCtrlActionBinding) bc.getControlBinding("eventProducer");
   
   ((DCBindingContainer) bc).getEventDispatcher().queueEvent(actionBnd.getEventProducer(), "myString");
   ```

2. Bind the producer component to the method in the managed bean.

   Example 40–11 shows code for a producer associated with a command button that invokes an action binding and the consumer is an `outputText` component that displays a string. They are both on the same page.

   ```xml
   <af:form id="f1">
   <af:button value="eventProducerButton1" id="cb1" action="#{MyBean.myActionPerformed}"/>
   <af:panelLabelAndMessage label="#{bindings.return.hints.label}" id="plam1">
       <af:outputText value="#{bindings.return.inputValue}" id="ot1"/>
   </af:panelLabelAndMessage>
   </af:form>
   ```

40.4.2 What Happens When You Create Contextual Events Using Managed Beans

The page definition file contains the method action bindings for the producer, the consumer, and the event map, as shown in Example 40–12.

   ```xml
   <executables>
   <variableIterator id="variables">
       <variable Type="java.lang.String" Name="eventConsumer_return" IsQueriable="false" IsUpdateable="0"
                DefaultValue="${bindings.eventConsumer.result}"/>
   </variableIterator>
   </executables>

   <bindings>
   <methodAction id="eventProducer" InstanceName="AppModuleDataControl.dataProvider"
                 DataControl="AppModuleDataControl" RequiresUpdateModel="true"
                 Action="invokeMethod" MethodName="eventProducer"
                 IsViewObjectMethods="false"
                 ReturnName="AppModuleDataControl.methodResults.eventProducer_AppModuleDataControl_dataProvider_eventProducer_result">
       <events xmlns="http://xmlns.oracle.com/adfm/contextualEvent">
           <event name="myEvent"/>
       </events>
   </methodAction>
   
   <methodAction id="eventConsumer" RequiresUpdateModel="true"
                 Action="invokeMethod" MethodName="eventConsumer"/>
   ```
40.5 Creating Contextual Events Using JavaScript

Every action and method binding that is accessible from a managed bean can be invoked from JavaScript. ADF Faces provides an `af:serverListener` operation component that can be used to call a managed bean method from client-side JavaScript. To invoke this component using the referenced managed bean method, use the `BindingContext` object to look up the current `BindingContainer` and to access the `OperationBinding` or a JUEventBinding binding. The `af:serverListener` component can also be used to send a message payload from the browser client to the managed bean method.

40.6 Creating the Event Map Manually

Under most circumstances, you can create the event map using the Event Map Editor as described in Section 40.3, "Creating Contextual Events Manually." However, in situations such as when the producer event is from a page in an embedded dynamic region, the Event Map Editor at design time cannot obtain the necessary information to create an event map.

40.6.1 How to Create the Event Map Manually

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see Section 40.6, "Creating the Event Map Manually."

You may also find it useful to understand functionality that can be used with contextual events. For more information, see Section 40.1.2, "Additional Functionality for Contextual Events."
To create the event map manually:

1. In the Applications window, double-click the page definition file that contains the binding for the consumer.

2. In the Structure window, right-click the topmost node that represents the page definition, and choose **Insert inside pagedef name > eventMap**.

3. In the Structure window, select the eventMap node, right-click and choose **Insert inside eventMap > event**.

4. In the Insert Event dialog, enter the name of the event and click OK. Repeat steps 3 and 4 to add more events.

5. Select the event node, right-click and choose **Insert inside event > producer**.

6. In the Insert Producer dialog, enter the name of the binding that is producing this event and click OK.

   You can also enter the name of the region which has the event producer, in which case all the consumers specified under this tag can consume the event. You can also enter "*" to denote that this event is available for all consumers under this tag.

7. Select the producer node, right-click, and choose **Insert inside producer > consumer**.

8. In the Insert Consumer dialog, enter the name of the handler that will consume the event and click OK.

   Repeat steps 7 and 8 to add more consumers.

9. If there are parameters being passed, add the parameter name and value.

   a. Select the consumer node, right-click, and choose **Insert inside consumer > parameters**.

   b. Select the parameters node, right-click, and choose **Insert inside parameters > parameter**.

   c. In the Insert Parameter dialog, enter the name of the parameter and the value of the parameter and click OK. The value can be an EL expression.

   Repeat this step to add more parameters.

### 40.7 Registering a Custom Dispatcher

By default, the contextual event framework uses **EventDispatcherImpl** to dispatch events that would traverse through the regions. You can create a custom event dispatcher to override the default event dispatcher to provide custom behaviors. After you have created the custom event dispatcher, you must register it in the **Databindings.cpx** file to override the default dispatcher.

### 40.7.1 How to Register a Custom Dispatcher

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create contextual events. For more information, see **Section 40.7, "Registering a Custom Dispatcher."**

You may also find it useful to understand functionality that can be used with contextual events. For more information, see **Section 40.1.2, "Additional Functionality for Contextual Events."**
To register a custom event dispatcher:

1. Create a custom event dispatcher Java class based on the EventDispatcher class.
2. Register the custom event dispatcher in the Databindings.cpx file with a fully qualified name using the following format:

   `EventDispatcher="package_name.CUSTOM_EVENT_DISPATCHER_NAME"`

   Example 40–13 shows the code for a custom event dispatcher called NewCustomEventDispatcher created in package NewPackage.

**Example 40–13 Adding Custom Event Dispatcher in the Databindings.cpx File**

```xml
<Application xmlns="http://xmlns.oracle.com/adfm/application" version="11.1.1.51.60" id="DataBindings" SeparateXMLFiles="false" Package="project3" ClientType="Generic"
EventDispatcher="NewPackage.NewCustomEventDispatcher">```

3. Create the event in the producer’s page definition. For more information, see Section 40.2, "Creating Contextual Events Declaratively," or Section 40.3, "Creating Contextual Events Manually."

4. Create the event map in the consumer region if the consumer is in a dynamic region. If the consumer is not in a dynamic region, you can also specify the event map in the parent page which holds both the producer and consumer regions. For more information, see Section 40.6, "Creating the Event Map Manually."
Part VI contains the following chapters:

- Chapter 41, "Enabling ADF Security in a Fusion Web Application"
- Chapter 42, "Testing and Debugging ADF Components"
- Chapter 43, "Refactoring a Fusion Web Application"
- Chapter 44, "Reusing Application Components"
- Chapter 45, "Customizing Applications with MDS"
- Chapter 46, "Allowing User Customizations at Runtime"
- Chapter 47, "Using the Active Data Service"
- Chapter 48, "Deploying Fusion Web Applications"
- Chapter 49, "Using State Management in a Fusion Web Application"
- Chapter 50, "Tuning Application Module Pools and Connection Pools"
Enabling ADF Security in a Fusion Web Application

This chapter describes how you can enable ADF Security in the Fusion web application to define resource grants for Oracle ADF resources and to restrict the user’s ability to view web pages associated with those resources.

This chapter includes the following sections:

- Section 41.1, "About ADF Security"
- Section 41.2, "ADF Security Process Overview"
- Section 41.3, "Enabling ADF Security"
- Section 41.4, "Creating Application Roles"
- Section 41.5, "Defining ADF Security Policies"
- Section 41.6, "Creating Test Users"
- Section 41.7, "Creating a Login Page"
- Section 41.8, "Testing Security in JDeveloper"
- Section 41.9, "Preparing the Secure Application for Deployment"
- Section 41.10, "Disabling ADF Security"
- Section 41.11, "Advanced Topics and Best Practices"

41.1 About ADF Security

The ADF Security framework is the preferred technology to provide authentication and authorization services to the Fusion web application. ADF Security is built on top of the Oracle Platform Security Services (OPSS) architecture, which itself is well-integrated with Oracle WebLogic Server. While other security-aware models exist that can handle user login and resource protection, ADF Security is ideally suited to provide declarative, permission-based protection for ADF bounded task flows, for top-level web pages that use ADF bindings (pages that are not contained in a bounded task flow), and at the lowest level of granularity, for rows of data defined by ADF entity objects and their attributes. In this document, these specific resources that the ADF Security framework protects are known as ADF security-aware resources.

You enable ADF Security for Fusion web applications when you run the Configure ADF Security wizard, as described in Section 41.3, "Enabling ADF Security.” The wizard configures ADF Security for the entire Fusion web application, so that any web page associated with an ADF security-aware resource is protected by default. This
About ADF Security

means that after you enable ADF Security, your application is locked down so that the pages are considered secure by default.

After you enable ADF Security you must grant users access rights so that they may view the web pages of the Fusion web application. Access rights that you grant users are known as a security policy that you specify for the page’s corresponding ADF security-aware resource. Ultimately, it is the security policy on the ADF resource that controls the user’s ability to enter a task flow or view a web page.

Because ADF Security is based on Java Authentication and Authorization Service (JAAS), security policies identify the principal (the user or application role), the ADF resource, and the permission (an operation defined by the resource’s ADF permission class). For example, the Summit sample application for ADF task flows secures the web pages contained by the customer-task-flow task flow to grant access only to logged-in users (also known as authenticated users). At runtime, the ADF Security framework performs authorization checking against the task flow’s security policy to determine the user’s right to complete the view operation. In this case, the security policy must grant the view permission to the user if they are to complete the checkout process.

To simplify the task of defining security policies for users and ADF resources, ADF Security defines a containment hierarchy that lets you define one security policy for the ADF bounded task flow and its contains web pages. In other words, when you define the security policy at the level of the bounded task flow, you protect the flow’s entry point and then all pages within that flow are secured by the policy it defines. Additionally, instead of granting access to individual users, you group users into application roles and grant the view permission to the role.

Specifically, you will define security policies in the Fusion web application for the following ADF security-aware resources to make web pages accessible to users:

- ADF bounded task flow protects the entry point to the task flow, which in turn controls the user’s access to the pages contained by the flow

  For example, a series of web pages may guide new customers through a registration process and the bounded task flow controls page navigation for the process. For a description of bounded task flows, see Section 20.1.2, "About Bounded Task Flows."

  The unbounded task flow is not an ADF security-aware component and thus does not participate in authorization checks. When you need to protect the constituent pages of an unbounded task flow, define grants for the page definition files associated with the pages instead.

- ADF page definition files associated with web pages

  For example, a page may display a summary of best selling products with data coordinated by the ADF bindings of the page’s associated ADF page definition file. For a description of page definitions and ADF bindings, see Section 17.7, "Working with Page Definition Files."

- ADF entity objects and attributes of entity objects that reference rows of data and help define collections for display in the user interface

  For example, a web page may display an ADF Faces table component that displays columns that ADF bindings map to the attributes of an entity object as its data source. In the case of entity objects, enabling ADF Security does not automatically secure entity objects rows. The data will remain accessible to users until you define a security policy to explicitly protect the entity object or its attributes. For a description of entity objects, see Section 4.1, "About Entity Objects."
JDeveloper tools support iterative development of security so you can easily create, test, and edit security policies that you create for ADF resources. You can proceed to create test users in JDeveloper and run the application in Integrated WebLogic Server to simulate how end users will access the secured resources. This chapter describes how to configure the repository of user identities and login credentials known as the identity store.

---

**Note:** References to the identity store in this chapter are always in the context of test user identities that you create for the purpose of running in Integrated WebLogic Server. Typically, you would not migrate these users to the staging environment when you deploy to Oracle WebLogic Server, as described in Section 41.9, "Preparing the Secure Application for Deployment."

---

To avoid a situation where you have enabled ADF Security but have not yet defined security policies to grant access to test users, the Configure ADF Security wizard lets you grant temporary view rights to all existing ADF resources (a view permission grant will be added to the security policy for each ADF resource). This wizard option gives you the choice to disable automatic grants and proceed to define security policies for ADF resources as you create each resource or to enable automatic view grants and gradually replace these grants with security policies that you define. To understand iterative security development choices, see Section 41.2, "ADF Security Process Overview."

**Tip:** Before you enable ADF Security and define security policies for the ADF security-aware resources, you will want to understand the rules that govern ADF authorization checking. Understanding these rules will help you to implement the security you intend. For a discussion of these rules, see Section 41.1.2, "ADF Security Use Cases and Examples."

### 41.1.1 Integration of ADF Security and Java Security

The ADF Security model for securing Fusion web application resources is not based on the URL mapping of a security constraint as exemplified by the Java EE security model. In actual practice, security constraints are not feasible for securing a JavaServer Faces (JSF) web application where page navigation is not supported by specific page URLs. For example, when the user navigates to the next page in a task flow, the URL remains the same throughout the flow. As each new page is displayed, there is no means to trigger a URL-based security constraint.

Instead, ADF Security implements a Java Authentication and Authorization Service (JAAS) security model. The JAAS model is policy-based since JAAS is built on the existing Java security model and integrates with any JAAS implementation, including the Oracle Platform Security Services (OPSS) implementation of the JAAS service. Whereas applications that utilize URL security constraints are security-unaware because they rely on the Java EE container to manage security, Fusion web applications require an explicit call to the ADF Security framework to authorize access to resources based on user-defined policies. Thus, when you enable ADF Security and define access policies for ADF resources, your application is security-aware.

ADF Security simplifies the implementation of a JAAS authorization model. This implementation minimizes the work needed to create a security-aware application by exposing security policies on ADF resources in a declarative fashion and performing authorization checks on these resources at runtime.
The policy store in JDeveloper is file-based and contains a list of entries known as grants, which define the security policy for the ADF resource. The grant entry includes all the permissions granted to the user to perform operations on the protected resource, for instance, accessing a web page associated with an ADF bounded task flow. Permissions are granted in the policy store to an application role principal.

ADF Security expands on the JAAS model by allowing you to define grants using the actions specified by the ADF Security framework permission classes. These classes are specific to the ADF resource and map the actions to an operation supported by the resource. The policy store for the Fusion web application therefore contains grants that specify:

- One or more permissions that associate an action defined by the resource’s permission class with an instance of the ADF resource in the application (currently, only the view action is supported for bounded task flows and page definitions resources)
- The grantee, which is an application role defined by your application that you populate with member users or, optionally, enterprise roles for whom you wish to confer the same access rights

In the case of entity objects, the permission class defines read, delete, and update actions.

For a description of the ADF permission classes and supported actions, see Appendix C, “ADF Security Permission Grants.”

### 41.1.2 ADF Security Use Cases and Examples

The use of ADF Security enables web applications to easily adjust to real-world business security requirements, because rather than securing paths to application resources, you secure the view operation on ADF resources with JAAS. JAAS-based ADF Security provides:

- Declarative security support for ADF resources, such as the bounded task flow
  
  Because Java EE security is URL-based or page-based, it is not possible to have a navigation control without custom code. With ADF Security, you can control whether or not the user can enter a task flow. Thus, a single security policy for a task flow can control access to multiple web pages. Additionally, because declarative security lets you secure the ADF resource, not the access path, you can reuse the ADF resource elsewhere in the application and it will remain secured.

- Simplified permission assignment by using application roles that allow for the inheritance of permissions
  
  While Java EE security roles that are used by Java EE security constraints are flat, JAAS permissions are granted to application roles, which can be nested and may be mapped to enterprise roles that the Oracle WebLogic Server domain defines.

- Utility methods for use in EL expressions to access ADF resources in the security context
  
  You can use the ADF Security EL expression utility methods to determine whether the user is allowed to perform a known operation. For example, you can determine whether the user is allowed to view a particular task flow.

Additionally, JDeveloper enables you to quickly create test users and passwords to test security in Integrated WebLogic Server. When you are ready to deploy to Oracle WebLogic Server, you can migrate the application-specific authorization policies to the
server and the administrator can configure the application to use an LDAP user repository.

Table 41–1 summarizes the effect that enabling ADF Security has on the application and the various ADF security-aware resources. For further discussion about how you can work most effectively with ADF Security, see Section 41.11.5, "Best Practices for Working with ADF Security."

**Table 41–1 Summary of ADF Security-Aware Resources**

<table>
<thead>
<tr>
<th>ADF Resource</th>
<th>How ADF Enforces Security</th>
<th>How to Grant Access</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bounded task flows in all user interface projects</td>
<td>Protected by default. Requires a grant to allow users to enter the bounded task flow.</td>
<td>Define the grant for the task flow. Do not define grants for individual page definition files associated with the web pages of the bounded task flow.</td>
</tr>
<tr>
<td>Page definition files in all user interface projects</td>
<td>Protected by default. Requires a grant to allow users to view the page associated with the page definition.</td>
<td>If the web page is contained by a bounded task flow, define the grant for the task flow. Define the grant for the page definition only when the web page is not contained by a bounded task flow or when the page is contained by an unbounded task flow. Note that the unbounded task flow is not an ADF security-aware component and allows no grants.</td>
</tr>
<tr>
<td>Entity objects in the data model project</td>
<td>Not protected by default. Requires a grant to prevent access by users.</td>
<td>Define a grant on the entity object to protect data only if you need to control access at the level of the entire data collection. The data displayed by all components in the user interface that reference the protected entity object will be protected. Use entity-level security carefully. Instead, consider defining security at the level of the entity attribute. Note that grants in the data model project are saved as metadata on the entity object itself and do not appear in the ADF policy store.</td>
</tr>

</tbody>
</table>
41.3 Additional Functionality for ADF Security

You may find it helpful to understand other Oracle ADF features before you start working with ADF Security. Following are links to other functionality that may be of interest.

- To understand the security features of Oracle Platform Security Services, see Securing Applications with Oracle Platform Security Services.

41.2 ADF Security Process Overview

You work in JDeveloper when you want to secure the ADF resources of your Fusion web application. ADF Security will protect your application’s bounded task flows and any web pages contained in an unbounded task flow. You enable this protection by running the Configure ADF Security wizard and later by defining ADF security policies to define user access rights for each resource.

As you create the user interface for your application, you may run the Configure ADF Security wizard at any time. You may choose to:

- Iterate between creating web pages in the UI project and defining security policies on their associated ADF resources
- Complete all of the web pages in the UI project and then define security policies on their associated ADF resources

**Note:** Before you proceed to secure the Fusion web application, you should become familiar with the ADF security model, as described in Section 41.1.2, "ADF Security Use Cases and Examples."

The iterative design and test process is supported by a variety of design time tools.

Each time you create a new bounded task flow or ADF page definition file in your user interface projects, the new ADF resource will be visible in the overview editor for the jazn-data.xml file. This editor is also called the overview editor for security policies. You use the overview editor to define security policies for ADF resources associated with web pages for the entire application. You can also use the overview editor to sort ADF resources and easily view those that have no security policy yet defined.

You use another editor to provision a few test users in the ADF identity store. The identity store you create in JDeveloper lets you define user credentials (user ID and password). The editor also displays the relationship between users you create and the application roles that you assign them to for the purpose of conferring the access rights defined by ADF security policies.

At design time, JDeveloper saves all policy store and identity store changes in a single file for the entire application. In the development environment, this is the jazn-data.xml file. After you configure the jazn-data.xml file using the editors, you can run the application in Integrated WebLogic Server and the contents of the policy store will be added to the domain-level store, the system-jazn-data.xml file, while the test users will be migrated to the embedded LDAP server that Integrated WebLogic Server uses for its identity store. The domain-level store allows you to test the security implementation by logging on as test users that you have created.

You access all design time tools for security under the main menu Application > Secure menu, as shown in Figure 41–1.
Design Phase

To enable ADF Security and set up the policy store for the application that you will run in JDeveloper:

1. Enable ADF Security to allow dynamic authentication and enforce authorization by running the Configure ADF Security wizard.
   
   When you run the wizard, if you choose to enable only dynamic authentication, skip the remaining design phase steps. The wizard configures files that integrate the security framework with OPSS on Oracle WebLogic Server.

2. Create an ADF security-aware resource, such as a bounded task flow with constituent web pages (or regions) or a top-level web page (or region) that is designed using ADF bindings.
   
   Note: After you run the Configure ADF Security wizard, any web page associated with an ADF security-aware resource will be protected. This means that you must define security policies to make the web pages accessible before you can run the application and test security.

3. Associate the ADF security-aware resource with one or more application roles that you create.
   
   Application roles you create are specific to the application and let you confer the same level of access to a set of users (also known as member users). In the test phase you will create some users and add them as members to the application roles you created.

4. Grant view permission to the ADF security-aware resource and each of its associated application roles.
   
   The grant confers access rights to the application role’s member users. Without the grant, the user would not be able to access the ADF security-aware resource. In the test phase, you will create some users and add them to your application roles.

Testing Phase

To provision the identity store and test security using Integrated WebLogic Server:

1. Create some users and, optionally, create their enterprise roles.
You will log in to the application using the user ID and password you define. An enterprise role is a logical role that lets you group users and associate these groups with application roles. The enterprise role is not needed for testing. For more information, see Section 41.4.3, "What You May Need to Know About Enterprise Roles and Application Roles."

2. Associate the users you created and, optionally, the enterprise roles, with one or more application roles.

A member user may belong to more than one application role when you wish to confer the access right granted to multiple application roles.

3. Optionally, replace the default login page with a custom login page.

The default login page generated by the Configure ADF Security wizard cannot utilize ADF Faces components. It is provided only as a convenience for testing ADF security policies. Your custom login page may be designed with ADF Faces components.

4. Run the application in JDeveloper and access any ADF security-aware resource.

The first time you attempt to access an ADF security-aware resource, the security framework will prompt you to log in.

5. Log in and check that you are able to access the page and its resources as you intended.

After you log in, the security framework checks the user’s right to access the resource. For example, if you receive an unexpected 401 unauthorized user error, verify that you have created grants as suggested in Section 41.11.5, "Best Practices for Working with ADF Security."

**Preparation for Staging**

To prepare the secure application for deployment to Oracle WebLogic Server in a staging or production environment:

1. Remove any grants to the test-all role for all ADF security-aware resources and replace with grants that you define.

Because ADF resources are secure by default, developers testing the application will be granted view access only after security policies are defined. The Configure ADF Security wizard gives you the option to generate grants to the test-all role that will make all ADF resources accessible. To avoid compromising enterprise security, you must eventually replace all temporary grants to the test-all role with explicit grants that you define.

2. Remove all user identities that you created.

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, rely on the system administrator to configure user identities through the tools provided by the domain-level identity management system.

3. Confirm that the application roles shown in the policy store are the ones that you want an administrator to eventually map to domain-level groups.

4. Decide whether or not you what to define a security constraint to protect ADF Faces resource files.

Resource files including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the
application. These files are not secured by ADF Security, but you can secure their Java EE access paths if you require all users to be authenticated before they can access the application.

5. Migrate the finalized policy store and credentials store to the target server.

Application policies and credentials can be automatically migrated to the domain policy store when the application is deployed to a server in the Oracle WebLogic environment. Support to automatically migrate these stores is controlled by the target server’s configuration. If Oracle Enterprise Manager is used to perform the deployment outside of JDeveloper, then the migration configuration settings can be specified in that tool. For information about migrating the jazn-data.xml security policies and the cwallet.sso credentials, see the "Configuring the OPSS Security Store" chapter in Securing Applications with Oracle Platform Security Services.

41.3 Enabling ADF Security

To simplify the configuration process which allows ADF Security to integrate with OPSS, JDeveloper provides the Configure ADF Security wizard. The wizard is the starting point for securing the Fusion web application using ADF Security. The wizard is an application-level tool that, once run, will enable ADF Security for all user interface projects that your application contains.

---

**Note:** Because the Configure ADF Security wizard enables ADF Security for all user interface projects in the application, after you run it, users will be required to have authorization rights to view any web page contained by a bounded task flow and all web pages associated with an ADF page definition. Therefore, after you run the wizard, the application is essentially locked down until you define security policies to grant view rights to the user. For an overview of the process, see Section 41.2, "ADF Security Process Overview."

---

41.3.1 How to Enable ADF Security

The Configure ADF Security wizard allows you to choose to enable authentication and authorization separately. You may choose to:

- Enable *only* user authentication.

  Although ADF Security leverages Java EE container-managed security for authentication, enabling only authentication means that you want to use the ADF authentication servlet to support user login and logout, but that you intend to define container-managed security constraints to secure web pages.

- Enable user authentication and also enable authorization.

  Enabling authorization means you intend to control access to the Fusion web application by creating security policies on ADF resources.

The ADF Security framework supports these two choices to give you the option to implement Java EE Security and still be able to support login and logout using the ADF authentication servlet. The benefit of enabling the ADF authentication servlet is that the servlet will automatically prompt the user to log in the first time the application is accessed. The ADF authentication servlet also allows you to redirect the user to a defined start page after successful authentication. You will also be able to manage the page redirect when the user logs out of the application. These redirect
features provided by ADF Security are not available using only container-managed security.

Note that ADF Security does not perform authentication, but relies on the Java EE container to invoke the configured login mechanism, as described in Section 41.8.4, "What Happens at Runtime: How ADF Security Handles Authentication."

**Best Practice:** Because Java EE security constraints cannot interact with the task flow to secure the current page of a task flow, container-managed security is not a useful solution when your application is designed with ADF task flows. When you use ADF task flows, select the ADF Authentication and Authorization option in the Configure ADF Security wizard. This option will allow you to define security policies to protect the task flows of your application.

Because ADF Security delegates authentication to the web container, when you run the Configure ADF Security wizard, the wizard prompts you to configure the authentication method that you want the web container to use. The most commonly used types of authentication are HTTP Basic Authentication and Form-Based Authentication. Basic authentication uses the browser login dialog for the user to enter a user name and password. Note that with basic authentication, the browser caches credentials from the user, thus preventing logout. Basic authentication is useful when you want to test the application without requiring a custom login page. Form authentication allows the application developer to specify a custom login UI. If you choose Form-based authentication, you can also use the wizard to generate a simple login page. The default login page is useful for testing your application with Integrated WebLogic Server.

**Note:** Because the generated login page is a simple JSP or HTML file, you will not be able to modify it with ADF Faces components. For information about replacing the default login page with a custom login page that uses ADF Faces components, see Section 41.7, "Creating a Login Page."

---

**Before you begin:**
It may be helpful to have an understanding of the Configure ADF Security wizard. For more information, see Section 41.3, "Enabling ADF Security."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

**To enable ADF Security for the application:**
1. In the main menu, choose Application and then Secure > Configure ADF Security.
2. In the ADF Security page, leave the default ADF Authentication and Authorization option selected. Click Next.

When you run the wizard with the default option selected, your application will enforce authorization for ADF security-aware resources. Enforcing authorization for ADF resources means that you intend to define security policies for these resources to make the web pages of your application accessible. Until you do so, all pages that rely on the ADF bounded task flows and ADF page definitions will remain protected.
The other two wizard options to configure ADF Security should not be used when you want to enable ADF Security. Those options allow you to temporarily disable ADF Security and run your application without security protection, as described in Section 41.10, "Disabling ADF Security."

Specifically, the first page of the wizard lets you choose among three options, with the default option set to enable **ADF Authentication and Authorization**, as shown in Figure 41–2:

- **ADF Authentication and Authorization** (default) enables the ADF authentication servlet so that you can redirect to a configured web page when the user logs in and logs out. This option also enables ADF authorization to enforce authorization checking against security policies that you define for ADF resources. This option assumes that you will define application roles and assign explicit grants to those roles to manage access to ADF security-aware resources.

- **ADF Authentication** enables the ADF authentication servlet to require the user to log in the first time a page in the application is accessed and supports page redirect by mapping the Java EE application root "/" to the a Java EE security constraint that will trigger user authentication. Since the wizard disables ADF authorization, authorization checking is not performed, whether or not security policies exist for ADF resources. Once the user is logged in, all web pages containing ADF resources will be available to the user.

- **Remove ADF Security Configuration** disables the ADF authentication servlet and prevents ADF Security from checking policy grants without altering the existing policy store. In this case, you may require users to log in, become authenticated, and test access rights against URL security constraints using standard Java EE security. Note that running the wizard with this option disables fine-grained security against ADF resources.
3. In the Authentication Type page, select the authentication type that you want your application to use when the user submits their login information. Click Next.

A known issue prevents the ADF authentication servlet from working with Basic type authentication and allows a user to access resources after logout. Use form-based authentication instead of basic authentication. For details about this issue, see Section 41.7.8, "What You May Need to Know About ADF Servlet Logout and Browser Caching."

If you select Form-based Authentication, you can also select Generate Default Pages to allow the wizard to generate a default login and error page. By default the wizard generates the login and error pages at the top level of the user interface project, as shown in Figure 41–3. If you want to change the location, specify the full path relative to the user interface project.

![Figure 41–3 Using the Configure ADF Security Wizard to Generate a Simple Login Page](image)

4. In the Automatic Policy Grants page, leave the default No Automatic Grants option selected. Click Next.

When you select No Automatic Grants, you must define explicit grants that are specific to your application. The test-all application role provides a convenient way to run and test application resources without the restricted access that ADF authorization enforces. However, it increases the risk that your application may leave some resources unprotected.

Alternatively, you can use the wizard to grant to the test-all application role. When you enable grants to the test-all role, you can postpone defining explicit grants to ADF resources until you are ready to refine the access policies of your

---

**Note:** In the current release, the Enable Identity Governance Framework (IGF) checkbox is disabled by default. Selecting this option provides no additional functionality. The feature will be enabled in a future release. For details about IGF, see Developing Applications with Identity Governance Framework.
Enabling ADF Security

application. If you decide to enable automatic grants, do not let application
development progress too far and the content of the application become
well-established before you replace grants to the test-all role with the your
application’s explicit grants. The explicit grant establishes the necessary privilege
(for example, view on a page) to allow users to access these resources. For more
information about the test-all role, see Section 41.8.3, "How to Use the Built-In
test-all Application Role."

5. In the Authenticated Welcome page, select Redirect Upon Successful
Authentication to direct the user to a specific web page after they log in. Click
Next.

If you leave the Redirect Upon Successful Authentication option unselected, the
user will be returned to the page from which the login was initiated. However,
when the user presses Ctrl-N or Ctrl-T to open a new browser window or tab,
they will receive a 403 or 404 error unless a welcome page definition appears in
the application’s web.xml file. You can use this option to specify a welcome page
so the definition appears in the application’s web.xml file.

Note that if the web page you specify contains ADF Faces components, you must
define the page in the context of /faces/. For example, the path for adffaces_
welcome.jspx would appear in the Welcome Page field as /faces/adffaces_
welcome.jspx.

For details about specifying other redirect options, see Section 41.7.5, "How to
Redirect a User After Authentication."

6. In the Summary page, review your selections and click Finish.

41.3.2 What Happens When You Enable ADF Security

After you run the Configure ADF Security wizard with the default ADF
Authentication and Authorization option selected in the ADF Security page, you will
have:

■ Enabled ADF authentication to prompt the user to log in and to allow page
redirects
■ Enabled ADF authorization checking so that only authorized users will have
access to ADF resources

The wizard updates all security-related configuration files and ensures that ADF
resources are secure by default. Table 41–2 shows which files the Configure ADF
Security wizard updates.
### Table 41–2  Files Updated for ADF Authentication and Authorization

<table>
<thead>
<tr>
<th>File</th>
<th>File Location</th>
<th>Wizard Configuration</th>
</tr>
</thead>
</table>
| **web.xml**      | `/public_html/WEB-INF directory relative to the user interface project` And, in JDeveloper, in the user interface project under the Web Content-WEB-INF node | - Defines the Oracle JpsFilter filter to set up the OPSS policy provider. The filter defines settings that indicate that your servlet has special privileges. It is important that the JpsFilter be the first filter definition in the web.xml file.  
- Adds the Oracle adfAuthentication servlet definition to require the user to log in the first time ADF resources are accessed. Note that ADF Security does not itself perform authentication, but leverages Java EE container-managed security for this purpose.  
- When you select the ADF Authentication and Authorization option in the wizard, maps the adfAuthentication servlet to a security constraint that will trigger user authentication dynamically.  
- When you select the ADF Authentication option in the wizard, maps the Java EE application root "/" to the allPages security constraint that will trigger user authentication dynamically.  
- Sets the authentication method for the Login configuration to handle user login.  
- Defines required security roles, including the role valid-users, which is used to trigger the security constraint that enables dynamic authentication. |
| **adf-config.xml** | `/.adf/META-INF directory relative to the web application workspace` And, in JDeveloper, in the Application Resources panel of the Applications window under the Descriptors-ADF META-INF node | - Defines the JAAS security context.  
- Enables the use of ADF Security security policies for authorization checking (the authorizationEnforce parameter in the `<JaasSecurityContext>` element is set to true).  
- Enables triggering a login dialog in Java SE applications, including ADF Swing applications (the authenticationRequire parameter in the `<JaasSecurityContext>` element is set to true). This parameter is not used in Fusion web applications. Fusion web applications rely on settings in the web.xml file to enable authentication. |
Enabling ADF Security

Because authentication is delegated to the web container, the wizard only updates the `web.xml` file to enable the ADF authentication servlet to trigger authentication dynamically. It defines servlet mapping for the ADF authentication servlet and adds two Java EE security constraints, `allPages` and `adfAuthentication`, to the `web.xml` file, as shown in Example 41–1.

![Example 41–1 ADF Authentication Descriptors in the web.xml File](image)

<table>
<thead>
<tr>
<th>File</th>
<th>File Location</th>
<th>Wizard Configuration</th>
</tr>
</thead>
<tbody>
<tr>
<td>jps-config.xml</td>
<td>/src/META-INF directory relative to the web application workspace</td>
<td>Enables OPSS security services specifically within the JDeveloper design time.</td>
</tr>
<tr>
<td></td>
<td>And, in JDeveloper, in the Application Resources panel of the Applications window under the Descriptors-META-INF node</td>
<td>When you test data model projects using the Oracle ADF Model Tester or run unit tests for security validation this workspace-specific file must be present. Note that this file is not used in the deployed Fusion web application. For example, when you deploy to Integrated WebLogic Server, OPSS security services are enabled by the DefaultDomain/config/fmwconfig/jps-config.xml file.</td>
</tr>
<tr>

<td>/public_html/WEB-INF directory relative to the web application workspace</td>
<td>Maps the valid-users security role to an implicit group called users. Oracle WebLogic Server configures all authenticated users to be members of the users group.</td>
</tr>
<tr>
<td></td>
<td>And, in JDeveloper, in the user interface project under the Web Content-WEB-INF node</td>
<td></td>
</tr>
<tr>
<td>jazn-data.xml</td>
<td>./src/META-INF directory relative to the web application workspace</td>
<td>Sets the default jazn.com realm name for the XML identity store that you configure for use with Integrated WebLogic Server. You will use this file to store user identities, user groups, and security policies for the ADF Security-enabled application. This file is used during development and enables support for security when running the Oracle ADF Model Tester. However, when you deploy your application, for example, to Integrated WebLogic Server, security policies will be migrated into the configured policy store in the DefaultDomain/config/fmwconfig/system-jazn-data.xml file.</td>
</tr>
<tr>
<td></td>
<td>And, in JDeveloper, in the Application Resources panel of the Applications window under the Descriptors-META-INF node</td>
<td></td>
</tr>
</tbody>
</table>

Table 41–2 (Cont.) Files Updated for ADF Authentication and Authorization

Because authentication is delegated to the web container, the wizard only updates the `web.xml` file to enable the ADF authentication servlet to trigger authentication dynamically. It defines servlet mapping for the ADF authentication servlet and adds two Java EE security constraints, `allPages` and `adfAuthentication`, to the `web.xml` file, as shown in Example 41–1.
Because the allPages constraint maps to the '/' URL, it protects the Java EE application root. This mapping enables the Oracle WebLogic Server web container to trigger user authentication dynamically even before ADF Security is accessed. When the user first accesses the application, it forces the container to challenge the user for the user name and password. Then when the user accesses a page protected by ADF Security, there is no longer a need to authenticate the user and no need to redirect to the ADF authentication servlet.

Because every user of the application is required to be able to log in, the security constraint defined against the adfAuthentication resource allows all users to access this web resource. As such, the security role associated with the constraint must encompass all users. To simplify this task, the Java EE valid-users role is defined. The weblogic.xml file maps this role to an implicit users group defined by Oracle WebLogic Server. This mapping ensures that every user will have this role because Oracle WebLogic Server configures all properly authenticated users as members of the users group, as described in Section 41.3.7, "What You May Need to Know About the valid-users Role."
Enabling ADF Security

To enable authorization, the wizard updates the `adf-config.xml` file and sets the `authorizationEnforce` parameter in the `<JaasSecurityContext>` element to `true`, as shown in Example 41–2.

Example 41–2 AuthorizationEnforce Flag Enabled in the adf-config.xml File

```xml
<JaasSecurityContext
    initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
    jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
    authorizationEnforce="true"
    authenticationRequire="true"/>
```

When authorization is enabled, the ADF security context gets the user principal from the `HttpServletRequest` once the user is authenticated by the container. The user submits a user name and password and that data is compared against the data in the identity store where user information is stored. If a match is found, the originator of the request (the user) is authenticated. The user principal is then stored in the ADF security context, where it can be accessed to obtain other security-related information (such as the group the user belongs to) in order to determine authorization rights. For details about accessing the ADF security context, see Section 41.11.4, "Getting Information from the ADF Security Context."

41.3.3 What Happens When You Generate a Default Form-Based Login Page

The wizard-generated login and error pages are simple HTML pages that are added to the top-level folder of your user interface project. The generated login page defines an HTML form that will submit the user’s login request with the standard `j_security_check` action. This action together with form-based authentication, which is the default option for container authentication provided by the wizard, allows the web container to authenticate users from many different web application resources.

The wizard updates the `web.xml` file to specify form-based authentication and identify the location of the pages, as shown in Example 41–3.

Example 41–3 Wizard-Generated Login Page Definition Added to in the web.xml File

```xml
<login-config>
    <auth-method>FORM</auth-method>
    <form-login-config>
        <form-login-page>/login.html</form-login-page>
        <form-error-page>/error.html</form-error-page>
    </form-login-config>
</login-config>
```

Your application will display the wizard-generated login page from a server-side redirect in response to the unauthenticated user attempting to access a protected...
Enabling ADF Security

resource. This is known as implicit authentication because the redirect to the login page only occurs when user navigates to a page that contains an ADF security-aware resource.

Note that web applications also have a notion of public pages and allow for explicit, as well as implicit authentication. This means that users should be able to log in to the application by clicking a login link before they navigate to secured content. For information about creating and using a login link, see Section 41.7, "Creating a Login Page."

41.3.4 What You May Need to Know About the Configure ADF Security Wizard

The first time you run the Configure ADF Security wizard and enable authentication and authorization, you secure ADF resources at the level of the application. Additionally, you select specific project-level settings for the user interface project, including the authentication type and the authentication welcome. The wizard adds these web application settings to the web.xml file in the project you select. When your application contains multiple user interface projects and web.xml files, you can return to the wizard and configure these settings in the web.xml file for another user interface project that you select.

41.3.5 What You May Need to Know About ADF Authentication

ADF applications that use Java EE container-managed authentication for login and ADF authentication for logout integrate with Oracle Single Sign-On (Oracle SSO) with no special requirements. The ADF authentication servlet handles the details of logout and invalidates the session. However, when the application uses login and logout methods provided by Servlet 3.0, Oracle SSO is not supported. Additionally, Servlet 3.0 login and logout is only compatible with application servers that fully support Java EE 6 or later.

On the first access to a page that relies on an ADF security-aware resource, if there is no subject defined, OPSS is configured by the JpsFilter to create a subject containing the anonymous user principal and the anonymous-role role principal. With this role principal, the unauthenticated user will be able to access public web pages that are not associated with any ADF security-aware resources (including ADF bounded task flows or page definitions).

In the case of pages associated with ADF security-aware resources, you must explicitly grant view permission to anonymous-role to make the page accessible to the anonymous user. For details about granting privileges to the anonymous user, see Section 41.5.1, "How to Make an ADF Resource Public."

41.3.6 What You May Need to Know About the Built-In test-all Role

The Configure ADF Security wizard lets you enable automatic grants to the built-in test-all application role for the purpose of granting view permission to all ADF security-aware resources in your application. Without a permission grant, either an automatic view grant or an explicit grant that you define, ADF Security authorization checking enforcement would prevent you from being able to run the application and access its resources. You can run the wizard with the test-all application role feature enabled and then gradually replace automatic view grants with explicit grants. Be aware that you must not deploy the application with grants to the test-all application role in place, since this feature makes all ADF resources public. If you choose to enable the built-in test-all application role in the wizard, see Section 41.9.1, "How to Remove the test-all Role from the Application Policy Store," before deploying your application.
41.3.7 What You May Need to Know About the valid-users Role

The valid-users role is a Java EE security role defined by ADF Security to ensure that all users will access the adfAuthentication servlet web resource defined in the web.xml file. The Configure ADF Security wizard updates the weblogic.xml file to map this ADF Security role to the users principal, as shown in Example 41–4. This mapping ensures that every user will have this role, because Oracle WebLogic Server configures all properly authenticated users as members of the users group.

Example 41–4 valid-users Role Mapping in the weblogic.xml File

```xml
<security-role-assignment>
    <role-name>valid-users</role-name>
    <principal-name>users</principal-name>
</security-role-assignment>
```

At runtime, the users principal is added automatically to a successfully authenticated subject by OPSS. From a security perspective, the valid-users role supports ADF authentication only in the case where you need to control access to web resources using security constraints alone. The end result of this mapping relies entirely on Java EE security and does not involve JAAS Permissions.

41.4 Creating Application Roles

You create application roles to represent the policy requirements of the application and to define groups of users with the same view permission rights. The application roles that you create in the application policy store are specific to your application. For example, in the context of the workflow, there may be application roles such as Application Customer Role and Application Employee Role, defined in the SummitADF_TaskFlows workspace of the Summit ADF sample applications.

At runtime, the access rights are conferred on the user through the application role for which the user is defined as a member. Thus, before you can define security policies, the policy store must contain the application roles that you intend to issue grants to. This can be an application role that you define (such as Application Customer Role) or it can be one of the two built-in application roles defined by OPSS: authenticated-role or anonymous-role. JDeveloper provides the built-in application roles to let you make ADF resources public, as described in Section 41.5.1, "How to Make an ADF Resource Public."

After you create the application role, you will:

- Grant permissions to the application roles, as described in Section 41.5, "Defining ADF Security Policies."
- Associate test users with each application role, as described in Section 41.6, "Creating Test Users."

**Best Practice:** The ADF Security framework enforces a role-based access control mechanism with permissions granted either to application roles or to individual users. Although you may only need to test security and therefore might not need to create groups of users, you should still create application roles (with at least one user member). Later when you define security polices on the ADF resources, the overview editor for the application policy store will allow you to select an application role for the grant.
41.4.1 How to Create Application Roles

JDeveloper lets you add application roles to the policy store of the jazn-data.xml file, which appears in the Descriptors/META-INF node of the Application Resources panel.

---

**Note:** When you create application roles, be sure to add the new application roles to the policy store, not the identity store. Roles that you add to the identity store define enterprise security roles and provide a way to conveniently group users in the identity store. For more details about enterprise roles, see Section 41.4.3, "What You May Need to Know About Enterprise Roles and Application Roles."

---

To create application roles in the policy store of the jazn-data.xml file, you use the Application Roles page of the overview editor for the jazn-data.xml file. This editor lets you view the relationship between identity store members and the application roles you create.

**Before you begin:**

It may be helpful to have an understanding of application roles. For more information, see Section 41.4, "Creating Application Roles."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

**To create application roles:**

1. In the main menu, choose **Application** and then **Secure > Application Roles**.
2. In the Application Roles page of the jazn-data.xml overview editor, select the policy store for your application from the **Security Policy** dropdown list.
   
   The policy store that JDeveloper creates in the jazn-data.xml file is automatically based on the name of your application.
3. In the **Roles** list, click the **New** icon.
4. In the **Name** field, enter the name of the role and click any other field to add the application role to the policy store.
5. If you have already set up test users in the identity store, you can map users and roles, as described in Section 41.6.3, "How to Associate Test Users with Application Roles."

41.4.2 What Happens When You Create Application Roles

When you add an application role to the policy store, JDeveloper updates the jazn-data.xml file located in the src/META-INF directory relative to the application workspace. Application roles are defined in <app-role> elements under <policy-store>, as shown in Example 41–5. Because the policy store <application> element names the application, at runtime all application roles that you create will be visible to your application only. Other web applications may define a policy store with their own set of application roles.

**Example 41–5 Application Role Definition in the Policy Store**

```xml
<policy-store>

<app-role>

</app-role>

</policy-store>
```
41.4.3 What You May Need to Know About Enterprise Roles and Application Roles

An enterprise role is a role that is maintained in the domain identity store (as opposed to an application identity store). Enterprise roles are available to every application deployed in the domain and are therefore also called external roles.

An application role is a role used by a Fusion web application. It is specific to the application, defined by the application policy, and not necessarily known to the Java EE container. Application roles are scoped in the sense that they can contain only users and roles defined in the application. Application roles must be mapped to enterprise roles.

You use the overview editor for the jazn-data.xml file to create enterprise roles to group users that you add to the identity store. You can use this mechanism to assign entire groups of users to application roles that you have defined for the purpose of conferring access rights defined by ADF security policies, as described in Section 41.6.3, "How to Associate Test Users with Application Roles."

However, Integrated WebLogic Server does not require you to create enterprise roles to run the application within JDeveloper. For the purpose of testing the application, it may be sufficient to create a few test users and assign them directly to application roles. When you run the application in JDeveloper, the users and any enterprise roles you defined will be created in the default security provider (which is embedded LDAP for Integrated WebLogic Server).

Typically, when you deploy the application for staging, you will migrate only the policy store to the target server. You can configure JDeveloper deployment options so that the identity store, including test users and enterprise roles, is not migrated, as described in Section 41.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."

After you deploy the secure application, Oracle Fusion Middleware will merge your application’s policy store with the policies of the domain-level policy store. To complete this task, the administrator for the Oracle WebLogic Server will eventually map the application roles of your policy store to the existing domain-level enterprise roles. This application role mapping at the domain level allows enterprise users to access application resources according to the ADF security policies you have defined. The domain-level application role mapping by the administrator also allows you to
develop the ADF security policies of your application without requiring any knowledge of the identity store in the production environment.

41.5 Defining ADF Security Policies

Authorization relies on a policy store that is accessed at runtime and that contains permissions that grant privileges to execute predefined actions, like view, on a specified object. Initially, after you run the Configure ADF Security wizard, the policy store defines no grants. And, because the default wizard option ADF Authentication and Authorization enables authorization checking, the web pages of your application that rely on the ADF security-aware resources will be inaccessible to users. You must use JDeveloper to define explicit grants for the resources that you want to permit users to access.

Best Practice: When you run the Configure ADF Security wizard with the default option ADF Authentication and Authorization selected, you will lock down the web pages of your application. This affords the most protection to the Fusion web application possible since you will define explicit grants to allow users to access only the pages you intend. For a discussion of this guideline and others, see Section 41.11.5, "Best Practices for Working with ADF Security."

Before you can define security policies, the policy store for your application must contain the application roles that you intend to issue grants to. This can be an application role that you define (such as Application Customer Role) or it can be one of the two built-in application roles defined by OPSS: authenticated-role or anonymous-role. You use application roles to classify users, so that each member of the same role possesses the same access rights. As such, the security policy names the application role as the principal of the grant, rather than specific users. For details about defining application roles, see Section 41.4, "Creating Application Roles."

For the user interface project, you use the overview editor for security policies to secure ADF resources, including ADF task flows and ADF page definitions. You open the editor on the jazn-data.xml file by double-clicking the jazn-data.xml file (located in the Application Resources panel) or by choosing Secure > Resource Grants from the Application menu in the main menu.

Note that when you open the jazn-data.xml file, the overview editor provides additional editor pages that you use to create test users, enterprise roles, and application roles.

For the data model project, you do not secure entity objects or their attributes using the overview editor for security policies. Instead, you set metadata directly on these objects to manage whether or not the databound UI component displays the data. For details about granting permissions for row-level security, see Section 41.5.11, "How to Define Policies for Data."

41.5.1 How to Make an ADF Resource Public

It is a common requirement that some web pages be available to all users, regardless of their specific access privileges. For example, the home page should be seen by all visitors to the site, while a corporate site should be available only to those who have identified themselves through authentication.

In both cases, the page may be considered public, because the ability to view the page is not defined by the users’ specific permissions. Rather, the difference is whether the user is anonymous or a known identity.
In the ADF security model, you differentiate between the absence of security and public access to content by granting access privileges to the anonymous-role principal. The anonymous role encompasses both known and anonymous users, thus permission granted to anonymous-role allows access to a resource by unauthenticated users, for example, guest users. To provide access to authenticated users only, the policy must be defined for the authenticated-role principal.

---

**Note:** For details about creating a public home page which contains links to other pages in the application, see Section 41.7.4, "How to Create a Public Welcome Page."

---

**Before you begin:**

It may be helpful to have an understanding of ADF security policies. For more information, see Section 41.5, "Defining ADF Security Policies."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete these tasks:

1. Create bounded task flows, as described in Section 20.2, "Creating a Task Flow."
2. Create web pages with an ADF page definition file, as described in Section 17.7, "Working with Page Definition Files."
3. Run the Configure ADF Security wizard, as described in Section 41.3, "Enabling ADF Security."
4. Create application roles, as described in Section 41.4, "Creating Application Roles."

**To grant public access to ADF security-aware resources:**

1. In the main menu, choose Application and then Secure > Resource Grants.
2. In the Resource Grants page of the overview editor for security policies, select one of the following resources from the Resource Type dropdown list:
   - Task Flow when you want to make a bounded task flow public. The application displays the web pages under the permission you define for the task flow itself. Thus, all constituent web pages of the bounded task flow will become public.
   - Web Page when you want to make individual web pages public. Typically, these pages are defined by an unbounded task flow and are top-level pages in the application, such as a home page.
3. In the Resources column, select the ADF resource for which you want to grant access rights.

The resource you select should display the lock icon in the first column next to the resource name. The lock icon indicates that the resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant. For example, in Figure 41–4, the ADF resource customer-registration-task-flow (a bounded task flow) shows the lock icon since no grant has been made.
Defining ADF Security Policies

**Tip:** Click the key toggle icon in the header for the overview editor’s first column to hide or show resources that already have grants and display only the resources without grants. The key icon indicates that the resource has a grant that will make the resource accessible to users with sufficient access rights.

**Figure 41–4 Selecting an ADF Security-Aware Resource in the Overview Editor**

4. In the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.

5. In the Select Application Roles dialog, select one of these built-in application roles:
   - **anonymous-role** means the resource will be accessible to anyone who visits the site. A grant to this role is necessary if you want to make a web page associated with an ADF security-aware resource accessible before a user logs in. For example, you would grant to **anonymous-role** for a task flow that manages customer registration.
   - **authenticated-role** means the resource will be accessible only to authenticated users (ones who visit the site and log in). For example, you would grant to **authenticated-role** for an employee registration task flow.

6. In the Select Application Roles dialog, click **OK**.

7. In the Resource Grants page of the overview editor, in the **Actions** column, leave the **view** action selected.

   By default, the overview editor shows **view** selected, as shown in **Figure 41–5**. The view action is the only action currently supported for Fusion web applications.

**Figure 41–5 Granting to anonymous-role in the Overview Editor**
41.5.2 What Happens When You Make an ADF Resource Public

When you define a security policy, the overview editor for security policies updates the jazn-data.xml file located in the /src/META-INF node relative to the web application workspace.

The overview editor writes the policy information to the <policy-store> section of the file. The security policy, or grant, contains both a grantee and one or more permissions. The grantee is the application role that the policy is being defined for—in this case, the anonymous role. Each permission defines the resource being secured and the action that can be performed against that resource.

Example 41–6 shows a security policy in the jazn-data.xml file that makes a customer registration task flow public. The grant to anonymous-role contains a single view permission for a bounded task flow, customer-registration-task-flow. With this grant, all users will be able to enter the customer registration task flow and complete the customer registration process. Additional grants to the anonymous role may be made and will appear in the <permissions> section of the anonymous role grant.

Example 41–6 Grants to anonymous-role in the Application-Level Policy Store

```xml
<policy-store>
  ...
  <jazn-policy>
    <grant>
      <grantee>
        <principals>
          <principal>
            <class>oracle.security.jps.internal.core.principals.JpsAnonymousRoleImpl</class>
            <name>anonymous-role</name>
          </principal>
        </principals>
      </grantee>
      <permissions>
        <permission>
          <class>oracle.adf.controller.security.TaskFlowPermission</class>
          <name>/WEB-INF/customer-registration-task-flow.xml#customer-registration-task-flow</name>
          <actions>view</actions>
        </permission>
        ...
      </permissions>
    </grant>
    ...
  </jazn-policy>
</policy-store>
```

41.5.3 What Happens at Runtime: How the Built-in Roles Are Used

The anonymous-role and authenticated-role names are special roles defined by Oracle Platform Security Services (OPSS).

When you run the Configure ADF Security wizard, the wizard configures the JpsFilter definition in the web.xml file to enable support for the anonymous role. The enabled anonymous role allows ADF Security to support browsing of the site by anonymous users—those users who have not yet logged in. In contrast, the...
authenticated role is not declared and is always recognized by default. ADF Security
supports both of these roles.

When an end user first accesses an ADF security-aware resource, the system creates a
subject and populates it with the anonymous role principal. As long as the ADF
security-aware resource being accessed has the view grant to anonymous role, the user
is permitted access. If the anonymous role is not a grantee of the ADF resource, the
user is prompted to log in. After logging in, the authenticated role is added to the
subject. The wizard also adds the JpsFilter definition to the web.xml file, where
remove.anonymous.role set to false ensures that the anonymous role principal is
available even after the user logs in. With the authenticated role principal, the user
may access resources that have an explicit grant to the authenticated role.

41.5.4 How to Define Policies for ADF Bounded Task Flows

You define the access policy for an ADF bounded task flow by creating permission
grants in the Resource Grants page of the overview editor for security policies. The
grants you create will appear as metadata in the policy store section of the
jazn-data.xml file. This metadata defines a permission target (in this case, the
bounded task flow definition name) for which you have issued grants to authorize the
members of a specific application role.

**Best Practice:** Do not create permission grants for the individual
web pages of a bounded task flow. When the user accesses the
bounded task flow, security for all pages will be managed by the
permissions you grant to the task flow. And, because the contained
web pages (with associated page definitions) will be inaccessible by
default, ADF Security prevents users from directly accessing the pages
of the task flow. This supports a well-defined security model for task
flows that enforces a single entry point for all users. For further
information about implementing security policies, see Section 41.11.5,
"Best Practices for Working with ADF Security."

You can sort the task flows in the overview editor by clicking the toggle buttons in the
Task Flow header, as described in Table 41-3.

<table>
<thead>
<tr>
<th>Button</th>
<th>Toggle Action</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><img src="image" alt="" /></td>
<td>Shows/hides bounded task flows with no grants</td>
<td>Represents a bounded task flow with no permission grants defined. The web pages that the task flow calls will not be accessible to any user.</td>
</tr>
<tr>
<td><img src="image" alt="" /></td>
<td>Shows/hides bounded task flows with grants</td>
<td>Represents a bounded task flow with one or more permission grants defined. The web pages that the task flow calls will be accessible to users who are members of the application role that received the grant.</td>
</tr>
</tbody>
</table>

The list of available actions displayed by the overview editor is defined by the task
flow permission class
(oracle.adf.controller.security.TaskFlowPermission). The permission
class maps these actions to the operations supported by the task flow. Table 41-4
shows the actions displayed by JDeveloper for ADF bounded task flows.

Note that the view action is the only action currently supported for Fusion web
applications. Do not select customize, grant, or personalize actions—they are
reserved for future use in task flow security.
To define a grant for the task flow security policy, use the Resource Grants page of the overview editor for the jazn-data.xml file.

**Before you begin:**
It may be helpful to have an understanding of ADF security policies. For more information, see Section 41.5, "Defining ADF Security Policies."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete these tasks:

1. Create bounded task flows, as described in Section 20.2, "Creating a Task Flow."

   **Best Practice:** If you are creating bounded task flows in separate UI projects of the same application, you will want to assign unique task flow definition names. This is necessary because a grant's task flow definition name is scoped in the jazn-data.xml policy store by path (for example, /WEB-INF/mytaskflow-definition.xml#mytaskflow-definition). Therefore creating bound task flows with unique definition names is the only way to impose project-level scoping of the grants.

2. Run the Configure ADF Security wizard, as described in Section 41.3, "Enabling ADF Security."

3. Create application roles, as described in Section 41.4, "Creating Application Roles."

**To define a permission grant on an ADF bounded task flow:**

1. In the main menu, choose Application and then Secure > Resource Grants.

2. In the Resource Grants page of the overview editor for security policies, select Task Flow from the Resource Type dropdown list.

   The overview editor displays all the task flows that your application defines. Task flows are defined by task flow definition files (.xml) that appear in the Web Content/Page Flows node of the user interface project.

3. In the Resources column, select the task flow for which you want to grant access rights.

   The first time you make a grant to a bounded task flow, the first column should display the Resources without any grants icon (represented by a "lock") next to the task flow name. The overview editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant.

<table>
<thead>
<tr>
<th>Grantable Action</th>
<th>Effect on the User Interface</th>
</tr>
</thead>
<tbody>
<tr>
<td>view</td>
<td>Controls who can read and execute a bounded task flow in a Fusion web application. This is the only operation that the task flow supports.</td>
</tr>
<tr>
<td>customize</td>
<td>Reserved for future use. This action is not checked at runtime.</td>
</tr>
<tr>
<td>grant</td>
<td>Reserved for future use. This action is not checked at runtime.</td>
</tr>
<tr>
<td>personalize</td>
<td>Reserved for future use. This action is not checked at runtime.</td>
</tr>
</tbody>
</table>

To define a permission grant on an ADF bounded task flow:

1. In the main menu, choose Application and then Secure > Resource Grants.

2. In the Resource Grants page of the overview editor for security policies, select Task Flow from the Resource Type dropdown list.

   The overview editor displays all the task flows that your application defines. Task flows are defined by task flow definition files (.xml) that appear in the Web Content/Page Flows node of the user interface project.

3. In the Resources column, select the task flow for which you want to grant access rights.

   The first time you make a grant to a bounded task flow, the first column should display the Resources without any grants icon (represented by a "lock") next to the task flow name. The overview editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant.
Defining ADF Security Policies

Figure 41–6  Hiding Task Flows with Grants in the Overview Editor

4. In the Granted to column, click the Add Grantee icon and select Add Application Role.

5. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

The Select Application Roles dialog displays application roles from the jazn-data.xml file. It also displays the built-in OPSS application roles, anonymous-role and authenticated-role, as described in Section 41.5.3, "What Happens at Runtime: How the Built-in Roles Are Used.”

If you do not see application roles that are specific to your application, create the role, as described in Section 41.4, "Creating Application Roles.”

6. In the Select Application Roles dialog, click OK.

7. In the Resource Grants page of the overview editor, in the Actions column, leave the view action selected.

By default, the overview editor shows the view action selected, as shown in Figure 41–7. The view action is the only action currently supported for Fusion web applications. Do not select customize, grant, or personalize actions—they are reserved for future use and will not be checked by ADF Security at runtime.

The TaskFlowPermission class defines task flow—specific actions that it maps to the task flow’s operations, as described in Table 41–4.

Figure 41–7  Granting to an Application Role for a Bounded Task Flow Definition in the Overview Editor

8. You can repeat these steps to make additional grants as desired.

Tip: Click the Resources with grants icon (represented by a "key") in the header for the Resources column to hide all task flows that already have grants. This will display only task flows without grants, as shown in Figure 41–6. Additionally, you can type a partial task flow name in the search field to display only the task flows with character-matching names.
The same task flow definition can have multiple grants made for different application roles. The grants appear in the policy store definition of the jazn-data.xml file, as described in Section 41.5.7, "What Happens When You Define the Security Policy."

41.5.5 How to Define Policies for Web Pages That Reference a Page Definition

You define the access policy for an ADF page definition by creating permission grants in the Resource Grants page of the overview editor for security policies. The grants you create will appear as metadata in the policy store section of the jazn-data.xml file. This metadata defines a permission target (in this case, the page definition name) for which you have issued grants to authorize the members of a specific application role.

Best Practice: Create permission grants for the individual web page only when the page is not a constituent of a bounded task flow. Page-level security is checked for pages that have an associated page definition binding file only if the page is directly accessed or if it is accessed in an unbounded task flow. For further information about implementing security policies, see Section 41.11.5, "Best Practices for Working with ADF Security."

You can sort the web page definition resources in the overview editor by clicking the toggle buttons in the Resources header, as described in Table 41–5.

<table>
<thead>
<tr>
<th>Button</th>
<th>Toggle Action</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>![Lock]</td>
<td>Shows/hides top-level pages with no grants</td>
<td>Represents a page definition with no permission grants defined for a web page that is contained in an unbounded task flow. The web page will not be accessible to any user.</td>
</tr>
<tr>
<td>![Lock]</td>
<td>Shows/hides top-level pages with grants</td>
<td>Represents a page definition with one or more permission grants defined for a web page that is contained in an unbounded task flow. The web page will be accessible to users who are members of the application role that received the grant.</td>
</tr>
<tr>
<td>![List]</td>
<td>Shows/hides pages included in a bounded task flow</td>
<td>Represents a page definition associated with a web page that also is contained in a bounded task flow. Do not grant to these web page definitions. Instead, define a security policy for the bounded task flow.</td>
</tr>
<tr>
<td>![Unsecure]</td>
<td>Shows/hides unsecure pages (with no page definition)</td>
<td>Represents a web page with no page definition defined that is contained in an unbounded task flow. (Pages like this that are contained by a bounded task flow are secured by the bounded task flow’s permission.) The web page will be accessible to all users since it is not secured by an associated ADF security-aware resource. Optionally, you can secure the page by adding an empty page definition file, as described in Section 41.5.9, &quot;What You May Need to Know About Defining Policies for Pages with No ADF Bindings.&quot;</td>
</tr>
</tbody>
</table>

The list of available actions displayed by the overview editor is defined by the region permission class (oracle.adf.share.security.authorization.RegionPermission). The permission class maps these actions to the operations supported by the ADF page definition for the web page. Table 41–6 shows the actions displayed by JDeveloper for ADF page definitions.
Defining ADF Security Policies

Note that the view action is the only action currently supported for Fusion web applications.

Table 41–6  Securable Actions of ADF Page Definitions

<table>
<thead>
<tr>
<th>Grantable Action</th>
<th>Effect on the User Interface</th>
</tr>
</thead>
<tbody>
<tr>
<td>view</td>
<td>Controls who can view the page. This is the only operation that the page definition supports.</td>
</tr>
</tbody>
</table>

To define a grant for the page definition security policy, use the Resource Grants page of the overview editor for the jazn-data.xml file.

**Before you begin:**

It may be helpful to have an understanding of ADF security policies. For more information, see Section 41.5, "Defining ADF Security Policies."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete these tasks:

1. Create the top-level web pages with an ADF page definition file, as described in Section 17.7, "Working with Page Definition Files."

   **Best Practice:** If you are creating top-level web pages in separate UI projects of the same application, you will want to assign unique page file names. This is necessary because a grant's page definition name is scoped in the jazn-data.xml policy store by package (for example, view.pageDefs.mytoppagePageDef). Therefore creating top-level pages with unique file names is the only way to impose project-level scoping of the grants.

2. Run the Configure ADF Security wizard, as described in Section 41.3, "Enabling ADF Security."

3. Create application roles, as described in Section 41.4, "Creating Application Roles."

**To define a permission grant on an ADF page definition:**

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.

2. In the Resource Grants page of the overview editor for security policies, select **Web Page** from the Resource Type dropdown list.

   The Resource Grants page of the overview editor displays all web pages, including those that have an associated ADF page definition. This includes any web page that uses ADF data bindings or any web page for which you have created an empty page definition. Page definitions are defined by PageDef.xml files that appear in the Application Sources node of the user interface project.

3. In the Resources column, select the page definition for which you want to grant access rights.

   The first time you make a grant to a page definition, the first column should display the Resource without any grants icon (represented by the "lock" icon) next to the page definition name. The editor displays the lock icon to indicate that a resource has no security policy defined and therefore is "locked"—which means it
remains inaccessible to users until you define a grant. For example, the page
definition account_updateUserInfo shown in Figure 41–8 displays the lock
icon since no grant has been made. Other page definitions in Figure 41–8 show the
Page included in bounded task flow icon because they are not top-level pages
and thus are securable by the containing bounded task flow.

Do not create grants for individual web page definitions that display the Page
included in bounded task flow icon. Security policies for the associated web
pages are secured by their bounded task flow. For example, in Figure 41–8, the
page definition associated with the account_addressDetails.jsff region
will be secured by the containing bounded task flow.

Tip: You can type a partial page definition name in the search field to
display only the page definitions with character-matching names. For
example, a search on the word general would display only the page
definitions that begin with the word general, as shown in
Figure 41–8.

Figure 41–8 Matching Page Definitions by Name in the Overview Editor

Tip: You can click the Resources with grants icon (represented by
the “key” icon) to hide all page definitions that already have grants.
Confirm that the Show pages included in a bounded task flow toggle
button in the header for the Resources column is toggled off to hide
all page definitions that are included in a bounded task flow (by
default, it is set to hide these pages). This will display top-level pages
that have no grants (and unsecurable pages, if any), as shown in
Figure 41–9.

Figure 41–9 Hiding Web Pages with Grants in the Overview Editor

4. In the Granted to column, click the Add Grantee icon and select Add Application
Role.

5. In the Select Application Roles dialog, select the application role that you want to
make a grantee of the permission.
The Select Application Roles dialog displays application roles from the `jazn-data.xml` file. It also displays the built-in OPSS application roles, `anonymous-role` and `authenticated-role`, as described in Section 41.5.3, “What Happens at Runtime: How the Built-in Roles Are Used.”

If you do not see application roles that are specific to your application, create the role, as described in Section 41.4, “Creating Application Roles.”

6. In the Select Application Roles dialog, click OK.

7. In the Resource Grants page of the overview editor, in the Actions column, leave the View action selected.

   By default, the overview editor shows view selected, as shown in Figure 41–10. The view action is the only action currently supported for Fusion web applications.

   The RegionPermission class defines page definition—specific actions that it maps to the page’s operations, as described in Table 41–6.

8. You can repeat these steps to make additional grants as desired.

   The same page definition can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in Section 41.5.7, “What Happens When You Define the Security Policy.”

41.5.6 How to Define Policies to Control User Access to ADF Methods

ADF methods that your application defines may be dropped into the user interface as command components. By default, users who have access to the page that displays the command component for the method will also have rights to execute the method. When you want to create additional security to restrict access to the method operation, you must create a resource grant and test the permission at the level of the user interface. ADF Security does not perform authorization checking for ADF methods; you must enable authorization checking in your application. Based on a resource permission you have granted to the user for the ADF method, the user interface will either enable or disable the command component.

To control user access to a method that your page displays as a command component, you complete these steps:
1. Create a resource grant for a custom resource type and resource.

2. Enforce the permission grant in the user interface.

### 41.5.6.1 Creating a Resource Grant to Control Access to ADF Methods

The resource type that you create will be set to the matcher class `oracle.security.jps.ResourcePermission`, which will allow you to grant permission to parts of the application that are not protected by ADF Security. For example, your page may display a button that lets users cancel a product shipment to customers. However, only members of a specific application role may be allowed to cancel a shipment. To enforce this rule, you can create a resource permission that may be checked declaratively in the user interface at runtime to enable or disable the button.

To create a resource permission for user interface components that you want to protect, use the overview editor for security policies.

**Before you begin:**

It may be helpful to have an understanding of how ADF Security handles ADF methods. For more information, see Section 41.5.6, "How to Define Policies to Control User Access to ADF Methods."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete these tasks:

1. Create the command component that executes the method that you want secure, as described in Section 30.2, "Creating Command Components to Execute Methods."

2. Run the Configure ADF Security wizard, as described in Section 41.3, "Enabling ADF Security."

3. Create application roles, as described in Section 41.4, "Creating Application Roles."

**To grant a resource permission on a custom resource type:**

1. In the main menu, choose Application and then Secure > Resource Grants.

2. In the Resource Grants page of the overview editor for security policies, next to the **Resource Type** dropdown list, click the **New Resource Type** button.

3. In the Create Resource Type dialog, enter the name of the resource type, a display name to display when granting resource permissions in JDeveloper, and a description.

   Enter a resource type and display name that is appropriate for the user interface resource that needs to be protected. For example, if you want to protect a method button that cancels a product shipment, you might enter the resource type `CancelShipment` and display name `Cancel Shipment`.

4. Next to the **Actions** list, click the **Add Action** button and enter the name of the action that you want to protect. Click **OK**.

   The action name can be any name that you want to associate with the custom resource type. For example, if you want to protect a method that invokes a method, you might enter the action name `invoke`. You can add multiple actions to the list when you need to support granting instances of the resource permission to separate application roles.
5. In the Resource Grants page of the overview editor for security policies, in the Resources column, click the Add Resource icon.

   The first time you make a grant to a custom resource type, no resource will be defined. You must create a custom resource for the policy that will be used to check user permissions in the user interface at runtime.

6. In the Create Resource dialog, enter the name of the resource and a display name to display when granting resource permissions in JDeveloper, and then click OK.

   Enter a resource name and a display name that describes the user interface resource that you want to protect. For example, if you want to protect a method button that cancels a product shipment, you might enter the resource name CancelShipmentButton and display name Cancel Shipment Button.

7. In the Granted to Roles column, click the Add Grantee icon and select Add Application Role.

8. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

   The Select Application Roles dialog displays application roles from the jazn-data.xml file. It also displays the built-in OPSS application roles, anonymous-role and authenticated-role, as described in Section 41.5.3, "What Happens at Runtime: How the Built-in Roles Are Used,"

   If you do not see application roles that are specific to your application, create the role, as described in Section 41.4, "Creating Application Roles."

9. In the Select Application Roles dialog, click OK.

10. In the Resource Grants page of the overview editor, in the Actions column, select the desired action.

    By default, the overview editor shows all actions of the custom resource type unselected. The available actions are defined by the resource type.

11. You can repeat these steps to make additional grants as desired.

    The same ADF method resource can have multiple grants made for different application roles. The grants appear in the policy store definition of the jazn-data.xml file, as described in Section 41.5.7, "What Happens When You Define the Security Policy."

41.5.6.2 Enforcing the Resource Grant in the User Interface

You use the Expression Builder dialog that you display for the UI component display property to define an EL expression that checks the user’s access rights to a previously defined custom resource type. When you run the application, the component will appear either enabled or disabled based on the outcome of the EL expression resource permission evaluation.

For example, you can define the userGrantedPermission expression on the disabled attribute of the af:button#cb1 button, as shown in Example 41–7. In this case, the expression tests whether the user has permission and then either enables the button or, when the user does not have permission, disables the button. Because the expression is not defined on the button’s rendered attribute, the page always displays the button.

Example 41–7 Resource Grant Check Expression

<af:button actionListener="#{bindings.myMethodName.execute}"
    text="myMethodName"
Before you begin:

It may be helpful to have an understanding of the limitations of ADF method authorization checking. For more information, see Section 41.5.6, "How to Define Policies to Control User Access to ADF Methods."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete this task:

Create the resource grant for a custom resource type, as described in Section 41.5.6.1, "Creating a Resource Grant to Control Access to ADF Methods."

To check the resource permission using an expression:

1. In the Applications window, double-click the page that contains the command component bound to the ADF method.
2. In the visual editor for the page, select the command component that is used to execute the ADF method.
3. In the Property window, click the Property Menu dropdown menu next to the Disabled field and choose Expression Builder.
4. In the Expression Builder, expand the ADF Bindings - securityContext node and select userGrantedPermission, and then, in the Expression field, enter a concatenated string that defines the permission.

Enter the permission string as a semicolon-separated concatenation of resourceName=aResourceName;resourceType=aResourceType;action=actionName. For example, to enable or disable a command button used to invoked the method in a page, you would enter an expression similar to the one shown in Example 41-7.

In Example 41-7, the expression determines whether a resource policy grants invoke privileges for the resource type named CancelShipment to the user’s defined application role. The resource policy must exist in the application policy store to test the expression at runtime.

5. Click OK.

41.5.7 What Happens When You Define the Security Policy

When you define a security policy, the overview editor for security policies updates the jazn-data.xml file located in the /src/META-INF node relative to the web application workspace.

The overview editor writes the policy information to the <policy-store> section of the file. The security policy, or grant, contains both a grantee and one or more permissions. The grantee is the application role that the policy is being defined for. Each permission defines the resource being secured and the action that can be performed against that resource.
Example 41–8 shows a security policy in the jazn-data.xml file that grants unauthenticated users access to an employee registration task flow and a top-level web page used to access the task flow. The grant to the anonymous-role application role contains a view permission for a bounded task flow, emp-reg-task-flow, and a view permission on the web page with the indexPageDef page definition. With this grant, unauthenticated users will be able to enter the employee registration task flow and view the welcome page.

For the web page, notice that permission has been defined on the indexPageDef page definition created for the welcome page (index.jsf). Also, note that this is a top-level web page that is not already secured by a bounded task flow.

Example 41–8  Grants in the Application-Level Policy Store

<grant>
  <grantee>
    <principals>
      <principal>
        <name>anonymous-role</name>
        <class>oracle.security.jps.internal.core.principals.JpsAnonymousRoleImpl</class>
      </principal>
    </principals>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.adf.controller.security.TaskFlowPermission</class>
      <name>/WEB-INF/flows/emp-reg-task-flow-definition.xml#emp-reg-task-flow-definition</name>
      <actions>view</actions>
    </permission>
    <permission>
      <class>oracle.adf.share.security.authorization.RegionPermission</class>
      <name>oracle.summit.view.pageDefs.indexPageDef</name>
      <actions>view</actions>
    </permission>
  </permissions>
</grant>

41.5.8 What Happens at Runtime: How ADF Security Policies Are Enforced

Grants that you make for ADF resources are standard JAAS Permissions. When you enable ADF Security in your application, Oracle Platform Security Service (OPSS) running in Oracle WebLogic Server will utilize the grants to allow authorization. In authorization mode, ADF Security uses fine-grained authorization, implemented with JAAS Permissions to perform security checks for access rights to pages. The ADF Security enforcement logic checks to see whether the user, represented by the JAAS subject, has the right permissions to access the resource.

The subject contains the user’s principals, which include a user principal that contains their name (could be anonymous, before logging on, or some user name after logging
Defining ADF Security Policies

Enabling ADF Security in a Fusion Web Application

on), and their list of role principals, which would include authenticated-role and some number of other roles that are obtained from the policy and identity stores. The principal is created to represent all of the user’s memberships in application roles defined in the policy store. In turn, each application role may have multiple Permissions associated with them. These are the ADF security policies that are created through the overview editor for the jazn-data.xml file.

---

**Note:** ADF security policies are scoped by application. This scoping allows two applications to refer to the same permission target, without producing unintentional results. You are not required to name application resources to impose application scoping of the policy store information.

---

Before you run the application using Integrated WebLogic Server, you will need to provision the identity store with test users and add these users to the application roles that you want to configure. The application roles can define members that are specific users or groups of users (also known as enterprise roles), as described in Section 41.6, "Creating Test Users."

Then at runtime, whether the current user has view permission on the page they are trying to access will be determined by the context of the page:

- If the page is an activity of a bounded task flow, the task flow controller determines the permission.
- If the page is a top-level page with an associated page definition file, the ADF Model layer determines the permission.

Oracle Platform Security Services then checks to see whether the subject contains the roles that have the corresponding permissions needed to access the page. If the user is authorized, then the task flow is entered.

In the case of a bounded task flow and top-level pages (defined by an unbounded task flow), if the user is not authorized, ADF Controller throws an exception and passes control to an exception handler that the task flow configuration specifies. For details about specifying an error page, see Section 41.7.5, "How to Redirect a User After Authentication."

41.5.9 What You May Need to Know About Defining Policies for Pages with No ADF Bindings

The default Configure ADF Security wizard option ADF Authentication and Authorization enables authorization checking and secures a web page whenever the page is associated with an ADF security-aware resource. Therefore, after you run the wizard, a web page will not be secured if both of these conditions exist:

- The page does not display databound ADF Faces components and therefore no ADF page definition exists for the page.
- The page is not a constituent page of a bounded ADF task flow. (Any page that the user accesses as a process of a bounded task flow is checked under the permission of the task flow.)

JDeveloper will generate an ADF page definition file for you whenever you design a web page using the Data Controls panel to create databound ADF Faces components. However, if your web page does not use ADF bindings, you can still create an empty page definition file by right-clicking the web page in the user interface project and choosing Go to Page Definition. The page definition file can remain empty because
the page does not need to work with ADF bindings to support databound ADF Faces components.

Once you associate a web page with an ADF page definition file, empty or not, authorization checking will be enforced when the user accesses the associated web page. You can define security policies for the page as you would any other ADF page definition. For details about making grants to an empty ADF page definition, see Section 41.5.5, "How to Define Policies for Web Pages That Reference a Page Definition."

**Before you begin:**

It may be helpful to have an understanding of security for individual page definition files. For more information, see Section 41.5.5, "How to Define Policies for Web Pages That Reference a Page Definition."

You may also find it helpful to understand how JDeveloper normally generates page definition files. For more information, see Section 17.7, "Working with Page Definition Files."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

**To create an empty page definition that you can define security policies for:**

1. In the Applications window, locate the web page you want to secure, right-click the node and choose Go to Page Definition.

2. In the confirmation dialog, click Yes to create a new page definition for the page.

   The page definition will be added to the pageDefs package.

### 41.5.10 How to Use Regular Expressions to Define Policies on Groups of Resources

When you want to define a grant that applies to multiple resources at once, you can create patterns as defined by the `java.util.regex.Pattern` class to form a regular expression that gets evaluated at runtime. For example, to match a grant to a set of resources, you can enter the expression `. *` (specifies any character zero or more times) on the name of the permission. ADF Security does not support the use of regular expressions on other security objects, such as the principal name.

You might use this feature to group bounded task flows that would have the same permissions into their own subfolders of `WEB-INF` and define the grant for the entire folder, as shown in Example 41–9. In this case, the expression uses the dot character (defined as, any character) followed by the asterisk quantifier (defined as, zero or more times).

**Example 41–9 Task Flow Permission for an Entire Folder Defined in the Application-Level Policy Store**

```xml
...  
<grant>
  <grantee>
    <principals>
      <principal>
        <class>oracle.security.jps.service.policystore.ApplicationRole</class>
        <name>anonymous-role</name>
      </principal>
    </principals>
  </grantee>
</grant>
```

...
Defining ADF Security Policies

Enabling ADF Security in a Fusion Web Application

<permissions>
  <permission>
    <class>oracle.adf.controller.security.TaskFlowPermission</class>
    <name>/WEB-INF/.*</name>
    <actions>view</actions>
  </permission>
</permissions>
</grant>

As the overview editor for the jazn-data.xml file does not support the use of regular expressions in the user interface, you must edit the file directly. Do not edit the policy store of the system-jazn-data.xml file directly. Instead, add grants using regular expressions to the jazn-data.xml file. These grants will then be merged to the policy store when you run or deploy the application.

The use of more complex regular expressions enables you to define business rules in the policy, thus creating a very targeted set of permissions. For example, you can grant the view permission on all page definitions and deny specific page definitions at the same time by defining an exclusion set in your regular expression. Example 41–10 shows how the view permission is granted to anonymous-role for all pages except those for which the page definition name starts with custom.

**Example 41–10 Using Regular Expressions and Metacharacters to Define a Policy Grant**

<grant>
  <grantee>
    <principals>
      <principal>
        <class>oracle.security.jps.service.policystore.ApplicationRole</class>
        <name>anonymous-role</name>
      </principal>
    </principals>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.adf.share.security.authorization.RegionPermission</class>
      <name>^[^custom].*</name>
      <actions>view</actions>
    </permission>
  </permissions>
</grant>

Table 41–7 shows some of the basic regular expression metacharacters that you can use in your policy definitions.

**Table 41–7 Description of Metacharacters**

<table>
<thead>
<tr>
<th>Metacharacter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>[abc]</td>
<td>a, b, or c (included in list)</td>
</tr>
<tr>
<td>[^abc]</td>
<td>any character except a, b, or c (negation)</td>
</tr>
<tr>
<td>[a-zA-Z]</td>
<td>a to z or A to Z, inclusive (range)</td>
</tr>
<tr>
<td>[a-d[m-p]]</td>
<td>a to d, or m to p (\text{union})</td>
</tr>
<tr>
<td>[a-z&amp;[def]]</td>
<td>d, e, or f (intersection)</td>
</tr>
<tr>
<td>[a-z&amp;[^bc]]</td>
<td>a through z, without b and c; [ad-z] (subtraction)</td>
</tr>
<tr>
<td>[a-z&amp;[^m-p]]</td>
<td>a through z, and not m through p</td>
</tr>
</tbody>
</table>

Table 41–7 shows some of the basic regular expression metacharacters that you can use in your policy definitions.
41.5.11 How to Define Policies for Data

ADF entity objects in the data model project are security-aware, meaning that predefined resource-specific permissions exist that a developer can grant. Additionally, you can secure just the individual attributes of entity objects. Entity objects that you secure restrict users from updating data displayed by any web page that renders a UI component bound by an ADF binding to the data accessed by the secured entity object. Additionally, when you secure an entity object, you effectively secure any view object in the data model project that relies on that entity object. As such, entity objects that you secure define an even broader access policy that applies to all UI components bound to this set of view objects.

To secure row data using ADF entity objects:

1. Define a permission map for the specific actions of the entity object or the attributes of the entity object that you want to secure.
2. Grant the permission to an application role that you have added to the policy store.

41.5.11.1 Defining Permission Maps on ADF Entity Objects

In the data model project, you use the overview editor for the entity object to define a permission map for the specific actions allowed by the entity object. The metadata consists of a permission class, a permission name, and a set of actions mapped to binding operations.

The list of available operations displayed by the overview editor is defined by the entity object permission class (oracle.adf.share.security.authorization.EntityPermission). The permission class maps the operations supported by the entity object to actions. Table 41–8 shows the securable operations of the entity object.

<table>
<thead>
<tr>
<th>Securable Operation</th>
<th>Expected Mapped Action</th>
<th>Corresponding Implementation</th>
</tr>
</thead>
<tbody>
<tr>
<td>read</td>
<td>Read</td>
<td>View the rows of a result set that has been restricted by a WHERE clause fragment.</td>
</tr>
<tr>
<td>update</td>
<td>Update</td>
<td>Update any attribute of the bound collection.</td>
</tr>
<tr>
<td>removeCurrentRow</td>
<td>Delete</td>
<td>Delete a row from the bound collection.</td>
</tr>
</tbody>
</table>

To secure all row-level data that the entity object accesses, use the overview editor for the entity object.

**Before you begin:**

It may be helpful to have an understanding of ADF security for entity objects. For more information, see Section 41.5.11, "How to Define Policies for Data."
Defining ADF Security Policies

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete this task:

Create entity objects in the data model project, as described in Chapter 4, "Creating a Business Domain Layer Using Entity Objects."

To secure an operation on an entity object:

1. In the Applications window, double-click the entity object that you want to secure.
2. In the overview editor, click the General navigation tab.
3. In the General page, expand the Security section and select the operations you want to secure for the entity object.

The Security section displays the securable operations that the EntityPermission class defines. The class maps the entity object—specific actions to the entity object’s operations, as described in Table 41–8.

For example, to enable read permission, select it as shown in Figure 41–11. The permissions appear in the XML definition of the entity object.

Figure 41–11 Permission Enabled on read Operation for an ADF Entity Object

<table>
<thead>
<tr>
<th>Operation</th>
<th>Enabled</th>
</tr>
</thead>
<tbody>
<tr>
<td>read</td>
<td></td>
</tr>
<tr>
<td>update</td>
<td></td>
</tr>
<tr>
<td>removeCurrentRow</td>
<td></td>
</tr>
</tbody>
</table>

41.5.11.2 Defining Permission Maps on ADF Entity Object Attributes

In the data model project, you use the overview editor for the entity object to define a permission map for the specific actions allowed by the entity object attribute. The metadata consists of a permission class, a permission name, and a set of actions mapped to binding operations.

The list of available operations displayed by the overview editor is defined by the entity object permission class (oracle.adf.share.security.authorization.EntityPermission). The permission class maps the operations supported by entity object attributes to actions. Table 41–9 shows the securable operations of entity object attributes.

Table 41–9 Securable Operations of ADF Entity Object Attributes

<table>
<thead>
<tr>
<th>Securable Operation</th>
<th>Expected Mapped Action</th>
<th>Corresponding Implementation</th>
</tr>
</thead>
<tbody>
<tr>
<td>update</td>
<td>Update</td>
<td>Update a specific attribute of the bound collection.</td>
</tr>
</tbody>
</table>

To secure individual columns of data that the entity object accesses, use the Attributes page of the overview editor for the entity object.

Before you begin:

It may be helpful to have an understanding of ADF security for entity objects. For more information, see Section 41.5.11, "How to Define Policies for Data."
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete this task:

Create entity objects in the data model project, as described in Chapter 4, "Creating a Business Domain Layer Using Entity Objects."

**To secure an operation on an entity object attribute:**

1. In the Applications window, double-click the entity object that defines the attribute you want to secure.
2. In the overview editor, click the Attributes navigation tab.
3. In the Attributes page, select the attribute to secure, and then click the Security tab and select the update operation.

The Security tab displays the securable operations that the EntityAttributePermission class defines. The class maps the entity object-specific actions to the entity object’s operations, as described in Table 41–9.

For example, to enable update permission, select it as shown in Figure 41–12. The permission map appears in the XML definition of the entity object.

*Figure 41–12  Permission Enabled on update Operation for an ADF Entity Object Attribute*

---

41.5.11.3 Granting Permissions on ADF Entity Objects and Entity Attributes

Once a permission target is configured, any data that derives from entity objects or their attributes remains unsecured until you explicitly define policy grants for the entity object’s permission target.

To define the access policy for an existing entity object or entity attribute permission target, use the overview editor for security policies.

**Before you begin:**

It may be helpful to have an understanding of ADF security for entity objects. For more information, see Section 41.5.11, "How to Define Policies for Data."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete these tasks:

1. Run the Configure ADF Security wizard, as described in Section 41.3, "Enabling ADF Security."
2. Create application roles, as described in Section 41.4, "Creating Application Roles."
3. Define the permission target for the entity object or the attributes of the entity object, as described in Section 41.5.11.1, "Defining Permission Maps on ADF Entity Objects."
To define the access policy for an entity object or entity attribute:

1. In the main menu, choose Application and then Secure > Resource Grants.

2. In the Resource Grants page of the overview editor for security policies, select ADF Entity Object or select ADF Entity Object Attribute from the Resource Type dropdown list.

   The Resource Grants page of the overview editor displays all entity objects (or entity attributes) for which you previously defined permission targets.

3. In the Resources column, select the ADF entity object or entity attribute for which you want to grant access rights.

   The first time you make a grant to an ADF entity object or entity attribute, the first column displays the Resource without any grants icon (represented by the "lock" icon) next to the method name, as shown in Figure 41–13. The editor displays the lock icons to indicate that a resource has no security policy defined and therefore is "locked"—which means it remains inaccessible to users until you define a grant.

4. In the Granted to Roles column, click the Add Grantee icon and select Add Application Role.

5. In the Select Application Roles dialog, select the application role that you want to make a grantee of the permission.

   The Select Application Roles dialog displays application roles from the jazn-data.xml file. It also displays the built-in OPSS application roles, anonymous-role and authenticated-role, as described in Section 41.5.3, "What Happens at Runtime: How the Built-in Roles Are Used,"

   If you do not see application roles that are specific to your application, create the role, as described in Section 41.4, "Creating Application Roles."

6. In the Select Application Roles dialog, click OK.

7. In the Resource Grants page of the overview editor, in the Actions column, select the action that you want to grant to a specific application role.

   For entity objects, the overview editor shows read action selected by default. You may select the update action and delete action if you have have configured their corresponding permission targets, as described in Table 41–8.

   For entity object attributes, the overview editor shows the update action selected by default, corresponding to the permission target described in Table 41–9. No other actions are supported for entity object attributes.

   Figure 41–14 shows the delete, read, and update privileges granted to the Application Employee Role application role for an entity object.
8. You can repeat these steps to make additional grants as desired.

The same ADF entity object or entity attribute can have multiple grants made for different application roles. The grants appear in the policy store definition of the `jazn-data.xml` file, as described in Section 41.5.7, "What Happens When You Define the Security Policy."

### 41.5.12 How to Aggregate Resource Grants as Entitlement Grants

You define end user access for individual securable Oracle ADF artifacts by creating resource grants. However, for ease of administration and maintenance, resource grants can also be defined as entitlement grants, in which case multiple securable application artifacts are aggregated into a named security group that can be granted to application roles using a single statement. For example, when you want to authorize access to the data exposed in the application by ADF Business Components entity objects, multiple entity objects may require the same security policy. Instead of individually granting access privileges to each entity object, you can group the privileges as a set in an entitlement and grant them all at once.

You create entitlement grants in the Entitlements Grants page of the overview editor for security policies. The grants you create will appear as metadata in the policy store section of the `jazn-data.xml` file. This metadata defines an entitlement (identified in the XML definition as `<permission-set>`) comprised of resource instance /action pairs that you select. This entitlement is a grantable entity that you then grant to an application role.

The list of resource types appears in the overview editor for security policies. The resource type you select filters the resource instances defined within the projects of your application’s workspace. The resource type selection also determines the list of available actions displayed by the overview editor. For example, when you select the Task Flow Permission resource type, the overview editor will display all of the task flows in the user interface projects that you select and also displays the view action that you can associate with the available ADF bounded task flow resources.

Table 41–10 lists the resource types displayed in JDeveloper and identifies the associated resource and supported actions for each type.

<table>
<thead>
<tr>
<th>Resource Type</th>
<th>Supports These Resources and Actions</th>
</tr>
</thead>
<tbody>
<tr>
<td>Task Flow</td>
<td>Defines view actions on ADF bounded task flows in a user interface project that you select.</td>
</tr>
<tr>
<td>Web Page</td>
<td>Defines view actions on regions and web pages backed by ADF page definition files in a user interface project that you select.</td>
</tr>
</tbody>
</table>
To define an entitlement grant for a securable Oracle ADF artifact, use the Entitlement Grants page of the overview editor for security policies.

**Before you begin:**
It may be helpful to have an understanding of ADF security for entity objects. For more information, see Section 41.5.12, "How to Aggregate Resource Grants as Entitlement Grants."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete this task:
- Create application roles, as described in Section 41.4, "Creating Application Roles."

**To define an entitlement grant for an Oracle ADF artifact:**

1. In the main menu, choose Application and then Secure > Entitlement Grants.
2. In the Entitlement Grants page of overview editor for security policies, click the Add Entitlements icon in the Entitlements section.
   - The overview editor displays all the resources that your application defines.
3. In the Entitlement Grants page, click the Resources tab and then click the Add Member Resource icon to add a member resource to the entitlement.
4. In the Select Resources dialog, select the resource from the Resource Type dropdown and then select the desired project in the Source Projects section.
   - The dialog displays all the projects in your application workspace.
5. In the Available Resources section, select the resource and click the Add icon.
   - The dialog displays all the resources define by your selected project.
6. In the Actions lists, select the desired action for the selected resource.
   - Figure 41–15 shows the overview editor with the View action selected for the task flow and added to MyEntitlement.

---

**Table 41–10 (Cont.) Resource Types of Securable Oracle ADF Artifacts**

<table>
<thead>
<tr>
<th>Resource Type</th>
<th>Supports These Resources and Actions</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADF Entity Object</td>
<td>Defines read, update, and delete actions on entity objects in a data model project that you select.</td>
</tr>
<tr>
<td>ADF Entity Object</td>
<td>Defines update actions on entity object attributes of a specific entity object in a data model project that you select.</td>
</tr>
</tbody>
</table>

ADF Entity Object

ADF Entity Object Attribute
7. Add other desired resources to the list.

8. In the Entitlement Grants page, click the Grants tab and then click the Add Role Grants icon to grant the entitlement to an application role.

9. In the Select Application Roles dialog, select one or more custom application roles. The dialog displays all the application roles from the jazn-data.xml file. You must not add a grant to a predefined application role (also called duty roles in the terminology of Oracle Fusion Applications). Only select custom application roles that either you created in JDeveloper or that were created by an IT security manager for this purpose.

10. Click OK.

11. You can repeat these steps to add other resources and make grants on those resources to the same entitlement for the same custom application role.

41.5.13 What Happens After You Create an Entitlement Grant

When you use the security policy editor in JDeveloper to create an entitlement grant, JDeveloper modifies the source for the application policy store in the jazn-data.xml file. The policy store section of the file contains a <resource-type> definition (that identifies the actions supported for resources of the selected type), a <resource> definition (to identify the resource instance that you selected from your application and mapped to a resource type), a <permission-set> definition (to define the resources and actions to be granted as an entitlement), and a <grant> definition with one or more entitlements (defined in the XML as a permission set) granted to the desired application roles (the grantee).

As Example 41–11 shows, entitlement-based security policies in the Oracle Fusion application are defined in the <jazn-policies> element and consist of one or more entitlements granted to a single application role.

Example 41–11  Entitlement-Based Policy Definition in the jazn-data.xml File

```xml
<?xml version="1.0" ?>
<jazn-data>
  <policy-store>
    <applications>
      <application>
        <name>MyApp</name>
```
<app-roles>
  <app-role>
    <name>AppRole</name>
    <display-name>AppRole display name</display-name>
    <description>AppRole description</description>
    <guid>F5494E490CFBB1DEBFBC11928D5F58</guid>
    <class>oracle.security.jps.service.policystore.ApplicationRole</class>
  </app-role>
</app-roles>

<role-categories>
  <role-category>
    <name>MyAppRoleCategory</name>
    <display-name>MyAppRoleCategory display name</display-name>
    <description>MyAppRoleCategory description</description>
  </role-category>
</role-categories>

<!-- resource-specific OPSS permission class definition -->

      </member-resource>
    </member-resources>
  </permission-set>
</permission-sets>

<!-- Oracle function security policies -->
<jazn-policy>
  <!-- function security policy is a grantee and permission set -->
41.6 Creating Test Users

JDeveloper provides editors to help you create both the identity and the policy stores. You create both repositories in an application-specific jazn-data.xml file. The editor for the identity store section of the file lets you enter the list of valid user IDs and their assigned passwords. The same editor lets you create application roles and assign the test users or enterprise roles as members of the application roles. Once defined, this information appears in the policy store section of the jazn-data.xml file.

41.6.1 How to Create Test Users in JDeveloper

You seed the identity store of your application with a temporary set of users to simulate the actual users’ experience in your production environment. When you run the application in Integrated WebLogic Server, you can log in as any test user and be conferred access rights to view the secure ADF resources of your application.

You can use the identity store to organize users into enterprise roles. Because you typically will configure JDeveloper’s deployment options to prevent migrating the identity store to a staging environment, enterprise roles that you create in the jazn-data.xml file are for convenience only. For more details about the use of enterprise roles, see Section 41.4.3, “What You May Need to Know About Enterprise Roles and Application Roles.”

```xml
<grant>
  <!-- application role is the recipient of the privileges -->
  <grantee>
    <principals>
      <principal>
        <class>
          oracle.security.jps.service.policystore.ApplicationRole
        </class>
        <name>AppRole</name>
        <guid>F5494E409CFB11DEBFEBC11296284F58</guid>
      </principal>
    </principals>
  </grantee>

  <!-- entitlement granted to an application role -->
  <permission-set-refs>
    <permission-set-ref>
      <name>MyEntitlement</name>
    </permission-set-ref>
  </permission-set-refs>
</grant>
```

Creating Test Users

Enabling ADF Security in a Fusion Web Application

To enable the user to view resources, you make grants against application roles rather than against the users who are the members of those roles. Therefore, after you seed the identity store with test users, you must associate each user or enterprise role group with an application role. This association confers the access rights defined by ADF security policies to users. For details about conferring access rights to users, see Section 41.6.3, "How to Associate Test Users with Application Roles."

Before you begin:
It may be helpful to have an understanding of the identity store. For more information, see Section 41.6, "Creating Test Users."
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

To create test users and groups:
1. In the main menu, choose Application and then Secure > Users.
2. In the Users page of the overview editor for security policies, select the realm for your application from the Realm dropdown list and perform the following steps.
   JDeveloper uses the realm jazn.com by default.
   a. In the Users list, click the New User icon.
   b. In the Name field, enter the user name.
      You should avoid choosing a user name already configured for Oracle WebLogic Server (for example, do not enter webcenter). For the list of user names installed by Oracle WebLogic Server, see the "Users, Groups, and Security Roles" chapter in Securing Resources Using Roles and Policies for Oracle WebLogic Server.
   c. In the Password field, enter the password for the user and click any other field to add the password to the identity store.
      The password must contain at least eight characters and at least one of the characters must be a special character (such as !, %, ^, &, $ and so on).
3. Optionally, in the overview editor, click the Enterprise Roles navigation tab, select the realm for your application from the Realm dropdown list, and perform the following steps.
   You create enterprise roles only when you want to organize users into groups that you will add to an application role. For the purpose of creating test users to run the application using Integrated WebLogic Server, you do not need to create enterprise role groups.
a. In the **Enterprise Roles** list, click the **New Role** icon.

b. In the **Name** field, enter the name of the enterprise role and click any other field to add the role to the identity store.

If you create enterprise role groups, you should avoid choosing a role name that is already configured for Oracle WebLogic Server (for example, do not enter Administrators). For a complete list of the default group names installed by Oracle WebLogic Server, see the "Users, Groups, and Security Roles" chapter in *Securing Resources Using Roles and Policies for Oracle WebLogic Server*.

### 41.6.2 What Happens When You Create Test Users

When you provision the identity store with user identities and enterprise role groups, JDeveloper updates the `jazn-data.xml` file located in the `/src/META-INF` node relative to the web application workspace.

The dialog writes the user information to the `<jazn-realm>` section of the file corresponding to the identity store. Each user identity has a user name and a user login password. Each enterprise role contains one or more member users.

**Example 41–12** shows the identity store in the `jazn-data.xml` file with two users and two enterprise roles. The user `cmagee` is a member of the **Enterprise Employee Group** enterprise role, while user `214` is a member of the **Enterprise Customer Group** enterprise role.

**Example 41–12  Users and Enterprise Roles in the Application-Level Identity Store**

```xml
<jazn-data>
  <jazn-realm default="jazn.com">
    <realm>
      <name>jazn.com</name>
      <users>
        <user>
          <name>cmagee</name>
          <display-name>Colin Magee</display-name>
          <description>Sales Rep</description>
          <credentials>{903}5AUHlE+qvDxxAhxIMoXJ/WLhMF0ynue7</credentials>
        </user>
        <user>
          <name>214</name>
          <display-name>Ojibway Retail</display-name>
          <description>Customer</description>
          <credentials>{903}rijN2KQCBSBoBQ/JNZlYl88gUJfJWk5Iqa</credentials>
        </user>
        ...
      </users>
      <roles>
        <role>
          <name>Enterprise Employee Group</name>
          <members>
            <member>
              <type>user</type>
              <name>cmagee</name>
            </member>
          </members>
        </role>
        <role>
          <name>Enterprise Customer Group</name>
        </role>
      </roles>
  </realm>
</jazn-realm>
</jazn-data>
```
41.6.3 How to Associate Test Users with Application Roles

Because the ADF Security framework enforces a role-based access control mechanism with permissions granted to application roles, you define a set of roles in the policy store that are specific to your application. For example, in the context of the work flow, there may be roles such as customer, product specialist, supervisor, and administrator.

After you create an application role, you can proceed to associate users that you created in the identity store with one or more roles. At runtime, users who are members of an application role will be conferred the access rights of their application roles. You can assign a user to more than one application role when you want to confer the right of multiple resource grants to a particular user.

For example, one authenticated user might belong to the supervisor role and an employee role, while another user might belong only to the employee role. The security policy for a bounded task flow that permits customer records to be browsed and edited may confer view permission to the supervisor role and limit view permission to the browse page for the employee role. Thus, grants to application roles support multiple levels of access. If the authenticated user is not a member of an application role with a view permission grant for the target ADF resource, the security framework will return an unauthorized user message.

Before you begin:

It may be helpful to have an understanding of the identity store. For more information, see Section 41.6, "Creating Test Users."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete these tasks:

1. Run the Configure ADF Security wizard, as described in Section 41.3, "Enabling ADF Security."
2. Create application roles, as described in Section 41.4, "Creating Application Roles."
3. Define security policies for ADF security-aware resources, as described in Section 41.5, "Defining ADF Security Policies."
4. Create test users, and, optionally, create enterprise role groups, as described in Section 41.6.1, "How to Create Test Users in JDeveloper."
Creating Test Users

To associate users with application roles:

1. In the main menu, choose Application and then Secure > Application Roles.

2. In the Application Roles page of overview editor for security policies, select the policy store for your application from the Security Policy dropdown list.

   The policy store that JDeveloper creates in the jazn-data.xml file are automatically based on the name of your application.

3. In the Roles list, select an existing application role and complete these tasks as appropriate:

   a. In the Mappings section, click the Add User or Role icon dropdown menu and choose Add User, then in the Select Users dialog select the previously created user from the list and click OK.

   b. Optionally, if you have defined enterprise roles in the identity store, in the Mappings section, click the Add User or Role icon dropdown menu and choose Add Enterprise Role, then in the Select Enterprise Roles dialog select the previously created enterprise role from the list and click OK.

41.6.4 What Happens When You Configure Application Roles

When you associate users with application roles, JDeveloper updates the jazn-data.xml file located in the /src/META-INF node relative to the web application workspace.

The dialog writes the user information to the <policy-store> section of the file. Each application role contains one or more member users or enterprise roles.

Example 41–13 shows the policy store in the jazn-data.xml file with the Application Employee Role application role, which contains two members, Enterprise Employee Group and Enterprise Manager Group.

Example 41–13 Users Associated with Application Roles in the Application-Level Policy Store

```xml
<policy-store>
  <applications>
    <application>
      <name>SummitADF</name>
      <app-roles>
        <app-role>
          <name>Application Employee Role</name>
          <class>oracle.security.jps.service.policystore.ApplicationRole</class>
          <display-name>Application Employee Role</display-name>
          <members>
            <member>
              <class>oracle.security.jps.internal.core.principals.JpsXmlEnterpriseRoleImpl</class>
              <name>Enterprise Employee Group</name>
            </member>
            <member>
              <class>oracle.security.jps.internal.core.principals.JpsXmlEnterpriseRoleImpl</class>
              <name>Enterprise Manager Group</name>
            </member>
            ...
          </members>
        </app-role>
        ...
      </app-roles>
    </application>
  </applications>
</policy-store>
```
ADF Security allows for implicit and explicit authentication:

- **Implicit Authentication**: In an implicit authentication scenario, if a user who is not yet authenticated tries to access a web page associated with ADF security-aware resources that are not granted to anonymous-role, then authentication is triggered dynamically. After the user successfully logs in, another check will be done to verify whether the authenticated user has view access granted on the requested page’s ADF security-aware resource.

- **Explicit Authentication**: In an explicit authentication scenario, your application has a public page that displays a login link, which, when clicked, triggers an authentication challenge to log in the user. The login link may optionally specify some other target page that should be displayed (assuming the authenticated user has access) after the successful authentication.

The implicit and explicit authentication scenarios are handled for you by default when you run the Configure ADF Security wizard, as described in Section 41.3.5, “What You May Need to Know About ADF Authentication.” However, when you customize the default, generated login page (or supply your own page) to use ADF Faces components, you will need to configure the container-managed deployment descriptor (web.xml file).

To explicitly handle user authentication:

1. Create a login link component and add it to the public home web page for your application.
2. Create a managed bean using API specific to Servlet 3.0 to handle the login attempts by the user.
3. Create a JSF login page using ADF Faces components.
4. Ensure that the login page’s resources are accessible.

For more information about implicit and explicit authentication, see Section 41.8.4, “What Happens at Runtime: How ADF Security Handles Authentication.”

### 41.7.1 How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication

You can create a standard login link component that can be added to any page in your application to enable users to authenticate or subsequently log off. This component keeps track of the authenticated state of the user and returns the appropriate login or logout URLs and icons. The login link component will redirect users back to a specific page once they are authenticated. Hence, using this login link component provides you with a single, consistent object.

To the unauthenticated user, the login link component will look similar to Figure 41–16.
Then when the user clicks the login link and logs in as a user with the appropriate credentials, the component will look similar to Figure 41–17.

**Before you begin:**

It may be helpful to have an understanding of ADF authentication. For more information, see Section 41.7, "Creating a Login Page."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete this task:

Copy your login and logout image files (GIF, JPG, or PNG files) to the **public_html** directory of your project.

---

**Note:** The images used should reference the appropriate skin image if your application uses skins. For more information about skins, see the "Customizing the Appearance Using Styles and Skins" chapter in *Developing Web User Interfaces with Oracle ADF Faces*.

---

**To create the login link component and add it to a page:**

1. In the Applications window, double-click the web page that will display the component.

2. In the ADF Faces page of the Components window, from the Common Components panel, drag a **Link** and drop it on the page.

3. In the Structure window, right-click **af:link** and choose **Go to Properties**.

4. In the Property window, to specify the label for the Link component, enter an Expression Language (EL) expression in the **Text** field.

   For example, you can enter an EL expression similar to this to conditionally render the link text:

   ```
   #{securityContext.authenticated ? "Click to log out": "Click to log in"}
   ```

   The **authenticated** property of the **securityContext** bean will evaluate to true and render the log out option if the current user is authenticated. Otherwise, the link is rendered with the login option.

5. In the Property window, to specify the URL for the Link component, enter an EL expression in the **Destination** field.
For example, this EL expression conditionally renders a URL to forward the user depending on whether or not they are authenticated:

```
```

When the user clicks the link, the URL parameters `end_url` and `success_url` forward the destination of the target page to the ADF authentication servlet. Note that the view activity name is passed on the URL parameters instead of the web page name. This ensures control flow rules are enforced for page navigation after login. The `authenticated` property of the `securityContext` bean will evaluate to true and forward to the welcome page if the current user is authenticated. When the user is not authenticated, there is no need to forward to the login page because the ADF authentication servlet triggers log in, which is handled by the container-managed security configuration. Note that log out is handled by the ADF authentication servlet which invalidates the session.

6. In the Property window, to specify the link component image for the Link component, enter an EL expression in the Icon field.

For example, this EL expression conditionally renders the link component image as the lock GIF if the user is not authenticated; otherwise, renders the image with the key GIF:

```
#{securityContext.authenticated ? '/images/lock.gif' : '/images/key.gif'}
```

Figure 41–18 shows how the login link component appears when added to the global menu facet of the page.

### 41.7.2 How to Create a Login Page Specifically for Explicit Authentication

The default login form that is generated for you when you run the Configure ADF Security wizard is provided as a convenience for testing your application within JDeveloper. The default form does not allow you to customize the page using ADF Faces components to match the user interface of the application. You can replace the default form with an ADF Faces-based login page that enables you to include customizable components, as shown in Figure 41–19.

However, if designing a login page with ADF Faces components is not a requirement, then a simple JSP or HTML login page can be also used. For details about generating a
simple login page when running the Configure ADF Security wizard, see Section 41.3.1, "How to Enable ADF Security."

41.7.2.1 Creating Login Code for the Backing Bean

Before you create the login page as an ADF Faces page, you need to create a managed bean to handle login attempts. In this login bean sample, authentication is handled programmatically using Servlet 3.0-specific API. The login bean handles the login action initiated from a login link with the doLogin() method. Upon successful login, this method invokes the ADF authentication servlet to redirect to a landing page. You will add this bean to the adfc-config.xml file and register it with request scope.

**Note:** This backing bean example described in this section does not authenticate with Oracle Single Sign-On (OSS). The backing bean handles authentication using login and logout methods provided by Servlet 3.0, which provides generic support for programmatic login on application servers that support Java EE 6 or later.

Before you begin:

It may be helpful to have an understanding of the login page. For more information, see Section 41.7.2, "How to Create a Login Page Specifically for Explicit Authentication."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete this task:

- Run the Configure ADF Security wizard to enable ADF Authentication and Authorization.

To create and register a backing bean for login:

1. In the Applications window, right-click the project in which you want to create the backing bean and choose New and then From Gallery.

2. In the New Gallery, expand General, select Java and then Class, and click OK.

3. In the Create Java Class dialog, enter the name for the login page backing bean class file and disable the default options Constructors from Superclass and Implement Abstract Methods, and click OK.

   For convenience, you might name the backing bean based on the name of your login page, for example, LoginName.java.

4. In the Applications window, expand Application Sources and double-click the new LoginName.java backing bean.

5. In the source editor, create two private fields by adding the following in the declaration section of the LoginName.java file:

   ```java
   private String _username;
   private String _password;
   ```

6. Generate or create public accessors for both fields.

   You can right-click in the source editor and choose Generate Accessors to add the following public accessors to the file:
public void setUsername(String _username) {
    this._username = _username;
}

public String getUsername() {
    return _username;
}

public void setPassword(String _password) {
    this._password = _password;
}

public String getPassword() {
    return _password;
}

7. Import the following classes:
   javax.faces.application.FacesMessage
   javax.faces.context.ExternalContext
   javax.faces.context.FacesContext
   javax.servlet.ServletException
   javax.servlet.http.HttpServletRequest
   javax.servlet.http.HttpSession

8. Add a doLogin() method to this Java class to handle user attempts to log in:

   public String doLogin() {
      FacesContext ctx = FacesContext.getCurrentInstance();

      if (_username == null || _password == null) {
         showError("Invalid credentials",
                     "An incorrect username or password was specified.", null);
      } else {
         ExternalContext etx = ctx.getExternalContext();
         HttpServletRequest request = (HttpServletRequest) etx.getRequestContextPath() +
         redirect(loginUrl);
         _username = null;
         _password = null;

         String loginUrl = etx.getRequestContextPath() +
         "/adfAuthentication?success_url=/faces/welcome";
         redirect(loginUrl);
      } catch (ServletException e) {
         showError("ServletException", "Login failed.
                     Please verify the username and password and try again.", null);
      }
      return null;
   }

The doLogin() method performs the following tasks:

Line 2 and Lines 6-9 get an object encapsulating the HTTP request from the
ExternalContext.
Lines 3-5 handle an error when credentials have not been provided. The showError() method is a method which you will implement to deal with miscellaneous problems with the login process.

Lines 11-13 attempt to log in the user issuing the request using the Servlet 3.0 API login() method. In this programmatic login example, which relies on the Servlet API, Oracle Single Sign-On (Oracle SSO) is not supported.

Lines 14-15 supply a URL to which to forward the user after successful login using the ADF authentication servlet to perform the redirect.

Line 16 calls a method, redirect(), which you will implement later in this section to forward the user to the URL specified in Line 14.

Lines 17-20 handle a ServletException, which can be thrown by many different problems with a login. For example, exceptions can result from incorrect credentials or attempts to log into a locked account or uses of an expired password. The showError() method is a method which you will implement to deal with miscellaneous problems with the login process.

Line 22 returns null so that ADF Controller will not attempt to follow a control flow case.

9. Create stubs for the methods redirect() and showError().

10. Add a redirect() method with its actions:

```java
private void redirect(String forwardUrl) {
    FacesContext ctx = FacesContext.getCurrentInstance();
    ExternalContext ectx = ctx.getExternalContext();
    try {
        ectx.redirect(forwardUrl);
    } catch (IOException ie) {
        showError("IOException", "An error occurred during redirecting.
                 Please consult logs for more information.", ie);
    }
}
```

The redirect() method performs the following tasks:

Line 2 gets the ADF Faces ctx, which forwards a response to a particular URI. Lines 3-5 use the ctx to redirect the current HTTP response to the URL.

Lines 6-8 handle an IOException, which is thrown when the request cannot be read or the response cannot be written to.

11. Implement a showError() method:

```java
private void showError(String errType, String message, Exception e) {
    FacesMessage msg =
            new FacesMessage(FacesMessage.SEVERITY_ERROR, errType, message);
    FacesContext.getCurrentInstance().addMessage('d2:it35', msg);
    if (e != null) {
        e.printStackTrace();
    }
}
```

This showError() method adds a summary error message to the FacesContext, and then prints the full stack trace of the exception to the console.

12. Optionally, when you want to trigger logout programmatically from a task flow method call activity, create a stub for a logoff() method and implement it as:
public String logoff() {
    FacesContext ctx = FacesContext.getCurrentInstance();
    ExternalContext ectx = ctx.getExternalContext();
    HttpServletRequest httpRequest = (HttpServletRequest) ectx.getRequest();
    try {
        httpRequest.logout(); // Servlet 3.0 logout
        HttpSession session = httpRequest.getSession(false);
        if (session != null) {
            session.invalidate();
        }
        String logoutUrl = ectx.getRequestContextPath() + "/faces" +
            ctx.getViewRoot().getViewId();
        redirect(logoutUrl);
    } catch (ServletException e) {
        showError("ServletException", "An error occurred during logout. Please consult logs for more information.", e);
    }
    return null;
}

This logoff() method uses the logout() method of Servlet 3.0 API to process a logoff action. This is as an alternative to using a logout link and the ADF authentication servlet to redirect the current HTTP response to the URL. For more information about handling logout non-programmatically, see Section 41.7.4.2, "Adding Login and Logout Links."

13. Save the Java file.

15. In the editor window, click the Overview tab.

16. In the overview editor, click the Managed Beans navigation tab.

17. In the Managed Beans page, in the Managed Beans section, click the Add icon and enter a name for the bean, enter the fully qualified class name, and select scope request.

    For example, the class name might look like oracle.summit.bean.LoginBean, as shown in Figure 41–20.

Figure 41–20 Login Bean Registered in adfc-config.xml File

18. Save all.

41.7.2.2 Creating an ADF Faces-Based Login Page Specifically for Explicit Authentication

A simple login page that utilizes ADF Faces layout components and ADF Faces user interface components includes two input fields and a button. You must bind the properties of these UI components to the login handler methods that you defined in the managed bean for the login page.
Creating a Login Page

Note that the page that you can create with this procedure does not support implicit authentication. When you choose to implement implicit authentication, you can customize the default, wizard-generated login form which supports container-managed authentication. The Java EE container expects a form that relies on the `j_security_check` mechanism to handle user-submitted `j_username`, and `j_password` input. In the explicit authentication scenario documented here, Java EE container-managed authentication is not used.

**Before you begin:**

It may be helpful to have an understanding of explicit authentication. For more information, see Section 41.7.2, "How to Create a Login Page Specifically for Explicit Authentication."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete this task:

Create the managed bean to handle the user’s login attempts, as described in Section 41.7.2.1, "Creating Login Code for the Backing Bean."

**To create the ADF Faces-based login page for explicit authentication:**

1. In the Applications window, right-click the project in which you want to create the login page and choose New and then New Gallery.
2. In the New Gallery, expand Web Tier, select JSF and then Page, and click OK.
3. In the Create JSF Page dialog, select JSP XML.
4. In the File Name field, specify a name for your login page. For example, enter `LoginPage.jspx`. Select no other options and do not select the option to expose UI components in a managed bean. You will manually bind the components to the managed bean you created for the login page.
5. Click OK.
6. Save the page.
7. In the ADF Faces page of the Components window, from the Layout panel, drag a Panel Box and drop it on the Structure window below the `af:form` node.
8. In the Property window, enter values for the Text, Horizontal, Width, and Height fields.
   For example, to create a basic login page, you can enter:
   - Text set to Login Information
   - Icon set to `/images/key_ena.png`
   - Width/Height set to 300/200 pixels
9. From the Components window, drag a Panel Form Layout and drop it below the `af:panelBox` node in the Structure window, as shown in Figure 41–21.
10. From the Common Components panel, drag an Input Text and drop it on the Panel Form Layout node for the username field and another Input Text for the password field.

11. In the Property window for the input fields, enter Username and Password in the Label fields and expand the Behavior section and select true from both fields’ Required dropdown list.

12. In the Property window, for the password field, expand the Appearance section select true from the Secret dropdown list.

13. To handle processing of the values for the two input fields, perform these steps for each field:

a. In the Structure window, select one of the input fields (for example, select the af:inputText - Username node), and then in the Property window click the Property Menu dropdown menu next to the Value field and choose Expression Builder.

b. In the Expression Builder, expand ADF Managed Beans and expand your login bean, and then select the expression value corresponding to your bean’s handler method.

   For example, if you selected the username input field in the Structure window, then you would select username from the Expression Builder dialog, as shown in Figure 41–22.

Figure 41–21 Login Page Structure with Panel Form Layout

Figure 41–22 username Selection in Expression Builder Dialog
c. Click OK.

The expression shown in the Property window binds the field to the managed bean you created for the login page. For example, for the username input field, the expression is similar to #{loginPageBean.username} as shown in Figure 41–23.

**Figure 41–23 username Value in Property Window**

```
[Image of Property Window]
```

14. From the Components window, from the Layout panel, drag a Panel Border Layout and drop it inside the footer node of the af:panelBox node, as shown in Figure 41–24.

**Figure 41–24 Login Page Structure with Panel Border Layout**

15. In the JSP/HTML visual editor, delete the panel border layout facets labeled End, Top, and Bottom. Leave only the Start facet.

16. In the Structure window, expand Panel Border Layout facets and select the start node, and then from the Components window drag and drop a Button.

17. In the Property window, enter Login in the button component’s Text field.

18. To handle processing of the login button action, perform these steps.

   a. In the Structure window, select af:button under the start node, and then in the Property window click the Property Menu dropdown menu next to the Action field and choose Expression Builder.

   b. In the Expression Builder, expand ADF Managed Beans and expand your login bean, and then select the expression value corresponding to your login method.

      For example, if you created a method in the login bean named doLogin(), then you would select doLogin in the Expression Builder dialog.

   c. Click OK.

The expression shown in the Property window binds the button to the managed bean you created for the login page. For example, for the login button, the expression is similar to #{loginPageBean.doLogin} as shown in Figure 41–25.
Figure 41–25  login Action in Property Window

19. Save the page.

41.7.2.3 Ensuring That the Login Page Is Public

Because the application is secured by ADF Security, all web pages defined within bounded task flows and any web page defined by an ADF page definition will be inaccessible by default. Since all users must be allowed to log on, the login page should remain publicly accessible, and thus you should add no databound components to the page. As long as the login page uses no databound components, then it will be accessible by default.

No further steps are required to ensure that the container will always redirect to the defined authentication point before allowing access to the page (which in this case is the authentication page).

41.7.3 How to Ensure That the Custom Login Page’s Resources Are Accessible for Explicit Authentication

When you run the ADF Security wizard and choose the ADF Authentication option (because you do not want to enable ADF authorization) and your application uses a custom login page or a custom error page, you may need to edit the default Java EE security constraint added to the web.xml file by ADF Security. As shown in Example 41–14, the default URL pattern (/*) defined in the allPages security constraint covers everything under the Java EE application root, meaning that the resource files (such as images, style sheets, or JavaScript library) used by the login page are also included.

Example 41–14  Java EE Security Constraint for ADF Authentication Only

```xml
<security-constraint>
    <web-resource-collection>
        <web-resource-name>allPages</web-resource-name>
        <url-pattern>/*</url-pattern>
    </web-resource-collection>
    <auth-constraint>
        <role-name>valid-users</role-name>
    </auth-constraint>
</security-constraint>
```

If the pages you create use resources, such as images, CSS files, or JavaScript libraries, the default allPages security constraint in the web.xml file will prevent those resources from loading at runtime. To allow your application to display those
resources, you should save the resources in a folder of their own and then edit the allPages security constraint so that the resources folder is not contained in the URL pattern.

Note that this resource issue does not apply when you run the ADF Security wizard and choose the **ADF Authentication and Authorization** option (the default). Specifically, in that case, the default generated constraint is on the ADF Authentication servlet and the constraint (/adfAuthentication) excludes any resource files.

### 41.7.4 How to Create a Public Welcome Page

Because web applications are generally secured, there is always a need for a starting point or home page for unauthenticated users. To create this public welcome page, you create an ADF Faces page to act as the entry point for the application, which contains links to other pages within the application. However, only links to public pages should be rendered to unauthenticated users and, conversely, links to secured pages should be rendered only after the user has logged in and has the appropriate privileges to view the target page.

**Best Practice:** When the user presses Ctrl-N or Ctrl-T to open a new browser window or tab and no welcome page is defined in the application’s `web.xml` file, the browser will display a 403 or 404 error. To prevent this error, you must specify a welcome page definition in the application’s `web.xml` file. You can create this definition when you run the Configure ADF Security wizard. For details about running the wizard, see Section 41.3.1, "How to Enable ADF Security."

#### 41.7.4.1 Ensuring That the Welcome Page Is Public

After you have created a regular ADF Faces page, the page will, by default, be public and accessible by unauthenticated users. If, however, you have associated the welcome page with an ADF resource, for example, by dropping databound ADF Faces components into the welcome page using the Data Controls panel, then ADF Security will secure the page by default. You can make any ADF resource publicly accessible using the overview editor for security policies to grant a view privilege on the resource to the provided `anonymous-role`. For details about the `anonymous-role` see, Section 41.5.2, "What Happens When You Make an ADF Resource Public."

#### 41.7.4.2 Adding Login and Logout Links

You can add login and logout links to your public welcome page so that users can explicitly log in and out while they are in the application. While Java EE container-managed security supports the concept of authentication when accessing a secured resource, there is no standard way to log out and stay within a secured application. However, it is a common practice in web applications to allow the user to stay on the same page if that page is public or to return the user to the welcome page if that page is secured. While adding the login and logout links to each page would let the user end their login session anywhere within the application (and return to the welcome page), having these links on the welcome page enables users to explicitly authenticate on entering the application.

For example, you can create an ADF Faces panel group with three components, including an output text area, an image, and a link. To render the appropriate login or logout link, you can use an EL expression that evaluates the user’s authentication status. Specifically, you can use `securityContext.authenticated` to access the ADF security context, as shown in Example 41-15. The expression evaluates to true or false and, in this example, the result determines which login/logout image and
Creating a Login Page

Enabling ADF Security in a Fusion Web Application

41-65

link to display. As Example 41-15 shows, the success_url and end_url parameters for the ADF authentication servlet are passed as the view activity welcome associated with the target page welcome.jsp. Passing the view activity name instead of the web page name for the URL parameters ensures the Fusion web application uses task flow control flow rules to handle page navigation.

Example 41–15  ADF Faces Components and EL Expressions to Render Login/Logout Link

```html
<af:panelGroupLayout inlineStyle="width:100%; height:15px;" id="ptpgl3">
  <af:spacer width="7" height="10" id="pts2"/>
  <af:outputText value="Welcome #{securityContext.userName}!"
    inlineStyle="font-weight:bold; width:100px;" id="ptot2"
    rendered="#{securityContext.authenticated}"/>
  <af:image source="#{securityContext.authenticated ? '/images/lock.gif' : '/images/key.gif'}" id="pti2" inlineStyle="width:16px; height:16px;" shortDesc="switchable icon"/>
  <af:link text="#{securityContext.authenticated ? &quot;Logout&quot; : &quot;Login&quot;}"
    inlineStyle="color:Blue; font-size:14px; font-weight:bold;"/>
  <f:facet name="separator">
    <af:spacer width="5" height="10" id="pts1"/>
  </f:facet>
</af:panelGroupLayout>
```

As an alternative to rendering the link directly within a page, you can create a login link component with the login and logout links that you can add to a page template, as described in Section 41.7.1, "How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication."

41.7.4.3 Hiding Links to Secured Pages

Since an anonymous user should not have access to any secured pages, any navigation component on the welcome page that points to a secured page should be hidden from view based on the following two criteria:

- Is the user authenticated with a known user identity?
- Does the specified user identity have permission to view the target?

If either of these criteria has not been met, the rendered attribute of any navigation component on a public page that points to a secured resource must have its rendered attribute set to false, thus hiding it from the anonymous user. To enforce these rules within your welcome page, see Section 41.11.1, "Using Expression Language (EL) with ADF Security."

41.7.5 How to Redirect a User After Authentication

When you have chosen to implement implicit authentication, after the user accesses a secured web page and logs in, the ADF authentication servlet will redirect back to the original page that initiated the login request. With ADF Security authentication enabled, the ADF authentication servlet automatically passes the original page as the ADF authentication success_url parameter on the URL. Typically, this is the desired behavior.

Additionally, when you have chosen to implement implicit authentication, you can protect the Fusion web application from malicious redirects by specifying the success_url parameter as an <init-param> within the web.xml file. Thus, for implicit authentication, when the user accesses the secured web page and gets redirected to log in, the ADF Security framework automatically passes the original
Creating a Login Page

page as the success_url parameter on the URL, which supersedes any web.xml setting. Therefore, in practice the only scenario in which an <init-param> setting in web.xml takes effect is when the user explicitly types the adfAuthentication URL into the browser.

However, when you choose to implement explicit authentication and display an explicit login link in your page, the ADF Security framework is not able to determine the originating page. In this case, your login link ensures the ADF Authentication servlet redirects to the desired page after authentication by passing the view activity name of the web page as the servlet success_url parameter, as shown in Example 41–16.

Example 41–16 Explicit Login Link with success_url Defined by Task Flow View Activity

<af:link text="Login" destination="/adfAuthentication?success_url=/faces/viewactivityname"/>

Best Practice: For explicit authentication, to ensure that the Fusion web application handles the ADF authentication redirect as an ADF Controller navigation event, specify the redirect target by its view activity name. If you were to specify the web page name instead, after the user logs in, the ADF Controller handler may not find the control flow rule associated with the target page. Specifically, without specifying a view activity as the redirect target, command components, such as the af:button component, will always return to the original page after login. Passing the view activity name as the redirect target of the ADF authentication servlet success_url and end_url parameters ensures the application handles navigation using control flow rules in all cases.

In the case of explicit authentication, following the best practice of defining the success_url with a task flow view activity name protects the Fusion web application from malicious redirects by ensuring the ADF authentication servlet ignores any adfAuthentication URL that a user may attempt to type into the browser. Alternatively, Fusion web applications that omit the success_url from the explicit login link may be protected by specifying the success_url parameter as an <init-param> within the web.xml file.

In cases where the user is authenticated but not authorized to view a web page, you can redirect the ADF authentication servlet to an error page in your application. Error handling in Fusion web applications is under the control of the ADF Controller exception handler unless you have created an application that does not use a task flow in its design. For example, in an unbounded task flow, where you have defined an unbounded task flow with a top-level welcome page and a browse page (secured through its ADF page definition), you would see an error page from the application, named authorizationErrorPage.jspx, specified in the adfc-config.xml file, as shown in Example 41–17.

Example 41–17 Error Page Redirect for Applications That Use Task Flows

<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <exception-handler>authorizationErrorPage</exception-handler>
  <view id="welcomePage">
    <page>/welcomePage.jspx</page>
  </view>
  <view id="browse">
    <page>/browse.jspx</page>
  </view>
</adfc-config>
<view id="authorizationErrorPage">
  <page>/authorizationErrorPage.jspx</page>
</view>

<control-flow-rule>
  <from-activity-id>welcomePage</from-activity-id>
  <control-flow-case>
    <from-outcome>goToSecuredPage</from-outcome>
    <to-activity-id>browse</to-activity-id>
  </control-flow-case>
</control-flow-rule>
</adfc-config>

For details about how to specify an error page as a view activity for the ADF Controller exception handler, see Section 24.5, "Handling Exceptions in Task Flows."

In cases where the user is not authenticated and an authorization failure occurs, the framework redirects to the ADF authentication servlet, which in turn triggers a Java EE constraint that prompts for login. In this case, container-managed security relies on the login page and error page that you specify in the <login-config> element of the web.xml file.

If you create a Fusion web application without utilizing task flows, then you can specify an <init-param> setting in web.xml for the ADF binding filter, as shown in Example 41–18. In this case, when no task flow is present in the application, page authorization checking is handled by the ADF binding filter, and the unauthorizedErrorPage parameter will be passed to the ADF binding request handler.

---

**Example 41–18  Error Page Redirect for Applications That Don’t Use Task Flows**

```xml
<filter>
  <filter-name>adfBindings</filter-name>
  <filter-class>oracle.adf.model.servlet.ADFBindingFilter</filter-class>
  <init-param>
    <param-name>unauthorizedErrorPage</param-name>
    <param-value>faces/authorizationErrorPage.jspx</param-value>
  </init-param>
</filter>
```

---

**41.7.6 How to Trigger a Custom Login Page Specifically for Implicit Authentication**

When you have chosen to implement implicit authentication to allow users to access protected resources (which may be by direct URL access or by navigating to an ADF Security protected resource), the ADF Security authentication servlet initiates the Java EE container to display the login form configured in the web.xml file. For implicit authentication, when you have customized the default, wizard-generated login form to use ADF Faces components, you must modify the URL pattern for the servlet mapping to reference the ADF Faces servlet.

You can accomplish this in the Authentication Type page of the Configure ADF Security wizard when you configure ADF Security, or in the web.xml file directly. If
you have already run the Configure ADF Security wizard, you can use the following procedure to confirm that the web.xml file has been updated as described.

When you have choose to implement explicit authentication and have created a public page to allow users to login to access protected resources, the login form you create will not be triggered by ADF Security. In the explicit authentication scenario, you do need to configure the web.xml file.

---

**Caution:** Configuring the web.xml file when your application implements explicit authentication programatically and you have created a login page as described in Section 41.7.2.2, "Creating an ADF Faces-Based Login Page Specifically for Explicit Authentication" may produce unpredictable results and login may fail. Only modify the web.xml file when you are implementing implicit authentication and you have created a form that relies on the j_security_check action, as does the default, wizard-generated login form.

---

**Before you begin:**

It may be helpful to have an understanding of the login page. For more information, see Section 41.7.2, "How to Create a Login Page Specifically for Explicit Authentication."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

**To reference an ADF Faces login page for implicit authentication:**

1. In the Applications window, expand WEB-INF and double-click web.xml.
2. In the overview editor for the web.xml file, click the Security navigation tab.
3. In the Security page, expand the Login Authentication section, and set the login page to include a reference to the ADF Faces servlet such that the login page can be part of the ADF Faces lifecycle /faces/ADFlogin.jspx page.

When you add a page using the file browser, the path entered in the web.xml file will not specify /faces. Modify the entry so that the path references the servlet mapping path for the ADF Faces servlet. For example, if the URL pattern specified by the mapping is /faces/*, then your path should look like /faces/yourpage.jspx, as shown in Figure 41–26.

---

**Figure 41–26 Adding a Reference to the Faces Servlet in the Login Configuration**

---

**41.7.7 What You May Need to Know About About Redirecting to a Different Host Server**

During logout it may be necessary to redirect the user to an arbitrary web page or host server that differs from the originating server of the Fusion web application. In this scenario, the application should be protected from a malicious redirect by ensuring the destination page URL is not placed by the application on the Request. To accomplish this, your application can use the ADF class oracle.adf.share.security.authentication.AuthenticationServiceUtil which handles
Creating a Login Page

Enabling ADF Security in a Fusion Web Application

ADF-specific login and logout methods by placing the target destination on the Session map.

Example 41–19 illustrates how to use the logout() method of the AuthenticationService interface. This method will internally put the passed in URL on the Session map and will ignore the end_url parameter that might explicitly be set on the URL by a user. Similarly, the login() method places the login URL destination on the Session map. When you need logout to redirect to a web page on a different server, your method implementation may pass the URL of the desired web page and still be protected from a malicious redirect.

Example 41–19  Security Bean Methods That Get URL from Session Object

```java
import javax.faces.context.ExternalContext;
import javax.faces.context.FacesContext;

import javax.servlet.http.HttpServletRequest;
import javax.servlet.http.HttpServletResponse;

import oracle.adf.share.security.AuthenticationService;
import oracle.adf.share.security.authentication.AuthenticationServiceUtil;

public class SecurityBean {
    public SecurityBean() {
        super();
    }

    public boolean isAuthenticated() {
        ExternalContext ectx = 
            FacesContext.getCurrentInstance().getExternalContext();
        return ectx.getUserPrincipal() != null;
    }

    public void logon() {
        if (!isAuthenticated()) {
            FacesContext ctx = FacesContext.getCurrentInstance();
            AuthenticationServiceUtil.getAuthenticationService().login("/faces" +
                ctx.getViewRoot().getViewId(), null, null);
        }
    }

    public void logoff() {
        if (isAuthenticated()) {
            AuthenticationServiceUtil.getAuthenticationService().
                logout("/faces/index", null);
        }
    }
}
```

An alternative to the programmatic approach handles placing the destination URL on the Session map by invoking the ADF authentication servlet in an explicit link with null value success_url and end_url parameters. In this case, the ADF authentication servlet will try to obtain the redirect values from the web.xml file and will ignore any values that a user might attempt to enter on the URL. This approach requires configuring the adfAuthentication servlet definition in the web.xml by specifying an <init-param> setting for the success_url and end_url parameters.
parameters. In effect, this is a declarative approach that results in a whitelist with a single destination for login and logout redirects.

41.7.8 What You May Need to Know About ADF Servlet Logout and Browser Caching

When basic type authentication is in effect as specified in the application’s `web.xml` file, the browser caches authentication credentials. This is a known issue with basic authentication that re-authenticates users after the logout redirect is performed by the ADF authentication servlet. In this scenario, in order to complete the logout session and prevent users from accessing resources, it is necessary to close the browser and restart a new browser session.

To ensure the ADF application completes logout and prevents a user from being able to access resources after logout, use form-based authentication instead of basic authentication. You can select form-based authentication when you run the Configure ADF Security wizard, as described in Section 41.3.1, "How to Enable ADF Security.”

41.7.9 What You May Need to Know About Displaying Error Pages in Internet Explorer

When you enable ADF Security to display a custom error page, any HTTP errors that the application generates in response to a request to view a page, should result in the error page being displayed. However, in certain versions of Internet Explorer, the browser will display either the custom error page or an error message built into Internet Explorer. If Internet Explorer displays only an error message you can disable the option to display error message numbers in the Advanced settings of the Internet Options dialog. In Internet Explorer 10, this option is enabled by default. You should disable `Show friendly HTTP error messages` when you want to display a custom error page that you enabled with the Configure ADF Security wizard.

To ensure custom error pages display in Internet Explorer 10:

1. In Internet Explorer toolbar, click the `Tools` button.
2. In the Internet Options dialog, click the `Advanced` tab.
3. In the Advanced tab, scroll and locate `Show friendly HTTP error messages`.
4. Click the option to disable it and click `OK`.

41.8 Testing Security in JDeveloper

Integrated WebLogic Server enables you to run the application directly within JDeveloper and determine whether or not to migrate security objects, including the application policies, users, and credentials that your application defines. By default, all security objects are migrated to Integrated WebLogic Server each time you run the application.

41.8.1 How to Configure, Deploy, and Run a Secure Application in JDeveloper

JDeveloper is configured by default to deploy the security objects from your application repositories to Integrated WebLogic Server each time you run the application. You can change this behavior by selecting security deployment options in the Application Properties dialog to:

- Decide whether to overwrite the domain-level policies with those from the application `jazn-data.xml` file
- Decide whether to overwrite the system credentials from the application’s `cwallet.sso` file
The `cwallet.sso` file (located in JDeveloper in the Application Resources panel of the Applications window under the Descriptors-META-INF node) stores credentials as securely kept objects that are presented to the authentication provider to be matched against identities. The file is encrypted and cannot be browsed or edited within JDeveloper. At design-time, different components make use of `cwallet.sso` file and are responsible for creating the necessary credentials in it.

- Decide whether to migrate the identity store portion of the `jazn-data.xml` file to the domain-level identity store

If you make no changes to the deployment settings, each time you run the application, JDeveloper will overwrite the domain-level security policies and system credentials. Additionally, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. However, if you prefer to run the application without updating the existing security objects in Integrated WebLogic Server, you have this option.

Before you begin:
It may be helpful to have an understanding of using Integrated WebLogic Server. For more information, see Section 41.8, "Testing Security in JDeveloper."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

To configure security deployment and run the application in JDeveloper:
1. In the main menu, choose Application and then Secure > Configure Security Deployment.

2. In the Application Properties dialog, in the Deployment page, in the Security Deployment Options section, select the security objects that you want to deploy to Integrated WebLogic Server.

   By default, each time you run the application, JDeveloper will overwrite the application policies and system credentials at the domain level with those from the application. If you prefer not to overwrite either of these repositories, deselect Application Policies or Credentials. When deselected, JDeveloper will merge only new policies or credentials into the domain-level stores.

   By default, each time you run the application, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. You can disable migration of the application identity store by deselecting Users and Groups.

3. Click OK.

4. In the Applications window, right-click the user interface project that contains the secured web pages and choose Run.

   When you choose Run on the user interface project, JDeveloper will run the application using the default run target you configured for the project. For example, you can configure a task flow activity as the run target to start your application. To configure the default run target, see Section 20.5, "Testing Task Flows."

   The Configure Default Domain dialog appears the first time you run the application and start a new domain in Integrated WebLogic Server. Use the dialog
to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

### 41.8.2 What Happens When You Configure Security Deployment Options

When you run the application using Integrated WebLogic Server, JDeveloper migrates the security policies and credentials to the domain level based on security deployment configuration settings specified in the Application Properties dialog. During the deployment process, JDeveloper updates the `weblogic-application.xml` file that it adds to the deployment archive file with the Application Properties settings, as shown in Example 41–20. Note that these settings are not added to the `weblogic-application.xml` file in the application source directory and thus are not visible.

**Example 41–20 Default Security Deployment Settings in the Archive weblogic-application.xml File**

```xml
<application-param>
  <param-name>jps.credstore.migration</param-name>
  <param-value>OVERWRITE</param-value>
</application-param>
<application-param>
  <param-name>jps.policystore.migration</param-name>
  <param-value>OVERWRITE</param-value>
</application-param>
```

The `OVERWRITE` value allows you to modify the security policies and credentials in your application and redeploy either to Oracle WebLogic Server running in development mode or to Integrated WebLogic Server (set up to run in development mode by default).

**Note:** When you eventually deploy to a production environment, the migration settings in the `weblogic-application.xml` file are ignored; it would be considered a security vulnerability to allow existing policies and credentials to be overwritten. For information about deploying to a production environment, see Section 41.9, “Preparing the Secure Application for Deployment.”

JDeveloper also updates the `weblogic-application.xml` file with OPSS lifecycle listeners, as shown in Example 41–21. To initiate the migration process before the application runs, the lifecycle listeners observe the migration settings for policies and credentials and overwrite the security objects at the domain level.

**Example 41–21 Security Migration Listeners in the Archive weblogic-application.xml File**

```xml
<listener>
  <listener-class>
    oracle.security.jps.wls.listeners.JpsApplicationLifecycleListener
  </listener-class>
</listener>
<listener>
  <listener-class>
    oracle.security.jps.wls.listeners.JpsAppVersionLifecycleListener
  </listener-class>
</listener>
```
During the migration process, JDeveloper maps the Oracle Platform Security Services (OPSS) application role member classes to the Integrated WebLogic Server member classes and migrates the users to WebLogic Server identity store users and migrates the roles to Integrated WebLogic Server identity store groups. In Oracle WebLogic Server, users is an implicit group equivalent to OPSS authenticated-role.

Identity store migration is not controlled by the application lifecycle listener settings in the weblogic-application.xml file. Instead, an Oracle WebLogic Mbean handles migrating the identities when running in Integrated WebLogic Server or when deploying from JDeveloper. If the user already exists, the Mbean will not migrate the entire user definition. Only the user password will be updated.

41.8.3 How to Use the Built-In test-all Application Role

When you run the Configure ADF Security wizard, you can enable the option to add the test-all application role to the policy store in the jazn-data.xml file. When you enable this option, you also specify the scope of grants to the application role for your application:

- Select **Grant to Existing Objects Only** when you want JDeveloper to grant view rights to the test-all application role and you want this policy to apply to all the ADF task flows and web pages that appear in your user interface project at the time you run the wizard.

- Select **Grant to All Objects** when you want JDeveloper to grant view rights to the test-all application role and you want this policy to apply to all existing and future ADF task flows and web pages that developers will create in the user interface project. Note that the wizard displays the option **Grant to New Objects** after you run the wizard the first time with the **Grant to All Objects** option selected.

After you run the wizard, the test-all role appears in the jazn-data.xml file and is visible in the overview editor for security policies. You will not need to populate the test-all role with test users since the wizard assigns the built-in application role anonymous-role to the test-all role. In this case, all users will automatically have the anonymous-role principal and will be permitted to access the application.

**Note:** Before you deploy the application, you must remove all occurrences of the test-all role from the policy store, as described in Section 41.9.1, "How to Remove the test-all Role from the Application Policy Store." This will prevent unauthorized users from accessing the web pages of your application.

You can rerun the wizard and disable automatic grants at any time. Once disabled, new ADF task flows and web pages that you create will not utilize the test-all role and will therefore require that you define explicit grants, as described in Section 41.5, "Defining ADF Security Policies."

41.8.4 What Happens at Runtime: How ADF Security Handles Authentication

When you test the application in JDeveloper using Integrated WebLogic Server, the identity store is migrated to the embedded LDAP server, with information stored in Oracle Internet Directory.

Figure 41–27 illustrates the authentication process when users attempt to access an ADF bounded task flow or any web page containing ADF bindings (such as mypage.jspx) without first logging in. Authentication is initiated implicitly because
the user does not begin login by clicking a login link on a public page. In the case of the secured page, no grants have been made to the anonymous user.

**Figure 41–27  ADF Security Implicit Authentication**

In *Figure 41–27*, the implicit authentication process assumes that the resource does not have a grant to `anonymous-role`, that the user is not already authenticated, and that the authentication method is Form-based authentication. In this case, the process is as follows:

1. When the bounded task flow or web page (with ADF bindings) is requested, the ADF bindings servlet filter redirects the request to the ADF authentication servlet (in the figure, Step 1), storing the logical operation that triggered the login.

2. The ADF authentication servlet has a Java EE security constraint set on it, which results in the Java EE container invoking the configured login mechanism (in the figure, Step 2). Based on the container's login configuration, the user is prompted to authenticate:
   a. The appropriate login form is displayed for form-based authentication (in the figure, Step 2a).
   b. The user enters their credentials in the displayed login form (in the figure, Step 2b).
   c. The user posts the form back to the container's `j_security_check()` method (in the figure, Step 2c).
d. The Java EE container authenticates the user, using the configured pluggable authentication module (in the figure, Step 2d).

3. Upon successful authentication, the container redirects the user back to the servlet that initiated the authentication challenge, in this case, the ADF authentication servlet (in the figure, Step 3).

4. On returning to the ADF authentication servlet, the servlet subsequently redirects to the originally requested resource (in the figure, Step 4).

Whether or not the resource is displayed will depend on the user’s access rights and on whether authorization for ADF Security is enforced, as explained in Section 41.8.5, "What Happens at Runtime: How ADF Security Handles Authorization."

Figure 41–28 illustrates the explicit authentication process when the user becomes authenticated starting with the login link on a public page.

**Figure 41–28    ADF Security Explicit Authentication**

In an explicit authentication scenario, an unauthenticated user (with only the anonymous user principal and anonymous-role principal) clicks the Login link on a public page (in the figure, Step 1). The login link is a direct request to the ADF authentication servlet, which is secured through a Java EE security constraint in the web.xml file.

In this scenario, the current page is passed as a parameter to the ADF authentication servlet. As with the implicit case, the security constraint redirects the user to the login page (in the figure, Step 2). After the container authenticates the user, as described in Step a through Step d in the implicit authentication case, the request is returned to the ADF authentication servlet (in the figure, Step 3), which subsequently returns the user to the public page, but now with new user and role principals in place.
41.8.5 What Happens at Runtime: How ADF Security Handles Authorization

When ADF authorization is enabled, the ADF bounded task flows and web pages outside of a task flow that have an ADF page definition will be secure by default. When a user attempts to access these web pages, ADF Security checks to determine whether the user has been granted access in the policy store. If the user is not yet authenticated, and the page is not granted to the anonymous-role, then the application displays the login page or form. If the user has been authenticated, but does not have permission, a security error is displayed. If you do not configure the policy store with appropriate grants, the pages will remain protected and therefore stay unavailable to the authenticated user.

Figure 41–29 illustrates the authorization process.

The user is a member of the application role staff defined in the policy store. Because the user has not yet logged in, the security context does not have a subject (a container object that represents the user). Instead, Oracle Platform Security Services provides ADF Security with a subject with the anonymous user principal (a unique definition of the user) and the anonymous-role principal.

With the anonymous-role principal, typically the user would be able to access only pages not defined by ADF resources, such as the public.jsp page, whereas all pages that are defined either by an ADF task flow or outside of a task flow using an ADF page definition file are secure by default and unavailable to the user. An exception to this security policy would be if you were to grant anonymous-role access to ADF resources in the policy store. In this case, the user would not be allowed immediate access to the page defined by an ADF resource.

When the user tries to access a web page defined by an ADF resource, such as mypage.jsp (which is specified by an ADF page definition, for example), the ADF Security enforcement logic intercepts the request and because all ADF resources are secured by default, the user is automatically challenged to authenticate (assuming that the anonymous-role is not granted access to the ADF resource).

After successful authentication, the user will have a specific subject. The security enforcement logic now checks the policy store to determine which role is allowed to
view `mypage.jspx` and whether the user is a member of that role. In this example for `mypage.jspx`, the view privilege has been granted to the staff role and because the user is a member of this role, they are allowed to navigate to `mypage.jspx`.

Similarly, when the user tries to access `secpage.jsp`, another page defined by ADF resources, for which the user does not have the necessary view privilege, access is denied.

Users and roles are those already defined in the identity store of the resource provider. Application roles are defined in the policy store of the `jazn-data.xml` file.

### 41.9 Preparing the Secure Application for Deployment

After testing in JDeveloper using Integrated WebLogic Server, you will eventually want to deploy the application to a standalone server. Initially, the server you target will be your staging environment where you can continue development testing using that server’s identity store before deploying to the production environment. Thus, you will typically not migrate the test users you created to run with Integrated WebLogic Server. The steps you perform to migrate credentials (in the `cwallet.sso` file) and security policies (in the `jazn-data.xml` file) to standalone Oracle WebLogic Server will depend on the configured mode of the target server and whether you deploy using JDeveloper or a tool outside of JDeveloper.

**Note:** For details about deploying from JDeveloper to a development environment, see Section 48, "Deploying Fusion Web Applications."

When the target server is configured for *development mode*, you can deploy directly from JDeveloper. In this case, JDeveloper automatically handles the migration of the policy store, system credentials, and identity store (users and groups) as part of the deployment process. Application security deployment properties are configured by default to allow the deployment process to overwrite the domain-level policy store and the system credentials. Additionally, the identity store deployment property is configured by default to migrate the identity store consisting of your test users. You can change this default deployment behavior in the Application Properties dialog, as described in Section 41.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."

**Note:** Note that migration of system credentials to Oracle WebLogic Server running in development mode will be performed only if the target server is configured to permit credential overwrite. For details about configuring Oracle WebLogic Server to support overwriting of system credentials, see the "Configuring the OPSS Security Store" chapter in *Securing Applications with Oracle Platform Security Services*.

When the target server is configured for *production mode*, you typically handle the migration task outside of JDeveloper using tools like Oracle Enterprise Manager. For details about using tools outside of JDeveloper to migrate the policy store to the domain-level in a production environment, see the "Configuring the OPSS Security Store" chapter in *Securing Applications with Oracle Platform Security Services*. Note that Oracle WebLogic Server running in production mode does not support the overwriting of system credentials under any circumstances.

---

Enabling ADF Security in a Fusion Web Application 41-77
Before you deploy the application, you will want to remove the test-all application role if you enabled the automatic grants feature in the Configure ADF Security wizard. Because the test-all role makes all ADF resources public, its presence increases the risk that your application may leave some resources unprotected. You must therefore remove the role before you migrate application-level policy store.

Additionally, when you prepare to deploy the application to Oracle WebLogic Server, you will want to remove the test identities that you created in the jazn-data.xml file. This will ensure that users you created to test security policies are not migrated to the domain-level identity store.

Best Practice: If you deploy your application to the standalone environment, you must not migrate users and enterprise roles in your local identity store that are already configured for Oracle WebLogic Server. For example, if you were to deploy the identity store with the user weblogic and enterprise role Administrators, you would overwrite the default administration configuration on the target server. To ensure you avoid all possible conflicts, you can disable migration of the identity store, as described in Section 41.9.2, "How to Remove Test Users from the Application Identity Store."

41.9.1 How to Remove the test-all Role from the Application Policy Store

The overview editor for security policies provides the facility to display all resources with view grants made to ADF Security’s built-in test-all role. You can use this feature in the overview editor to delete the test-all role grant and replace it with a grant to the roles that your application defines.

Alternatively, you could delete the test-all role using the overview editor for the jazn-data.xml file, by selecting the test-all role in the Application Roles page of the editor and clicking the Delete Application Role button. However, when you remove the test-all role this way, you will still need to create a grant to replace the ones that you delete. Because the overview editor lets you combine both of these tasks, the following procedure describes its usage.

Before you begin:

It may be helpful to have an understanding of the Oracle WebLogic Server. For more information, see Section 41.9, "Preparing the Secure Application for Deployment."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

To remove the test-all application role and substitute custom application roles:
1. In the main menu, choose Application and then Secure > Resource Grants.
2. In the Resource Grants page of the overview editor for security policies, select Task Flow from the Resource Type dropdown list and then select the Show task flows with test-all grants only checkbox to view the list of task flows with grants to this built-in role.

If no grant exists for the test-all role, then the Resources list in the overview editor will appear empty. The test-all role is defined only when enabled in the Configure ADF Security wizard. If it is enabled, you will see those task flows with test-all grants listed, as shown in Figure 41-30.
Preparing the Secure Application for Deployment

41.9.2 How to Remove Test Users from the Application Identity Store

The standalone Oracle WebLogic Server that you will deploy to will have its own identity stored already configured. To ensure that you do not migrate test users and enterprise role groups you created in JDeveloper to the domain level, you should remove the test user realm from the jazn-data.xml file.

Alternatively, if you are deploying from JDeveloper, you can disable the migration of users and groups by deselecting the Users and Groups option in the Application Properties dialog, as described in Section 41.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."

Before you begin:

It may be helpful to have an understanding of the Oracle WebLogic Server. For more information, see Section 41.9, "Preparing the Secure Application for Deployment."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

To remove test users and enterprise role groups from the identity store:

1. In the main menu, choose Application menu and then Secure > Users.
2. In the editor window for the jazn-data.xml file, click the Source tab.
3. In the source for the jazn-data.xml file, click the - icon next to the `<jazn-realm>` element so the entire element appears collapsed as shown in Figure 41–31.

Figure 41–31 Selecting the `<jazn-realm>` Element in the XML Editor

4. With the element selected, press Delete and save the file.

41.9.3 How to Secure Resource Files Using a URL Constraint

Resource files, including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the application. ADF Security does not secure these files. Although securing such files is not a requirement for securing the web pages of the application, in some cases it may be desirable to protect resource files to fully harden your application. Please note that JavaScript files are downloaded to the browser and, as such, can be read at that time.

To serve up resource files, the ADF Faces framework relies on org.apache.myfaces.trinidad.webapp.ResourceServlet, which delegates to a resource loader. The Fusion web application’s web.xml file contains a servlet mapping that maps the resource servlet to URL patterns. By default, JDeveloper uses the patterns /adf/* for MyFaces Trinidad Core, and /afr/* for ADF Faces.

Because ADF Security does not protect the resource servlet, you can protect the Java EE access paths for the resource servlet with a security constraint. To implement your own security for the resource files in the web.xml file, define a security constraint for the /adflib/*, /adf/* and /afr/* paths and assign a specific security role to them. This security constraint will require all users to be authenticated before they can access the first page of the Fusion web application.

Example 41–22 shows the security role resource_role and the constraint with the URL patterns mapped to this role. After you define the security role, the administrator for the target server must map this role to an Oracle WebLogic Server enterprise role (user group) or create an enterprise role with the same name (in which case no mapping is required).

Example 41–22 URL Constraint in web.xml File for Resource Files

```
<security-role>
    <description>Java EE role to map to an enterprise role. All users who will be allowed to run Fusion web app must be members of that role.
```
41.10 Disabling ADF Security

JDeveloper allows you to disable ADF Security when you want to temporarily run the application without enforcing authorization checks against the application policy store. This will allow you to run the application and access all resources without the protection provided by existing security policies.

41.10.1 How to Disable ADF Security

To disable ADF Security at the level of your application, run the wizard and choose one of these options:

- **ADF Authentication** disables ADF authorization but leaves the ADF authentication servlet enabled. For example, you may want to run your application in JDeveloper with authorization checking against security policies temporarily disabled. This option will require the user to log in the first time a page in the application is accessed by mapping the Java EE application root "/" to the allPages Java EE security constraint that will trigger user authentication. ADF resources will not be security-aware because authorization checking is not enforced. Thus, once the user is logged in, all web pages containing ADF resources will be available to the user.

- **Remove ADF Security Configuration** disables the ADF authentication servlet and disables authorization checking on ADF resources. In this case, you can run the application with no user authentication and no security for ADF resources in place.

You may select either option with the intention of reenabling ADF Security at any time. The wizard specifically does not alter the application policy store that contains the security policies that application developers defined for ADF resources. This means that you can return to the wizard at any time, select the ADF Authentication and Authorization option, and reenable ADF Security against your application’s existing policy store and identity store.

**Before you begin:**

It may be helpful to have an understanding of disabling ADF Security. For more information, see Section 41.10, "Disabling ADF Security."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, “Additional Functionality for ADF Security.”
To disable ADF authorization checking:
1. In the main menu, choose Application and then Secure > Configure ADF Security.
2. In the ADF Security page, select either the ADF Authentication option or the Disable ADF Security Configuration option. Click Next.

   After you run the wizard with either of these options, the ADF resources of your user interface projects will no longer be security-aware.
3. Click Finish.

41.10.2 What Happens When You Disable ADF Security

If you run the Configure ADF Security wizard with the Remove ADF Security Configuration option selected, it removes the ADF-specific metadata in the web.xml file and adf-config.xml file, as described in Table 41–2.

Similarly, running the wizard with the ADF Authentication option selected to disable only authorization checking performs the following updates:

- Leaves the ADF-specific metadata in the web.xml file unchanged and adds the allPages security constraint.
  
  With the allPages security constraint present, users will be expected to authenticate when they first access the application.

- Sets the authorizationEnforce parameter in the <JaasSecurityContext> element of the adf-config.xml file to false, as shown in Example 41–23.

**Example 41–23 AuthorizationEnforce Flag Disabled in the adf-config.xml File**

```
<JaasSecurityContext
    initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
    jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
    authorizationEnforce="false"
    authenticationRequire="true"/>
```

The adf-config.xml file is located in the /.adf/META-INF folder of your workspace. In JDeveloper, you can locate the file in the Application Resources panel of the Applications window by expanding the Descriptors-ADF META-INF node. Note that if you view the adf-config.xml file in an editor outside of JDeveloper, you must save the workspace to see the wizard-applied changes in the file.

41.11 Advanced Topics and Best Practices

After you have completed the process of enabling ADF Security, you may want to customize your application to work with ADF Security in the user interface. For example, you can use Expression Language (EL) to render UI components in the web page based on evaluation of custom permissions that you define just for a group of UI components. Additionally, you can define methods within a managed bean to expose information, such as the user name and role membership, in your application.

41.11.1 Using Expression Language (EL) with ADF Security

You can use Expression Language (EL) to evaluate the policy directly in the UI, while the use of Java enables you to evaluate the policy from within a managed bean. ADF Security implements several convenience methods for use in EL expressions to access ADF resources in the security context. For example, you can use the EL expression
convenience methods to determine whether the user is allowed to access a particular task flow. Good security practice dictates that your application should hide resources and capabilities for which the user does not have access. And for this reason, if the user is not allowed access to a particular task flow, you would evaluate the user’s permission grant to determine whether or not to render the navigation components that initiate the task flow.

41.11.1.1 How to Evaluate Policies Using EL

The use of EL within a UI component allows for the component’s attribute values to be defined dynamically, resulting in modification of the UI component at runtime. In the case of securing resources, the UI component attribute of interest is the rendered attribute, which allows you to show and hide components based on available permissions. By default, the rendered attribute is set to true. By dynamically changing this value based on the permission, you can set the UI component to be shown or hidden. For example, if the user has the appropriate permission, the rendered attribute should be set to true so that the UI component is shown. If they do not have permission, the attribute should be set to false and the UI component hidden from view.

To evaluate a policy using EL, you must use the ADF Security methods in the securityContext EL namespace. These methods let you access information in the ADF security context for a particular user or ADF resource.

Table 41–11 shows the EL expression that is required to determine whether a user has the associated permission. If the user has the appropriate permission, the EL expression evaluates to true; otherwise, it returns false.

<table>
<thead>
<tr>
<th>Expression</th>
<th>Expression action</th>
</tr>
</thead>
<tbody>
<tr>
<td>#{securityContext.taskflowViewable['MyTaskFlow']}</td>
<td>Where MyTaskFlow is the WEB-INF node-qualified name of the task flow being accessed. Returns true if the user has access rights. Returns false if the user does not have sufficient access rights.</td>
</tr>
<tr>
<td>#{securityContext.taskflowViewable ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}</td>
<td>Where MyPagePageDef is the qualified name of the page definition file associated with the web page being accessed. Returns true if the user has access rights. Returns false if the user does not have sufficient access rights.</td>
</tr>
<tr>
<td>#{securityContext.regionViewable['MyPagePageDef']}</td>
<td></td>
</tr>
</tbody>
</table>

Note: The ability to evaluate a policy is limited to the current request. For this reason, it is important to understand where the policy evaluation occurs, because evaluating the policy at anything other than the request scope can lead to unexpected results.

In the case of page permission, the value of the page definition can be specified dynamically by using late-binding EL within a managed bean, as described in Section 41.3.7, "What You May Need to Know About the valid-users Role."

Table 41–12 shows the EL expression that lets you get general information from the ADF security context not related to a particular ADF resource. For example, you can
access the current user name when you want to display the user’s name in the user
interface. You can also check whether the current user is a member of certain roles or
granted certain privileges. Your application may use this result to dynamically hide or
show menus.

<table>
<thead>
<tr>
<th>Expression</th>
<th>Expression Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>#{securityContext.userName}</td>
<td>Returns the user name of the authenticated user.</td>
</tr>
<tr>
<td>#{data.adfContext.tenantName}</td>
<td>Returns the tenant name of the authenticated user. The tenant name is an alias that the user knows for themselves and can use to login.</td>
</tr>
<tr>
<td>#{data.adfContext.tenantId}</td>
<td>Returns the tenant ID of the authenticated user.</td>
</tr>
<tr>
<td>#{securityContext.authenticated}</td>
<td>Returns true if the user is logged in. Returns false if the user is not logged in. This is useful for rendering a dynamic link for login/logout, or for rendering a “Welcome, username” message when the user has been authenticated. For an example that uses this expression, see Section 41.7.4.2, “Adding Login and Logout Links.”</td>
</tr>
<tr>
<td>#{securityContext.userInRole[‘roleList’]}</td>
<td>Where roleList is a comma-separated list of role names. Returns true if the user is in at least one of the roles. Returns false if the user is in none of the roles, or if the user is not currently authenticated.</td>
</tr>
<tr>
<td>#{securityContext.userInAllRoles[‘roleList’]}</td>
<td>Where roleList is a comma-separated list of role names. Returns true if the user is in all of the roles. Returns false if the user is not in all of the roles, or if the user is not currently authenticated.</td>
</tr>
<tr>
<td>#{securityContext.userGrantedPermission[‘permission’]}</td>
<td>Where permission is a string containing a semicolon-separated concatenation of permissionClass=&lt;class&gt;;target=&lt;artifact_name&gt;;action=&lt;action&gt;. Returns true if the user has access rights. Returns false if the user does not have sufficient access rights. Note that the convenience methods taskflowViewable and regionViewable shown in Table 41–11 provide the same functionality.</td>
</tr>
<tr>
<td>#{securityContext.userGrantedResource[‘resource’]}</td>
<td>Where resource is a string containing a semicolon-separated concatenation of resourceName=&lt;name&gt;;resourceType=&lt;type&gt;;action=&lt;action&gt;. Returns true if the user has access rights. Returns false if the user does not have sufficient access rights. You can use this expression to test the permission grant in the display property of a resource that is not contained in a task flow (like an ADF Faces panel or a menu item). You first create a custom resource type for the UI component that you want to protect. For more details, see Section 41.11.2, “How to Protect UI Components Using OPSS Resource Permissions and EL.”</td>
</tr>
</tbody>
</table>

**Before you begin:**
It may be helpful to have an understanding of using EL. For more information, see Section 41.11.1, "Using Expression Language (EL) with ADF Security."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

To associate the rendering of a navigation component with a user's granted permissions on a target task flow or page definition:

1. In the Applications window, double-click the page that contains the navigation component that you wish to conditionally render.

2. In the visual editor for the page, select the component that is used to navigate to the secured page.

3. In the Property window, click the Property Menu dropdown menu displayed next to the Rendered field and choose Expression Builder, as shown in Figure 41–32.

4. In the Expression Builder, expand the ADF Bindings - securityContext node and select the appropriate EL value, and then in the Expression field, enter the qualified name of the ADF resource that the user will attempt to access.

   For example, as shown in Figure 41–33, to limit access to a task flow that your application displays, you would create an expression like:

   ```
   #{securityContext.taskflowViewable
       ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}
   ```

   In this example, the expression determines the user's access rights to view the target task flow audit-expense-report. If the user has the access rights, then the expression evaluates to true and the rendered attribute receives the value true.
5. Click OK.

When you run the application, the component will be rendered or hidden based on the user's ability to view the target page.

41.11.1.2 What Happens When You Use the Expression Builder Dialog

When you use the Expression Builder to define an expression for the `<af:commandNavigationItem` rendered attribute, JDeveloper updates the component definition in the open `.jspx` file. The component's `rendered` attribute appears with an expression that should evaluate to either true or false, as shown in Example 41–24. In this example, the component is a navigation link with the link text `Checkout` defined by another expression. The page that contains the navigation link renders the component only when the user has sufficient rights to access the checkout task flow.

Example 41–24  EL Expression in Source for `.jspx` File

```
<af:commandNavigationItem
  text="#{res['global.nav.checkout']}
  action="globalCheckout"
  id="cni3"
  rendered="#{securityContext.taskflowViewable
    ['/WEB-INF/checkout-task-flow.xml#checkout-task-flow']}"/
```

Tip: In the Expression Builder dialog, expand Description for additional information about any security EL method you select.
41.11.1.3 What You May Need to Know About Delayed Evaluation of EL

The ability to evaluate a security permission is scoped to the request. If you want to evaluate permissions to access a target page from a managed bean that is scoped to a higher level than request (for example, a global menu that is backed by a managed bean), you must implement delayed EL evaluation (late-binding). By passing in the target page as a managed property of the bean, you ensure that the EL expression is evaluated only after the required binding information is available to the managed bean. Because EL is evaluated immediately when the page is executed, placing the EL expression directly in the properties of a UI component, backed by a managed bean, would result in an out-of-scope error.

Example 41–25 shows a property (authorized) of a managed bean that returns true or false based on a user’s ability to view a named target page. In this case, the _targetPageDef variable is a managed property containing the name of the target page. Within the UI, the EL expression would reference the authorized property.

Example 41–25  Delayed EL Evaluation in a Managed Bean

```java
public boolean isAuthorized()
{
    if (_targetPageDef != null) {
        FacesContext fctx = FacesContext.getCurrentInstance();
        ADFContext adfCtx = ADFContext.getCurrent();
        SecurityContext secCtx = adfCtx.getSecurityContext();
        boolean hasPermission = secCtx.hasPermission(new RegionPermission
            (_targetPageDef, RegionPermission.VIEW_ACTION));
        if (hasPermission) {
            return hasPermission;
        } else {
            fctx.addMessage(null, new FacesMessage(
                FacesMessage.SEVERITY_WARN, "Access Permission not defined! " , null));
            return false;
        }
    }
}
```

41.11.2 How to Protect UI Components Using OPSS Resource Permissions and EL

Security expressions in the ADF Security EL namespace described in Table 41–12 let you check the user permission, authentication and role membership status before displaying UI components in your page. When you need fine-grained protection over UI components to secure functional parts of the application that are not part of task flow security or web page security, you use the EL value userGrantedResource and a resource grant that you define for a custom resource type. For instance, through a resource grant that you create for a menu item, the application may either enable or disable a Cancel Shipment menu item to limit who may perform customer order updates.

Resource grants for custom resources types rely on the ResourcePermission class, which is provided by Oracle Platform Security Services (OPSS) and packaged with the application.

You use the overview editor for security policies to create a security policy for the custom resource type. And, in your web page, you use the security expression to evaluate the user’s access rights to the UI component projected by the resource grant.
**Best Practice:** Custom resource types in combination with the `ResourcePermission` matcher class let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user’s ability to view UI components without having to overload the built-in actions defined by the ADF resources’ permission classes. Be aware that you do not need to create custom resource types to manage access to web pages. This level of access is provided by the default ADF Security view permission that you work with in the overview editor for security policies.

To grant resource policies for a custom resource type:

1. Create the custom resource type for the UI component you want to protect.
2. Create the resource grant for the custom resource.
3. Associate the rendering of a UI component with a role’s granted resource permission.

### 41.11.2.1 Creating the Custom Resource Type

You use the Create Resource Type dialog to create a resource type for the UI component that you want to protect. JDeveloper will match your resource type definition to the OPSS permission class `oracle.security.jps.ResourcePermission`. This class allows you to specify custom actions that you can grant to functional parts of your application that are not protected by task flow security or web page security. For example, you might want to create a resource type to protect sensitive parts of the application accessed by the user through a menu UI component.

The Create Resource Type dialog lets you identify the type of resource you wish to protect (for example, the name `MenuProtection` would identify the menu UI component), a display name visible in the security policy store (for example, `Menu Protection`), and a description of how the resource type will be used in the resource grant (for example, `Resource permission to grant menu item permissions`). The dialog also lets you enter one or more custom action names that you will use to grant permission. For example, you might name the action `process` for use in a security policy that grants access to a protected menu item.

**Before you begin:**

It may be helpful to have an understanding of the ADF Permission class. For more information, see Section 41.11.2, "How to Protect UI Components Using OPSS Resource Permissions and EL."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

**To create the custom resource type:**

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, click **New Resource Type**.
3. In the Create Resource Type dialog, enter the name and display name that describes the UI component.
For example, to protect menu items, you might enter `MenuProtection` for the name and `Menu Protection` for the display name.

4. In the **Actions** list, click **Add** and enter the name of the actions that your permission will grant and click **OK**.

For example, when protecting a menu item, you might enter `process` to signify that permission to process the menu selection is being granted. You can enter multiple action names when you intent to grant specific actions to individual users or roles. The overview editor displays the custom permission grant, as shown in Figure 41–34.

**Figure 41–34 Creating a Custom Resource Type**

![Creating a Custom Resource Type](image)

41.11.2.2 Creating a Resource Grant for a Custom Resource Type

You use the overview editor for the `jazn-data.xml` file to create the ADF Security policy for a custom resource. The finished source should look similar to the permission grant defined in the policy store, as shown in Example 41–26.

**Example 41–26 Custom Resource Permission Grant Definition**

```xml
<grant>
    <grantee>
        <principals>
            <principal>
                <name>AccountManagersadmin</name>
                <class>oracle.security.jps.service.policystore.ApplicationRole</class>
            </principal>
        </principals>
    </grantee>
    <permissions>
        <permission>
            <class>oracle.security.jps.ResourcePermission</class>
            <name>resourceType=MenuProtection,resourceName=CancelShipment</name>
        </permission>
    </permissions>
</grant>
```
The <permission> target name identifies the custom resource type and name that you assigned the resource. For example, a resource name that lets users cancel shipments from a menu selection in their account might be named CancelShipment.

The actions are those that your custom resource type defines. For example, in the Menu Protection resource type defines the single action process to grant permission to process the menu selection.

**Before you begin:**

It may be helpful to have an understanding of the ResourcePermission class. For more information, see Section 41.11.2, "How to Protect UI Components Using OPSS Resource Permissions and EL."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete this task:

Create the custom resource type, as described in Section 41.11.2.1, "Creating the Custom Resource Type."

**To create the resource grant for a custom resource type:**

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, select the custom resource from the **Resource Type** dropdown list.
3. In the **Resources** column, click the **Add Resource** icon.
4. In the Create Resource dialog, enter the name, display name, and description for the resource that the security policy will specifically protect and then click **OK**.
5. In Resource Grants page of the overview editor, in the **Granted to** column, click the **Add Grantee** icon and choose **Add Application Role**.
6. In the **Actions** column, select action that you defined for the custom resource type.

The overview editor displays the resource grant, as shown in Figure 41–35.

**Figure 41–35 Creating a Grant for a Custom Resource in the Overview Editor**

41.11.2.3 Assigning the Rendering of a UI Component with a Resource Grant

You use the Expression Builder dialog for the UI component display property to define an EL expression that controls rendering the component. For example, to protect a
menu item in an application that allows authorized users to cancel shipments, the application specifies a `userGrantedResource` expression on the `disabled` property of the menu item defined by `af:commandMenuItem`. As Example 41–27 shows, the expression tests whether the user has been granted the resource type and then either displays the menu item or, when the user has not been granted the resource, disables the menu item.

**Example 41–27 Expression to Evaluate User’s Resource Grant**

```
#{!securityContext.userGrantedResource
  ['resourceName=CancelShipment;resourceType=MenuProtection;action=process']}
```

Figure 41–36 shows how the expression appears in the Expression Builder dialog.

**Figure 41–36 Defining EL in the Expression Builder Dialog**

Before you begin:

It may be helpful to have an understanding of the `ResourcePermission` class. For more information, see Section 41.11.2, "How to Protect UI Components Using OPSS Resource Permissions and EL."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 41.1.3, "Additional Functionality for ADF Security."

You will need to complete these tasks:

1. Create the custom resource type, as described in Section 41.11.2.1, "Creating the Custom Resource Type."
2. Create the ADF security policy using the custom permission, as described in Section 41.11.2.2, "Creating a Resource Grant for a Custom Resource Type."
To associate the rendering of a UI component with a user’s granted resource:

1. In the Applications window, double-click the page that contains the UI component that you wish to conditionally render.

2. In the visual editor for the page, select the component that is used to navigate to the secured page.

3. In the Property window, click the Property Menu dropdown menu displayed next to the Rendered field and choose Expression Builder.

4. In the Expression Builder, expand the ADF Bindings - securityContext node and select userGrantedResource, and then, in the Expression field, enter a concatenated string that defines the permission.

   Enter the permission string as a semicolon-separated concatenation of resourceName=theResourceInstanceName;resourceType=customResourceTypeName;action=actionName. For example, to protect a menu item in an application that allows authorized users to cancel shipments, you would enter an expression similar to the one shown in Example 41–28, where the resource type for userGrantedResource identifies the resource type used in the custom resource grant.

   Example 41–28  EL Expression to Evaluate User’s Resource Grant

   `#{!securityContext.userGrantedResource["resourceName=CancelShipment;resourceType=MenuProtection;action=process"]}`

   In Example 41–28, the expression evaluates the permission based on the custom resource type named MenuProtection that you added to the application policy store.

5. Click OK.

41.11.3 How to Perform Authorization Checks for Entity Object Operations

In the Fusion web application, you can enable security for the data collection when you secure the operations of the entity object. The user must have sufficient privileges to view, update, or delete the data for the entire row set.

The oracle.jbo.ViewCriteriaRow API allows you to perform authorization checks for the standard operations (read, update, removeCurrentRow) at the level of entity rows. Example 41–29 shows how to use the authorization checking API, getSecurityHints() and allowsOperation(), on the entity row, to test whether the user has permission to delete data.

Example 41–29  Invoking the Authorization Checking API for Entity Rows

```java
if(row.getSecurityHints().allowsOperation("removeCurrentRow").hasPermission())
    // code for the data
else
    // display error message
```

Note that the allowsOperation() method expects as input the secured operation name rather than the name of the action that secures it. The operation name for deleting an entity row is removeCurrentRow (where delete is the action name).

When you want to perform authorization checks for the entity object that underlies data bound components in a JSF page of the Fusion web application, you can use EL expressions. For example, the following EL expression returns true if the user has been granted the permission to perform the operation specified. The `<operationName>`
used in the expression must be the read, update, or removeCurrentRow operation that you enabled for the entity object.

#{row.hints.allows.<operationName>}

Authorization checking expressions are evaluated in the context of a row collection. When you want to check entity permissions outside of the context of the row collection, you must use the userGrantedResource method as shown in Table 41–12.

41.11.4 Getting Information from the ADF Security Context

The implementation of security in a Fusion web application is by definition an implementation of the security infrastructure of the ADF Security framework. As such, the security context of the framework allows access to information that is required as you define the policies and the overall security for your application.

41.11.4.1 How to Determine Whether Security Is Enabled

Because the enforcement of ADF Security can be turned on and off at the container level independent of the application, you should determine whether ADF Security is enabled prior to making authorization checks. You can achieve this by calling the isAuthorizationEnabled() method of the ADF security context, as shown in Example 41–30.

Example 41–30 Using the isAuthorizationEnabled() Method of the ADF Security Context

```java
if (ADFContext.getCurrent().getSecurityContext().isAuthorizationEnabled()){
    //Authorization checks are performed here.
}
```

41.11.4.2 How to Determine Whether the User Is Authenticated

As the user principal in a Fusion web application is never null (that is, it is either anonymous for unauthenticated users or the actual user name for authenticated users), it is not possible to simply check whether the user principal is null to determine if the user has logged on or not. As such, you must use a method to take into account that a user principal of anonymous indicates that the user has not authenticated. You can achieve this by calling the isAuthenticated() method of the ADF security context, as shown in Example 41–31.

Example 41–31 Using the isAuthenticated() Method of the ADF Security Context

```java
// ============ User's Authenticated Status =============
private boolean _authenticated;
public boolean isAuthenticated() {
    _authenticated = ADFContext.getCurrent().getSecurityContext().isAuthenticated();
    return _authenticated;
}
```

41.11.4.3 How to Determine the Current User Name, Tenant Name, or Tenant ID

Fusion web applications support the concept of public pages that, while secured, are available to all users. Furthermore, components on the web pages, such as portlets, require knowledge of the current user identity. As such, the user name in a Fusion web application will never be null. If an unauthenticated user accesses the page, the user name anonymous will be passed to page components. When the Fusion web application registers an tenant name for the user, the tenant name may also be
obtained. The tenant name is an alias that the user knows for themselves and can use to login.

You can determine the current user’s name by evaluating the `getUserName()` method of the ADF security context, as shown in Example 41–32. This method returns the string `anonymous` for all unauthenticated users and the actual authenticated user’s name for authenticated users.

**Example 41–32 Using the `getUserName()` Method of the ADF Security Context**

```java
// ============ Current User's Name/PrincipalName =============
public String getCurrentUser() {
    _currentUser = ADFContext.getCurrent().getSecurityContext().getUserName();
    return _currentUser;
}
```

Because the traditional method for determining a user name in a Faces-based application
(FacesContext.getCurrentInstance().getExternalContext().getRemoteUser()) returns `null` for unauthenticated users, you need to use additional logic to handle the public user case if you use that method.

You can determine the current user’s tenant name by evaluating the `getTenantName()` method of the ADF context, as shown in Example 41–33.

**Example 41–33 Using the `getTenantName()` Method of the ADF Context**

```java
// ============ Current User's Tenant Name =============
public String getTenantName() {
    _tenantName = ADFContext.getCurrent().getTenantName();
    return _tenantName;
}
```

You can determine the current user’s tenant ID by evaluating the `getTenantId()` method of the ADF context, as shown in Example 41–34. This method returns the string `anonymous` for all unauthenticated users and the actual authenticated user’s name for authenticated users.

**Example 41–34 Using the `getTenantId()` Method of the ADF Context**

```java
// ============ Current User's Tenant ID =============
public String getTenantId() {
    _tenantId = ADFContext.getCurrent().getTenantId();
    return _tenantId;
}
```

### 41.11.4.4 How to Determine Membership of a Java EE Security Role

As Fusion web applications are JavaServer Faces-based applications, you can use the `isUserInRole(roleName)` method of the Faces external context, as shown in Example 41–35, to determine whether a user is in a specified role. Because ADF Security is based around JAAS policies, you should not need to use Java EE security roles to secure pages associated with ADF security-aware resources based on role membership. However, you might use the method to check the role for a page that is not associated with an ADF security-aware resource.

In this example, a convenience method (`checkIsUserInRole`) is defined. The use of this method within a managed bean enables you to expose membership of a named role as an attribute, which can then be used in EL.
Example 41–35 Using the `isUserInRole(roleName)` Method of the Faces Context

```java
public boolean checkIsUserInRole(String roleName) {
    return (FacesContext.getCurrentInstance().getExternalContext().isUserInRole(roleName));
}

public boolean isCustomer() {
    return (checkIsUserInRole("Application Customer Role"));
}
```

41.11.4.5 How to Determine Permission Using Java

To evaluate the security policies from within Java, you can use the `hasPermission` method of the ADF security context. This method takes a permission object (defined by the resource and action combination) and returns `true` if the user has the corresponding permission.

In Example 41–36, a convenience function is defined to enable you to pass in the name of the page and the desired action, returning `true` or `false` based on the user's permissions. Because this convenience function is checking page permissions, the `RegionPermission` class is used to define the permission object that is passed to the `hasPermission` method.

Example 41–36 Using the `hasPermission()` Method to Evaluate Access Policies

```java
private boolean TestPermission(String PageName, String Action) {
    Permission p = new RegionPermission("view.pageDefs." + PageName + "PageDef", Action);
    if (p != null) {
        return ADFContext.getCurrent().getSecurityContext().hasPermission(p);
    } else {
        return (true);
    }
}
```

As it is possible to determine the user's permission for a target page from within a backing bean, you can use this convenience method to dynamically alter the result of a Faces navigation action. In Example 41–37, you can see that a single command button can point to different target pages depending on the user's permission. By checking the view permission from the most secured page (the manager page) to the least secured page (the public welcome page), the command button’s backing bean will apply the appropriate action to direct the user to the page that corresponds to their permission level. The backing bean that returns the appropriate action is using the convenience method defined in Example 41–36.

Example 41–37 Altering a Page Navigation Result Based on an Authorization Check

```java
//Command Button Definition
<af:button text="Goto Your Group Home page"
    binding="#{backing_content.commandButton1}"
    id="commandButton1"
    action="#{backing_content.getSecureNavigationAction}"/>

//Backing Bean Code
public String getSecureNavigationAction() {
    String ActionName;
    if (TestPermission("ManagerPage", "view"))
        ActionName = "goToManagerPage";
    else if (TestPermission("EmployeePage", "view"))
```
ActionName = 'goToEmployeePage';
else
  ActionName = 'goToWelcomePage';
return (ActionName);
}

41.11.5 Best Practices for Working with ADF Security

These best practices summarize the rules that govern enforcement of security by the ADF Security framework. Understanding these best practices will help you to secure the application to allow users to access the web pages you intend.

Do build your application with ADF Security enabled from the start.
When you enable security, you essentially lock down the application and you will be required to make explicit permission grants to specific ADF security-aware resources you create. Knowing about these resources and making grants on them as you build the application will enable you to iteratively test security to ensure that you structure your application in a way that achieves the desired result.

Do define permission grants for bounded task flows.
Pages that the user accesses within the process of executing a bounded task flow will not be individually permission-checked and will run under the permission grants of the task flow. This means that any page that you add to the task flow should not have its own page definition-level security defined. Upon requesting a flow, the user will be allowed either to view all the pages of the task flow or to view none of the pages, depending on their level of access.

Do not define permission grants for individual pages of a bounded task flow.
It is important to realize that task flows do not prevent users from accessing pages directly. Any web page that is located in a directory that is publicly accessible can be reached from a browser using a URL. To ensure that pages referenced by a bounded task flow cannot be accessed directly, remove all permission grants that exist for their associated page definition file. When pages require additional security within the context of a bounded task flow, wrap those pages in a sub-task flow with additional grants defined on the nested task flow.

Do use task flows to reduce the number of access points exposed to end users.
When you use task flows you can reduce the number of access points that you expose to end users. For example, configure an unbounded task flow to display one page that provides navigation to the remaining pages in your application. Use bounded task flows for the remaining pages in the application. By setting the URL Invoke property of these bounded task flows to url-invoke-disallowed, your application has one access point (the page on the unbounded task flow). For more information about the URL Invoke property, see Section 21.6.4, "How to Call a Bounded Task Flow Using a URL."

Do specify an alternative task flow for unauthorized users.
End users who attempt to invoke a bounded task flow in a region for which they do not have the necessary permission will see a region that renders as blank in place of the requested task flow. The region when left blank may confuse end users as it does not provide feedback as to why the requested task flow does not appear. Consider configuring an alternative task flow that does not require authorization when this scenario occurs. For more information configuring an alternative task flow, see Section 23.12, "Handling Access to Secured Task Flows by Unauthorized Users."
**Do define permission grants for individual pages outside of a bounded task flow.**

Page-level security is checked for pages that have an associated page definition binding file *only* if the page is directly accessed or if the page is accessed in an *unbounded* task flow. There is a one-to-one relationship between the page definition file and the web page it secures.

If you want to secure a page that uses no ADF bindings, you can create an empty page definition binding file for the page.

**Do define custom permissions to render UI component based on the user's access rights.**

Custom ADF permission classes let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user’s ability to view UI components without having to overload the built-in actions defined by the ADF resources’ permission classes.

**Do define entity object attribute permissions to manage the user's access rights to row-level data displayed by UI components.**

Entity objects and entity object attributes both define permission classes that let you define permissions for the read, update, and delete operations that the entity object initiates on its data source. In the case of these data model project components, you must explicitly grant permissions to an application role in order to opt into ADF Security authorization. However, once you enable authorization for an entity object, all rows of data defined by the entity object will be protected by the grant. At this level of granularity, your table component would render in the web page either with all data visible or with no data visible—depending on the user’s access rights. As an alternative to securing the entire collection, you can secure individual columns of data. This level of granularity is supported by permissions you set on the individual attributes of entity objects. When entity objects are secured, users may see only portions of the data that the table component displays.

**Do use task flow or page-level permission grants to avoid exposing row-level create/insert operations to users with view-only permission.**

The correct way to control access to a page that should allow only certain users to update new rows in a table is to use task flow or page-level permission grants. However, as an alternative, it is possible to secure table buttons corresponding to particular operations by specifying an EL expression to test the user’s access rights to view the button. When the custom permission is defined and the `userGrantedPermission` expression is set on the `Rendered` property of the button, only users with sufficient privileges will see the button. This may be useful in a case where the user interface displays a page that is not restricted and view-only permission for row-level data is defined for the entity object. In this case, when viewed by the user, the Delete button for the editable table associated with the entity object will appear disabled. However, in the case of an input table, the user interface does not disable the button for the `CreateInsert` operation even though the user may not have update permission.

**Do not use JDeveloper as a user identity provisioning tool.**

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, always rely on the system administrator to configure user identities through the tools provided by the
domain-level identity management system. You should delete all users and groups that you create in the jazn-data.xml file before deploying the application.

**Do not allow users to access a web page by its file name.**

When you deploy the Fusion web application, you should always permit users to access the web page from a view activity defined in the ADF Controller configuration file. Do not allow users to access the JSPX file directly by its physical name (for example, similar to the file name AllDepartments.jspx).

Assuming the view activity is named AllDepartments, then there are two ways to call the page:

1. localhost:7101/myapp/faces/AllDepartments
2. localhost:7101/myapp/faces/AllDepartments.jspx

The difference is that the call 1) is in the context of the ADF Controller task flow, which means that navigation on the page will work and any managed beans that are referenced by the page will be properly instantiated. The call in 2) also serves the page, however, the page may not function fully. This may be considered a security breach.

To prevent direct JSPX file access, move the JSPX file under the /public_html/WEB-INF directory so that direct file access is no longer possible. To access a document, users will have to call its view activity name.

Note that this suggestion does not protect documents that are unprotected in ADF Security. It only helps to lock down access to the physical file itself.

Thus, the following security guidelines still apply:

1. Apply ADF Security permissions to all JSPX documents associated with view activities defined in the adfc-config.xml file.
2. Move all JSPX documents in the user interface project under the /public_html/WEB-INF directory to prevent direct file access.
3. Limit the pages in the adfc-config.xml to the absolute minimum and place all other pages into bounded task flows.
4. Make bounded task flows inaccessible from direct URL access (which is the default configuration setting for new task flows).
5. Apply ADF Security permissions to bounded task flows.
This chapter describes the tools for logging and testing an application that uses Oracle ADF. It contains debugging procedures for setting breakpoints using the ADF Declarative Debugger. Finally, it explains how to write and run regression tests for your ADF Business Components-based business services.

This chapter includes the following sections:

- Section 42.1, "About ADF Debugging"
- Section 42.2, "Correcting Simple Oracle ADF Compilation Errors"
- Section 42.3, "Correcting Simple Oracle ADF Runtime Errors"
- Section 42.4, "Reloading Oracle ADF Metadata in Integrated WebLogic Server"
- Section 42.5, "Validating ADF Controller Metadata"
- Section 42.6, "Using the ADF Logger"
- Section 42.7, "Using the Oracle ADF Model Tester for Testing and Debugging"
- Section 42.8, "Using the ADF Declarative Debugger"
- Section 42.9, "Setting ADF Declarative Breakpoints"
- Section 42.10, "Setting Java Code Breakpoints"
- Section 42.11, "Regression Testing with JUnit"

### 42.1 About ADF Debugging

Like any debugging task, debugging the web application’s interaction with Oracle Application Development Framework (Oracle ADF) is a process of isolating specific contributing factors. However, in the case of web applications, generally this process does not involve compiling Java source code. Your web pages contain no Java source code, as such, to compile. In fact, you may not realize that a problem exists until you run and attempt to use the application. For example, these failures are only visible at runtime:

- A page not found servlet error
- The page is found, but the components display without data
- The page fails to display data after executing a method call or built-in operation (like Next or Previous)
- The page displays, but a method call or built-in operation fails to execute at all
- The page displays, but unexpected validation errors occur
The failure to display data or to execute a method call arises from the interaction between the web page’s components and the ADF Model layer. When a runtime failure is observed during ADF lifecycle processing, the sequence of preparing the model, updating the values, invoking the actions, and, finally, rendering the data failed to complete.

Fortunately, most failures in the web application’s interaction with Oracle ADF result from simple and easy-to-fix errors in the declarative information that the application defines or in the EL expressions that access the runtime objects of the page’s ADF binding container.

In your databound Fusion web application, you should examine the declarative information and EL expressions as likely contributing factors when runtime failures are observed. To understand editing the declarative files, see Section 42.2, "Correcting Simple Oracle ADF Compilation Errors," and Section 42.3, "Correcting Simple Oracle ADF Runtime Errors."

One of the most useful diagnostic tools is the ADF Logger. You use this logging mechanism in JDeveloper to capture runtime traces messages. With ADF logging enabled, JDeveloper displays the application trace in the Message Log window. The trace includes runtime messages that may help you to quickly identify the origin of an application error. Read Section 42.6, "Using the ADF Logger," to configure the ADF Logger to display detailed trace messages.

Supported Oracle ADF customers can request Oracle ADF source code from Oracle Worldwide Support. This can make debugging ADF Business Components framework code a lot easier. Read Section 42.8.1, "Using ADF Source Code with the Debugger," to understand how to configure JDeveloper to use the Oracle ADF source code.

If the error cannot be easily identified, you can utilize the ADF Declarative Debugger in JDeveloper to set breakpoints. When a breakpoint is reached, the execution of the application is paused and you can examine the data that the ADF binding container has to work with, and compare it to what you expect the data to be. Depending on the types of breakpoints, you may be able to use the step functions to move from one breakpoint to another. For more information about the debugger, read Section 42.8, "Using the ADF Declarative Debugger."

JDeveloper provides integration with JUnit for your Fusion web application through a wizard that generates regression test cases. Read Section 42.11, "Regression Testing with JUnit," to understand how to write test suites for your application.

### 42.2 Correcting Simple Oracle ADF Compilation Errors

When you create web pages and work with the ADF data controls to create the ADF binding definitions in JDeveloper, the Oracle ADF declarative files you edit must conform to the XML schema defined by Oracle ADF. When an XML syntax error occurs, the JDeveloper XML compiler immediately displays the error in the Structure window.

Although there is some syntax checking during design time, the JDeveloper compiler is currently limited by an inability to resolve EL expressions. EL expressions in your web pages interact directly with various runtime objects in the web environment, including the web page’s ADF binding container. At present, errors in EL expressions can be observed only at runtime. Thus, the presence of a single typing error in an object-access expression will not be detected by the compiler, but will manifest at runtime as a failure to interact with the binding container and a failure to display data in the page. For information about debugging runtime errors, see Section 42.3, "Correcting Simple Oracle ADF Runtime Errors."
Correcting Simple Oracle ADF Compilation Errors

**Tip:** The Expression Builder is a dialog that helps you build EL expressions by providing lists of objects, managed beans, and properties. It is particularly useful when creating or editing ADF databound EL expressions because it provides a hierarchical list of ADF binding objects and their valid properties from which you can select. You should use the Expression Builder to avoid introducing typing errors. For details, see Section 17.8, "Creating ADF Data Binding EL Expressions."

Example 42–1 illustrates two simple compilation errors contained in a page definition file: `false` instead of `false` and `ChangeEventPolicy="ppr"/>` instead of `ChangeEventPolicy="ppr"/>

(that is, the attribute is missing a closing angle bracket).

**Example 42–1  Sample Page Definition File with Two Errors**

```xml
<?xml version='1.0' encoding='UTF-8' ?>
<pageDefinition xmlns='http://xmlns.oracle.com/adfm/uimodel'
    Package='oracle.summit.view.pageDefs'
    SkipValidation='false'>
    <parameters/>
    <executables>
        <iterator Binds="InventoryForOrderItem" RangeSize='-1'
            DataControl="BackOfficeAppModuleDataControl"
            id="InventoryForOrderItemIterator"
            ChangeEventPolicy="ppr"/>
        ...
    </pageDefinition>
```

During compilation, the Structure window displays the XML errors in the page, as shown in Figure 42–1.

**Figure 42–1  The Structure Window Displays XML Errors**

![Structure Window](Image)

The Compiler-Log window also displays the compilation errors in the page, as shown in Figure 42–2.
To view and correct schema validation errors:
1. In the main menu, choose View and then Structure to open the Structure window or choose View and then Log to open the Log Window.
2. In either window, double-click the error message.
3. In the XML editor, locate the highlighted lines.
   The highlighted lines will be lines with errors.
4. Correct any errors.
   After an error has been corrected, the corresponding error message will be automatically removed from the Structure window.
5. Optionally, you can recompile the project by choosing Run > Make and checking to see whether the compiler still produces the error message.

42.3 Correcting Simple Oracle ADF Runtime Errors

Failures of the ADF Model layer cannot be detected by the JDeveloper compiler, in part because the page’s data-display and method-execution behavior relies on the declarative ADF page definition files. The ADF Model layer utilizes those declarative files at runtime to create the objects of the ADF binding container.

To go beyond simple schema validation, you will want to routinely run and test your web pages to ensure that none of the following conditions exists:

- The project dependency between the data model project and the user interface project is disabled.
  By default, the dependency between projects is enabled whenever you create a web page that accesses a data control in the data model project. However, if the dependency is disabled and remains disabled when you attempt to run the application, an internal servlet error will be generated at runtime:
  
  oracle.jbo.NoDefException: JBO-25002: Definition model.DataControls.dcx of type null not found

  To correct the error, double-click the user interface project, and select the Dependencies node in the dialog. Make sure that the ModelProjectName.jpr option appears selected in the panel.

- Page definition files have been renamed, but the DataBindings.cpx file still references the original page definition file names.
  While JDeveloper does not permit these files to be renamed within the IDE, if a page definition file is renamed outside of JDeveloper and the references in the
DataBindings.cpx file are not also updated, an internal servlet error will be
generated at runtime:

```
oracle.jbo.NoDefException: JBO-25002: Definition
oracle.<path>.pageDefs.<pagedefinitionName> of type Form
Binding Definition not found
```

To correct the error, open the DataBindings.cpx file and use the source editor
to edit the page definition file names that appear in the `<pageMap>` and
`<pageDefinitionUsages>` elements.

- The web page file (.jsp or .jspx) has been renamed, but the
  DataBindings.cpx file still references the original file name of the same web
  page.

  The page controller uses the page’s URL to determine the correct page definition
to use to create the ADF binding container for the web page. If the page’s name
from the URL does not match the `<pageMap>` element of the
DataBindings.cpx file, an internal servlet error will be generated at runtime:

```
javax.faces.el.PropertyNotFoundException: Error testing
property <propertyname>
```

To correct the error, open the DataBindings.cpx file and use the source editor
to edit the web page file names that appear in the `<pageMap>` element.

- Bindings have been renamed in the web page EL expressions, but the page
  definition file still references the original binding object names.

  The web page may fail to display information that you expect to see. To correct the
error, compare the binding names in the page definition file and the EL expression
responsible for displaying the missing part of the page. Most likely the mismatch
will occur on a value binding, with the consequence that the component will
appear but without data. Should the mismatch occur on an iterator binding name,
the error may be more subtle and may require deep debugging to isolate the
source of the mismatch.

- Bindings in the page definition file have been renamed or deleted, and the EL
  expressions still reference the original binding object names.

  Because the default error-handling mechanism will catch some runtime errors
from the ADF binding container, this type of error can be very easy to find. For
example, if an iterator binding named `findUsersByNamIter` was renamed in
the page definition file, yet the page still refers to the original name, this error will
display in the web page:

```
JBO-25005: Object name <iterator> for type Iterator Binding
Definition is invalid
```

To correct the error, right-click the name in the web page and choose Go to Page
Definition to locate the correct binding name to use in the EL expression.

- EL expressions were written manually instead of using the expression picker
dialog and invalid object names or property names were introduced.

  This error may not be easy to find. Depending on which EL expression contains
the error, you may or may not see a servlet error message. For example, if the error
occurs in a binding property with no runtime consequence, such as displaying a
label name, the page will function normally but the label will not be displayed.
However, if the error occurs in a binding that executes a method, an internal
servlet error `javax.faces.el.MethodNotFoundException: methodname`
will display. Or, in the case of an incorrectly typed property name on the method
expression, the servlet error
    javax.faces.el.PropertyNotFoundException: propertyname will display.

If this list of typical errors does not help you to find and fix a runtime error, you can initiate debugging within JDeveloper to find the contributing factor. For an Oracle ADF application, start setting ADF declarative breakpoints to find the problem. Using the ADF Declarative Debugger to set ADF declarative breakpoints is described in Section 42.8, "Using the ADF Declarative Debugger," and Section 42.9, "Setting ADF Declarative Breakpoints." This process involves pausing the execution of the application as it proceeds through the application and examining data. You can also use the ADF Declarative Debugger to set Java code breakpoints, as described in Section 42.10, "Setting Java Code Breakpoints."

42.4 Reloading Oracle ADF Metadata in Integrated WebLogic Server

JDeveloper support for hot reloading of Oracle ADF metadata is an alternative to quitting the running application, editing your project’s XML definition files, redeploying, and rerunning the application in Integrated WebLogic Server to view the latest changes.

Changes that you make to the Fusion web application projects will not be picked up automatically by an application that you have deployed to Integrated WebLogic Server. You can, however, reload metadata from the data model project and user interface project any time you want to synchronize the running application with changes you have made to your application’s XML definition files.

To reload metadata so your changes are reflected in the deployed Fusion web application, you must recompile the project and refresh the web browser.

Metadata that JDeveloper will hot reload in Integrated WebLogic Server, include:

- In the data model project, changes to the definition files of business components.
- In the user interface project, changes to the binding definitions in the page definition files and changes to task flows in the task flow definition files.

This support makes it possible to make incremental changes and test them.

42.5 Validating ADF Controller Metadata

Basic validation is performed when ADF Controller retrieves metadata. The most serious errors, for example, a task flow that is missing a default activity, result in parsing exceptions.

The enable-grammar-validation setting in adf-config.xml allows you to validate the grammar in ADF Controller metadata before deploying an application. When enable-grammar-validation is set to true, ADF Controller metadata is validated against ADF Controller XSDs. For example, invalid characters in ADF Controller metadata, such as a slash (/) in a view activity ID, are flagged as exceptions.

By default, enable-grammar-validation is set to false. For performance reasons, it should be set to true only during application development or when troubleshooting an application.
42.6 Using the ADF Logger

If you are not able to easily find the error in either your web page or its corresponding page definition file, you can use the JDeveloper debugging tools to investigate where your application failure occurs.

You configure the logging session by editing the `logging.xml` configuration file using the editor for Oracle Diagnostic Logging Configuration. Logging configuration can be set at any time, even while the application is running in JDeveloper.

Unlike many files in JDeveloper, you cannot directly open the `logging.xml` file. Instead you use menu commands at these locations to open the Oracle Diagnostic Logging Configuration editor:

- Right-click an active server instance in the Application Servers window.
- Click the Actions dropdown menu displayed in the Log window’s debugger process panel, after you have started the application in debug mode.

You use the Oracle Diagnostic Logging Configuration editor to set the desired logging level to control the level and number of messages that are displayed. You can set the logging level for both persistent and transient loggers and declare handlers for each logger.

JDeveloper creates diagnostic log files in the Oracle Diagnostic Logging (ODL) format, used by Oracle Fusion Middleware components. Log file naming and the format of the contents of log files conform to an Oracle standard. By default, the diagnostic messages are in text format. For more information about the ODL format, see *Administering Oracle Fusion Middleware*.

In the editor, as an alternative to the default ODL format, you can configure the Java Logger to display Java diagnostic messages.

After you have created a log, you can view and filter the log messages with Oracle Diagnostic Log Analyzer. This tool allows you to set filters for different log levels, define message time frames, and search on message text.

You can then use the ADF Declarative Debugger to set breakpoints and examine the application. For more information, see Section 42.9, "Setting ADF Declarative Breakpoints," and Section 42.10, "Setting Java Code Breakpoints."

### 42.6.1 How to Set ADF Logging Levels

You can use the Oracle Diagnostic Logging Configuration editor to configure the logging levels specified in the `logging.xml` configuration file. The file can be configured before and while the application is running in Integrated WebLogic Server. The changes will apply without the need to restart the server.

When Integrated WebLogic Server is running, you can define both persistent and transient loggers. When Integrated WebLogic Server is not running, you can only define persistent loggers. The transient loggers will last only for the session and will not be entered in the `logging.xml` configuration file. If the server is not running, you must explicitly save the configuration changes to the `logging.xml` file for the updates to take effect in the next server run.

You can access the Oracle Diagnostic Logging Configuration editor from the Application Servers window or from the Log window, which is shown in Figure 42–3.
However, while the server is running, when you access the editor via the Log window menu, then the editor has the ability to add transient loggers.

Figure 42–4 shows the Oracle Diagnostic Logging Configuration while the server is running.

You can only use JDeveloper menu commands to open the *logging.xml* configuration file and launch the editor for Oracle Diagnostic Logging Configuration. However, you may find the following information about the location of the configuration file useful.
If you are using Integrated WebLogic Server in JDeveloper on the Windows platform, you can find the logging.xml configuration file in a location similar to:

C:\Users\username\AppData\Roaming\JDeveloper\<your_JDev_system_folder>\DefaultDomain\config\fmwconfig\servers\DefaultServer

The log files for Integrated WebLogic Server are in a location similar to:

C:\Users\username\AppData\Roaming\JDeveloper\<your_JDev_system_folder>\DefaultDomain\servers\DefaultServer\logs

The log files for a standalone WebLogic Server instance are in a location similar to:

$domain_home/servers/<your_servername>/logs

You can configure logging levels before a test run from the Application Servers window, or, while the application is running, from the Log window’s run panel toolbar, or, during a debug session, from the Log window’s debug process toolbar.

To configure the log levels:

1. In the main menu, choose Window and then Application Servers.

2. In the Application Servers window, expand Application Servers, and right-click IntegratedWebLogicServer and choose Configure Oracle Diagnostic Logging for "IntegratedWebLogicServer".

   Or, after you start the application, from the Log window’s Running: IntegratedWebLogicServer panel, choose Actions - Configure Oracle Diagnostic Logging. The Running Log window is only visible while you run the application.

   Or, while you debug the application, from the Log window’s debug process panel, choose Actions - Configure Oracle Diagnostic Logging. The debug process panel is only visible in the Log window after you have started the application in debug mode.

3. In the editor for Oracle Diagnostics Logging Configuration, select ODL Log Levels or Java Log Levels for the logger type you want to view.

4. If you want to see persistent loggers only, select Hide Transient Loggers.

5. To add a logger:
   a. If the server is running, click the Add icon dropdown menu and choose Add Persistent Logger or Add Transient Logger. If the server is not running, click Add to add a persistent logger. You cannot add a transient logger.

   b. In the Add Logger dialog, enter a logger name.

   c. Select the logging level.

   d. Click OK.

6. For any logger, including a newly created logger, you can specify its handlers by selecting from a list of available handlers by clicking the Add icon for the Handler Declarations section.

   Or, you can select Use Parent Handlers to assign its parent’s handler to the logger. By default, a logger uses its parent’s handler.
42.6.2 How to Create an Oracle ADF Debugging Configuration

Oracle ADF leverages the Java Logging API (\texttt{java.util.logging.Logger}) to provide logging functionality when you run a debugging session. The Java Logging is a standard API that is available in the Java platform at \url{http://docs.oracle.com/javase/7/docs/api/java/util/logging/package-summary.html}.

To log a complete hierarchy tree of ADF event messages, you must configure a Java log level that is not more restrictive than CONFIG (or an ODL log level that is not more restrictive than Notification:16) for the single package:

- \texttt{oracle.adfdiagnostics} will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

Figure 42–5 shows specific the logger configured to enable the most detailed Oracle ADF log messages. Note that the \texttt{oracle.adfdiagnostics} package is set to CONFIG and not to a higher, more restrictive log level (where SEVERE, WARNING, and INFO are Java log levels higher than CONFIG and FINE, FINER, and FINEST are lower levels than CONFIG). Enabling a logger for the \texttt{oracle.adfdiagnostics} package ensures that the logger records a complete hierarchy of ADF events.

For backward compatibility, the Java system property \texttt{jbo.debugoutput} set to the value \texttt{console} or \texttt{ADFLogger} (to route diagnostics through the standard Logger implementation, which can be controlled in a standard way through the \texttt{logging.xml} file) is supported. The easiest way to set this system property while running your application inside JDeveloper is to edit your project properties and in the Run/Debug page, select a run configuration and click \texttt{Edit}. Then add the string \texttt{-Djbo.debugoutput=console} to the \texttt{Java Options} field.

To create an ADF Model debugging configuration:

1. In the main menu, choose \texttt{Window} and then \texttt{Application Servers}. 

\textbf{Note:} You can declare and add log handler definitions by clicking the \texttt{Source} tab and entering them in the XML editor.
2. In the Application Servers window, expand **Application Servers**, and right-click **IntegratedWebLogicServer** and choose **Configure Oracle Diagnostic Logging**.

Or, after you start the application, from the Log window’s Running: IntegratedWebLogicServer panel, choose **Actions - Configure Oracle Diagnostic Logging**. The Running Log window is only visible while you run the application.

Or, while you debug the application, from the Log window’s debug process panel, choose **Actions - Configure Oracle Diagnostic Logging**. The debug process panel is only visible in the Log window after you have started the application in debug mode.

3. In the editor for Oracle Diagnostics Logging Configuration, select **ODL Log Levels** or **Java Log Levels** for the logger type you want to view.

4. Expand the **oracle** node and select a log level that are not more restrictive than **CONFIG** (for Java Log) or that are not more restrictive than **Notification** (for ODL Log) for the following package:

   - **oracle.adfdiagnostics** will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

   Enabling a logger for this package ensures that the logger records a complete hierarchy of ADF events.

5. Select the Java log level **FINEST** for other desired Oracle ADF loggers.

**To create an ADF view Javascript logging configuration:**

1. In the Applications window, double-click the application or project **web.xml** file.

2. In the source editor, add the following elements to the file:

   ```xml
   <context-param>
   <param-name>oracle.adf.view.rich.LOGGER_LEVEL</param-name>
   <param-value>FINE</param-value>
   </context-param>
   ```

42.6.3 How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers

For non-Oracle ADF loggers, before you use the actual debugger, running the application with Java log level set to FINE, FINER, or FINEST will enable framework diagnostics logging. The debug diagnostic messages can be helpful to see what happens when the problem occurs. To enable debug diagnostic messages, use the Oracle Diagnostics Logging Configuration Editor to configure the desired loggers with a Java log level set to FINEST. If you have configured diagnostic logging for the supported loggers, JDeveloper will direct debug diagnostics messages to the JDeveloper Log window.

Currently, Oracle ADF does not support logging with Java log level FINE, FINER, or FINEST. For more details about Oracle ADF loggers, see Section 42.6.2, "How to Create an Oracle ADF Debugging Configuration."

42.6.4 How to Use the Log Analyzer to View Log Messages

You can use Oracle Diagnostic Log Analyzer to view the log entries of a log file. The log analyzer allows you to filter the entries by log level, entry type, log time, and entry
content (using one or more search criteria). You can also order the messages and show and hide columns for better viewing.

**Figure 42–6** shows Oracle Diagnostic Log Analyzer set to view Java Log levels.

**Figure 42–6  Oracle Diagnostic Log Analyzer Displays Java Log Messages**

You can also use the log analyzer on log files created in other test runs. For instance, you can analyze the log sent to you by another developer for another application.

### 42.6.4.1 Viewing Diagnostic Messages in the Log Analyzer

You can configure logging levels before a test run from the Application Servers window or during a debug session from the Log window toolbar. The level you specify will determine the type and quantity of log messages.

In the case of ADF events, all messages are generated for the ODL log at the level Notification or for the Java log at the level Info. Fewer ADF messages will be generated at the Incident Error/Severe and Error/Warning levels.

After you select the log level for the messages you wish to view, you can use the Search panel of the By Log Message page to filter the messages to display from the log file.

**Note:** For further details about search criteria that you can specify to search on ADF-specific messages, see Section 42.6.4.3, "Sorting Diagnostic Messages By ADF Events."

You can start the log analyzer before a test run from the **Tools** menu or during a debug session from the log window toolbar.

**Before you begin:**

It may be helpful to have an understanding of logging. For more information, see Section 42.6, "Using the ADF Logger."
You will need to complete these tasks:

1. Set logging levels, as described in Section 42.6.1, "How to Set ADF Logging Levels."

2. Enable logging, as described in Section 42.6.3, "How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers."

3. Create a log file, either from your test run or from another source.

**To start the log analyzer:**

1. In the main menu, choose Tools and then Oracle Diagnostic Log Analyzer.
   
   Or, from the Log window Action menu, choose Analyze Log and then either Current in Console or Open Selected (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, select By Log Message.

3. In the By Log Message page, in the Log field, enter the path and name of the log file or click Browse Log Files to navigate to the log file.

   **Tip:** The Choose Log File dialog helps you to navigate to the directory that contains the log files generated by JDeveloper. Click the Browse Log Files icon next to the Log text field, and then click the Server Logs icon from the scroll list. From the list of log files, you can select more than one log file to analyze at a time.

4. From the dropdown list, select either ODL Log Level or Java Log Level.

5. Select the corresponding checkbox for each type of log entry you want to view. You must select at least one type.

   The available ODL log level types are:
   - INCIDENT ERROR
   - ERROR
   - WARNING
   - NOTIFICATION - corresponds to ADF event messages
   - TRACE
   - UNKNOWN.

   The available Java log level types are:
   - SEVERE
   - WARNING
   - INFO
   - CONFIG - corresponds to ADF event messages
   - FINE
   - FINER
   - FINEST
   - UNKNOWN

6. Specify a time period for the entries you want to view. You can select the most recent period or a range.
7. To filter the results, use the Search panel to query the log for a text pattern. For additional search criteria, click Add. The supported search criteria include:

- **Enterprise Name**: Filters the log by the name of the enterprise.
- **Detail**: Filters text in statements from the stack where the method was invoked.
- **EnterpriseID**: Filters the log by the ID of the enterprise.
- **Message**: Filters text in the logged messages.
- **ADF Message Data**: Filters the log for data related to ADF lifecycle phase names, view object names, view object query statements, data control names, binding container names, and iterator binding names logged during the execution of ADF events.
- **Source Method**: Filters the log by the method where the message is logged. For example, you can filter on the method execute to view all messages logged for view object query execution or ADF lifecycle phase execution.
- **Application**: Filters the log by the application name where the message is logged. This is useful when the application is running in a composite application and you want to view messages for a specific application.
- **Source Class**: Filters the log by the fully qualified class name of the method where the message is logged. For example, you can enter the partial package name oracle.adf or the full package name oracle.jbo to filter for all classes related to Oracle ADF.
- **Module**: Filters the log by the fully qualified package name of the class where the message is logged. This is same package as the source class.
- **Message Id**: Filters the log by the ID of the logged messages. Many messages share the same ID. For example, message ID ADFC-52008 might have four INFO messages and one Warning message. You can select Group by Id in the log analyzer Results panel to group messages by their common ID.

8. To initiate the filters and display the log messages, click Search.

9. To order the results by the message ID, select the Group by Id checkbox.

10. To group the messages by time period or by request, in the Related column, select either Related by Time or Related by Request.

    When you select Related by option, the log analyzer groups the messages in the Results Messages panel according to the selected criteria (time, HTTP request, or enterprise name).

11. To open the ADF request (if any) that the message is a part of, in the Related column, select Related by ADF Request.

    When you select Related by ADF Request, the log analyzer displays the related request in the By ADF Request page.

12. To show or hide columns in the Results section, click the dropdown list to the right of the column headers and select among the list of displayed columns to change the visibility of a column.

### 42.6.4.2 Using the Log Analyzer to Analyze the ADF Request

Because Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases, you can use the log analyzer to
investigate the details of the active (or previous) page request in your running application. Specifically, the By ADF Request page of the log analyzer lets you view ADF event messages in a hierarchical list, organized by the sequence of their execution. It also provides a graphical representation of the duration of each event. When you run your application and start the log analyzer with ADF logging configured, you can use this page to quickly identify whether a component of your application is contributing to a performance bottleneck due to unusually long execution times.

---

**Note:** In contrast to the By Log Message page, the By ADF Request page of the log analyzer displays a hierarchical view of ADF event messages. The difference between these two pages is that the By ADF Request page focuses only on ADF page requests made when a page or region is submitted. For details about the ADF page lifecycle, see Chapter 27, "Understanding the Fusion Page Lifecycle."

---

You can enter search criteria in the By ADF Request page to display one or more specific requests from the log file. You can combine any of the following search criteria to filter the log file:

- The number of requests to display
- The timestamp for the request recorded in the log
- The logged-in user name, enterprise name, request header (to specify a search based on the page or region name), message, source class, module, server, detail, enterprise ID, ADF message data, application name in a composite application, source method, message ID, or ECID (a globally unique ID associate with every top-level task; sub-tasks invoked by that top-level task operate with an execution context that shares the same ECID)

After the request is completed, the log analyzer displays a summary of the ADF requests in a single table. Figure 42–7 shows the summary table that displays the list of ADF web requests.
Using the ADF Logger

**Figure 42–7  Oracle Diagnostic Log Analyzer Displays Summary of ADF Web Requests**

For each ADF request displayed in the summary table, you can click the request link to view details about the request event hierarchy. Figure 42–8 shows the ADF Requests panel with the JSF lifecycle Restore View and Render Response phases displayed and their duration in milliseconds. The bar graph for the root node of the request event hierarchy (ADF web request) displays the total execution time.

**Figure 42–8  Oracle Diagnostic Log Analyzer Displays ADF Web Request Event Hierarchy**

---

**Note:** The Percentage Request Time bar graphs (black and gray) indicate which portion of the request’s execution time resulted from ADF source code that was instrumented to generate ADF event messages (shown in black) and which portion resulted from ADF source code that is uninstrumented and therefore cannot generate ADF event messages (shown in gray). Additionally, note that the individual phases of the request do not sum to equal the total request time. This is due to the fact that only those phases of the lifecycle that are useful are represented in the log analyzer.

To examine the request in more detail, you can expand the tree for any ADF lifecycle node to further investigate where in the application the performance bottleneck occurred. Drilling down and then selecting the ADF event node in the request message.
Using the ADF Logger

Testing and Debugging ADF Components

Before you begin:
It may be helpful to have an understanding of logging. For more information, see Section 42.6, "Using the ADF Logger."

You will need to complete these tasks:

1. Set logging levels, as described in Section 42.6.1, "How to Set ADF Logging Levels."

   To log a complete hierarchy tree of ADF event messages, you must configure an ODL log level that is not more restrictive than NOTIFICATION:16 or a Java log level that is not more restrictive than CONFIG for the following single package:
   - oracle.adfdiagnostics will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

   **Tip:** The default log level for the Root Logger displayed by the editor for Oracle Diagnostics Logging Configuration ensures that ADF event messages are logged.

2. Enable logging, as described in Section 42.6.3, "How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers."

3. Create a log file, either from your test run or from another source.
To display ADF request messages in the log analyzer:

1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.
   Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, click the **By ADF Request** tab.

3. In the By ADF Request page, specify how many of the most recent request you want to display.
   The default displays only the most recent request.

4. Specify a time period for the entries you want to view. You can select the most recent **period** or a range.

5. To filter the request to display, use the search fields to query the log for a text pattern. For additional search fields, click the **Add Row** icon.

6. To initiate the filters and display matching ADF requests, click **Search**.

7. In the ADF Requests panel, click the desired request link to view the event hierarchy and look for ADF events that display long execution times as indicated by the **Time (ms)** bar graphs.

8. Select the desired ADF event and examine the ADF Message Data Details panel for details about the ADF component associated with the ADF event.

9. Examine the component in your application and determine whether optimization is possible.

### 42.6.4.3 Sorting Diagnostic Messages By ADF Events

Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases and during operations executed in the ADF Model data binding layer, ADF Controller source, and ADF Business Components source. Combined, the log analyzer refers to these messages as ADF events. You can use the log analyzer to investigate ADF events in your running application. The By Log Message page of the log analyzer lets you view ADF event messages in a flat list, organized by time of execution, with the option to switch to the By ADF Request page to view the ADF events in a hierarchical list, organized by the sequence of their execution.

ADF event messages contain useful information that helps you identify which ADF components in your application generated the event. For example, you can search the log for ADF event messages to identify the components related to displaying data in the page, executing queries, or initiating actions:

- **Executing iterator binding**: Displays the names of the iterators executed to manage displaying data in the page. This can be useful for diagnosing slow query updates.

- **Execute query**: Displays the name of the view object associated with the executed query. This can be useful when you want to view the query statement, bind parameters, and name of the view object.

- **Executing method binding**: Displays the names of the Java methods executed on the bound data source. This can be useful for diagnosing slow method execution.

After you display an ADF event message in the log analyzer, you can organize the event in the context of other logged messages. You can select options from the **Related** column to display:
All messages leading up to the ADF event (related by time)
All messages in the same web request as the ADF event (related by request)
Only ADF event messages in the same web request (related by ADF request)

Tip: The Related by ADF Request option displays detailed ADF data for the ADF event messages. This is the view to use, for example, when you want to display the query statement associated with the Execute query message.

Figure 42–10 shows the log analyzer search result for the ADF event message Create Application Module. The Results panel displays all messages that match the search criteria and the bottom panel displays detailed information about the component.

When you select Related by ADF Request in the Related column of the Results panel, the log analyzer switches to display the By ADF Request page with the ADF event messages arranged hierarchically to show their execution dependencies. The By ADF Request page of the log analyzer is the preferred way to diagnose performance issues. For details about the By ADF Request page, see Section 42.6.4.2, "Using the Log Analyzer to Analyze the ADF Request." In the By Log Message page, the elapsed time is information that you can leave visible or hide from the Results panel.

Before you begin:
It may be helpful to have an understanding of logging. For more information, see Section 42.6, "Using the ADF Logger."

You will need to complete these tasks:

1. Set logging levels, as described in Section 42.6.1, "How to Set ADF Logging Levels."

   To log ADF event messages, do not configure an ODL log level that is more restrictive than NOTIFICATION:16 or a Java log level that is more restrictive than CONFIG for the following package:
oracle.adfdiagnostics will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

**Tip:** The default log level for the Root Logger displayed by the editor for Oracle Diagnostics Logging Configuration ensures ADF event messages are logged.

2. Enable logging, as described in Section 42.6.3, "How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers."

3. Create a log file, either from your test run or from another source.

**To display messages related by ADF events:**

1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.
   Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, click the **By Log Message** tab.

3. In the By Log Message page, select the desired logger type, log levels, and log time.
   To search the log for ADF event messages, you must minimally select log level **Notification** (for ODL log level) or **Info** (for Java log level).

4. In the search dropdowns, choose the search criteria **Message** and **Contains**, and then enter any of the following ADF event messages and click **Search**.
   - Executing iterator binding - this can be useful for diagnosing slow query updates.
   - Executing method binding - this can be useful for diagnosing slow method execution.
   - Execute query - this can be useful when you want to view the query statement, bind parameters, and name of the view object.

You can also filter the log on these additional ADF event messages:

- Refreshing binding container
- Attaching an iterator binding to a datasource
- Converting rows into hierarchical nodes
- Estimated row count
- Get LOV list
- Filter LOV list
- Validate Entity
- Lock Entity’s Parent
- Lock Entity
- Before posting the entity's changes
- Posting the entity’s changes
- Posting in batches
Before committing the entity's changes
- After committing the entity's changes
- Before rolling back the entity's changes
- After rolling back the entity's changes
- Entity notifying an event
- Entity notification name
- Removing Entity
- Updating audit columns
- Applying Effective Date change
- Entity DML
- Entity read all attributes
- Create Application Module
- Create nested Application Module
- Passivating Application Module
- Activating Application Module
- Establish database connection
- Commit transaction
- Rollback transaction
- Validate transaction
- Validate value

Examine the data portion of the Results panel for the ADF event information.

5. To view a hierarchical sequence of ADF events, with the desired ADF event message selected in the Results panel, in the Related column, click the icon for the desired event row and choose Related By ADF Request from the dropdown menu.

The editor for Oracle Diagnostic Log Analyzer displays the By ADF Request page for the selected ADF event. Examine the bottom portion of the Results panel for additional ADF data for the ADF event. For example, you can see the query statement associated with the Execute query message in the ADF Data area of the Results panel.

42.6.5 What You May Need to Know About the Logging.xml File

By default, the level is set to WARNING for all Oracle loggers. For Oracle ADF packages set level="FINE" for detailed logging diagnostics.

For the ADF view layer packages oracle.adf.view.faces and oracle.adfinternal.view.faces, edit these elements:

```xml
<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.adfinternal" level="FINE"/>
```

For the ADF Model layer packages, edit these elements:

```xml
<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.jbo" level="FINE"/>
```
For the ADF Controller layer packages, edit these elements:

```xml
<logger name="oracle.adf.controller" level="FINE"/>
<logger name="oracle.adf.internal.controller" level="FINE"/>
```

Alternatively, you can create a debug configuration in JDeveloper that you can choose when you start a debugging session.

Example 42–2 shows the portion of the logging.xml file where you can change the granularity of the log messages. Note in the example that the log for oracle.adf.faces has been changed to FINE to display more messages.

**Example 42–2  Sample Section of the logging.xml Configuration File**

```xml
</logging_configuration>
...  
<loggers>
    <logger name="oracle.adf" level="INFO"/>
    <logger name="oracle.adf.faces" level="FINE"/>
    <logger name="oracle.adf.controller" level="INFO"/>
    <logger name="oracle.bc4j" level="INFO"/>
    <logger name="oracle.adf.portal" level="INFO"/>
    <logger name="oracle.vcr" level="INFO"/>
    <logger name="oracle.portlet" level="INFO"/>
    <logger name="oracle.adf.internal" level="INFO"/>
    <logger name="oracle.adfdt" level="INFO"/>
    <logger name="oracle.adfdt.internal" level="INFO"/>
</loggers>
</logging_configuration>
```

For the latest information about the different levels of the Java Logging system, go to [http://www.oracle.com/technetwork/java/index.html](http://www.oracle.com/technetwork/java/index.html). Normally, the Java logging system supports the following log levels:

- **SEVERE** (most restrictive, highest log level)
- **WARNING**
- **INFO**
- **CONFIG** (the highest low level supported for Oracle ADF)
- **FINE**
- **FINER**
- **FINEST** (least restrictive, lowest log level)

### 42.6.6 What You May Need to Know About ADF Logging and Oracle WebLogic Server

After you have deployed the Fusion web application to Oracle WebLogic Server, the operations performed by the application are logged directly to the Managed Server where the application is running:

```
DOMAIN_HOME/servers/server_name/logs/server_name-diagnostic.log
```

The log files for the different Managed Servers are also available from the Oracle WebLogic Server Administration Console. To verify the logs, access the Oracle WebLogic Server Administration Console [http://<admin_server_host>:<port>/console](http://<admin_server_host>:<port>/console) and click **Diagnostics-Log Files**.

This log’s granularity and logging properties can be changed using Oracle Enterprise Manager Fusion Middleware Control (Fusion Middleware Control).
Middleware Control is a web browser-based, graphical user interface that you can use to monitor and administer a farm.

When the Fusion web application is deployed to a high availability environment, you can receive warning diagnostic messages specific to high availability by setting the level to FINE.

For details about using Fusion Middleware Control to change the log settings of Managed Servers and Oracle ADF, see Administering Oracle Fusion Middleware.

42.7 Using the Oracle ADF Model Tester for Testing and Debugging

The Oracle ADF Model Tester (also referred to as the tester) is a Java application that you launch from JDeveloper when you want to interact with the business objects of the ADF Business Components data model project. The Oracle ADF Model Tester runs outside of JDeveloper and provides a full UI for testing and examining the data model project. You can run the tester to examine the view instances of the ADF application module, navigate the hierarchical relationship of view links, and execute custom methods from the application module’s client interface, view object interface, and view row interface. The tester also interacts with the ADF Declarative Debugger to allow you to set breakpoints on the custom methods of these interfaces.

Additionally, the tester simulates many features that the user interface might expose by allowing you to view, insert, and update the contents of business objects in the database specified by the application module’s configuration file (bc4j.xcfg). Specifically, you can use the tester to verify many aspects of the data model design, including master-detail relationships between view instance, view instances and their attributes, view instance query result sets, search forms using view criteria, validation rules defined for attribute values, and dropdown lists on LOV-defined attributes (list of values). For more information about ways to interact with the tester to test your business objects, see Section 8.3, ”Testing View Object Instances Using the Oracle ADF Model Tester.” Additional information about testing with the Oracle ADF Model Tester also appears in sections specific to each business object throughout the chapters in the ”Building Your Business Services” part of this book.

42.7.1 How to Run in Debug Mode and Test with the Oracle ADF Model Tester

Often you will find it useful to analyze and debug custom code in the service methods of your client interface implementation classes. When you use the Oracle ADF Model Tester, you can do this without needing to run the application with the user interface. You can use the Oracle ADF Model Tester as a testing tool to complement your debugging process.

**Caution:** The Oracle ADF Model Tester that you run in debug mode will not inherit your JDeveloper IDE Java options. To ensure that specific run/debug Java options are used with the tester, you must edit the run configuration for the data model project. You can modify the default run confirmation in the Run/Debug page of the Project Properties dialog.

**Before you begin:**

It may be helpful to have an understanding of the using the runtime testing tools. For more information, see Section 42.7, ”Using the Oracle ADF Model Tester for Testing and Debugging.”
You will need to complete these tasks:

1. Set the desired Java options for your preferred run configuration, as described in the “Running and Debugging Java Programs” chapter in Developing Web User Interfaces with Oracle ADF Faces.

2. Set breakpoints in the custom methods of your client interface, as described in Section 42.9, “Setting ADF Declarative Breakpoints.”

To launch the Oracle ADF Model Tester and go into debug mode:

1. In the Applications window, right-click the desired application module and choose Debug.

2. In the Oracle ADF Model Tester, open the method testing panel for the desired client interface, as described in Section 13.9.4, “How to Test Custom Service Methods Using the Oracle ADF Model Tester.”

3. In the method panel, select the desired method from the dropdown list, enter values to pass as method parameters, and click Execute.

Return to JDeveloper to step through your code using the ADF Declarative Debugger. When you complete method execution, the method panel displays the return value (if any) and test result. The result displayed in the Oracle ADF Model Tester will indicate whether or not the method executed successfully.

42.7.2 How to Run the Oracle ADF Model Tester and Test with a Specific Application Module Configuration

When you right-click the application module in the Applications window and choose Run or Debug, JDeveloper will run the Oracle ADF Model Tester using the default configuration defined for the application module. If you want to test your business components with a different application module configuration (which can specify a different data source and its own set of runtime parameters), you can do so from the overview editor for the bc4j.xcfg file. The file is not visible in the Applications window and is only accessible from the Configurations page of the overview editor for the application module.

To run the Oracle ADF Model Tester with a specific application module configuration:

1. In the Applications window, double-click the application module that you want to test.

2. In the overview editor, click the Configurations navigation tab and then click the bc4j.xcfg configuration file link.

3. In the overview editor, select the configuration from the Configurations list.

4. Right-click the selected configuration and choose Run or Debug to launch the Oracle ADF Model Tester.

42.7.3 What Happens When You Run the Oracle ADF Model Tester in Debug Mode

The Oracle ADF Model Tester behaves as any other Java program. Specifically, it does not inherit Java options that you may have specified for the JDeveloper IDE. The tester instead uses the run configuration that you have specified for the data model project and any Java options that you may have set in that configuration.

JDeveloper lets you run the Oracle ADF Model Tester in two modes: either in debug mode or non-debug mode. When run in debug mode, the tester interacts with the ADF
Declarative Debugger so that you execute custom methods using breakpoints you insert in custom code of the client interfaces. For instance, if you set a breakpoint on a method in the client interface and execute that method in the tester, then in debug mode, you can step through the code before the tester returns a success/fail result. In non-debug mode, the tester will immediately return a result to indicate whether the method executed successfully. Additionally, in either debug or non-debug mode, the tester can display runtime artifacts from the system catalog created at runtime for the application module.

**42.7.4 How to Verify Runtime Artifacts in the Oracle ADF Model Tester**

When you want to run the Oracle ADF Model Tester, but do not require the use of the ADF Declarative Debugger you can display information about the runtime artifacts from the application module’s system catalog. The system catalog displays business object metadata and other information that you may find useful when you need to compare business objects.

To launch the Oracle ADF Model Tester without debugging:
1. In the Applications window, right-click the desired application module and choose **Run**.
2. In the Oracle ADF Model Tester, choose **Create - Create SysCat AM**.
3. In the data model tree, expand the **SysCatAMDefs**, right-click **ViewDefs**, and choose **Show Table**.
4. In the data viewer, scroll vertically to locate the desired view instance in the **SCName** (system catalog name) field.

Exposing the system catalog in the tester allows access to metadata and other information specific to the runtime objects without running the debugger. For example, you can check whether a view instance has a custom Java implementation class or not.

**42.7.5 How to Refresh the Oracle ADF Model Tester with Application Changes**

The Oracle ADF Model Tester is a highly interactive tool. When you run the tester and determine a change is needed in the data model project, you can return to JDeveloper to edit the desired application module instances and refresh the Oracle ADF Model Tester data model to display the changes. This way you can verify your changes without needing to rerun the tester.

To reload application metadata in the Oracle ADF Model Tester:
1. In the data model project, edit your business objects and save the changes in the JDeveloper.
2. Recompile the data model project.
   For example, you can right-click the data model project in the Applications window and choose **Make** to complete the recompile step.
   Although the metadata changes that you make are not involved in compiling the project, the compile step is necessary to copy the metadata to the class path and to allow the Oracle ADF Model Tester to reload it.
3. In the Oracle ADF Model Tester, in the toolbar, click **Reload application metadata**.
   Alternatively, you can choose **Reload Application** from the **File** menu of the Oracle ADF Model Tester.
Using the ADF Declarative Debugger

42.8 Using the ADF Declarative Debugger

The ADF Declarative Debugger provides declarative breakpoints that you can set at the ADF object level (such as task flows, page definition executables, method and action bindings, ADF lifecycle phases), as well as standard Java breakpoints. ADF declarative breakpoints provide a high-level object view for debugging ADF applications. For example, you can break before a task flow activity to see what parameters would be passed to the task flow, as shown in Figure 42–11. To perform the same function using only Java breakpoints would require you to know which class or method to place the breakpoint in. ADF declarative breakpoints should be the first choice for ADF applications.

Figure 42–11 ADF Declarative Breakpoint on a Task Flow Activity

The ADF Declarative Debugger also supports standard Java code breakpoints. You can set Java code breakpoints in any ADF application. You may be able to use Java code breakpoints when an ADF declarative breakpoint does not break in the place you want.

The ADF Declarative Debugger is built on top of the Java debugger, so it has the features and behaviors of the Java debugger. But instead of needing to know the Java class or method, you can set ADF declarative breakpoints in visual editors.

The ADF Declarative Debugger provides standard debugging features such as the ability to examine variable and stack data. When an application pauses at any breakpoint (ADF Declarative or Java code breakpoint), you can examine the application status using a variety of windows. You can check where the break occurs in the Breakpoints window. You can check the call stack for the current thread using the Stack window. When you select a line in the Stack window, information in the Data window, Watches window, and all Inspector windows is updated to show relevant data. You can use the Data window to display information about arguments, local variables, and static fields in your application.

The ADF Structure window displays the runtime structure of the project. The ADF Data window automatically changes its display information based on the selection in the ADF Structure window. For example, if a task flow node is selected, the ADF Data window displays the relevant debugging information for task flows, as shown in Figure 42–12.
You can mix ADF declarative breakpoints with Java code breakpoints as needed in your debugging session. Although you can use step functions to advance the application from Java code breakpoint to Java code breakpoint, the step functions for ADF declarative breakpoints have more constraints and limitations. For more information about using step functions on ADF declarative breakpoints, see Table 42–3.

For information on how to use ADF declarative breakpoints, see Section 42.9, "Setting ADF Declarative Breakpoints."

For information on how to use Java breakpoints on classes and methods, see Section 42.10, "Setting Java Code Breakpoints."

In a JSF application (including Fusion web applications), when a breakpoint breaks, you can use the EL Evaluator to examine the value of an EL expression. The EL Evaluator has the browse function that helps you select the correct expression to evaluate. For more information, see Section 42.8.4, "How to Use the EL Expression Evaluator."

Whether you plan to use ADF declarative breakpoints or Java breakpoints, you can use the ADF Declarative Debugger with Oracle ADF source code. You can obtain Oracle ADF source code with Debug libraries. For more information about loading source code, see Section 42.8.1, "Using ADF Source Code with the Debugger."

### 42.8.1 Using ADF Source Code with the Debugger

If you have valid Oracle ADF support, you can obtain complete source code for Oracle ADF by opening a service request with Oracle Worldwide Support. You can request a specific version of the Oracle ADF source code. You may be given download and password information to decrypt the source code ZIP file. Contact Oracle Worldwide Support for more information.

Adding Oracle ADF source code access to your application debugging session will:

- Provide access to the JDeveloper Quick Javadoc feature in the source editor. Without the source code, you will have only standard Javadoc.
- Enhance the use of Java code breakpoints by displaying the Oracle source code that’s being executed when the breakpoint is encountered. You can also set breakpoints easier by clicking on the margin in the source code line you want to break on. Without the source code, you will have to know the class, method, or line number in order to set a breakpoint within Oracle code.
- For Java code breakpoints set within the source code, you will be able to see the values of all local variables and member fields in the debugger.
The ADF source code ZIP file may be delivered within an encrypted "outer" ZIP file to protect its contents during delivery. The "outer" ZIP name is sometimes a variant of the service request number.

After you have received or downloaded the "outer" ZIP archive file, unzip it with the provided password to access the actual source code ZIP file. The ADF source code ZIP name should be a variant of the Oracle ADF version number and build number. For example, the Oracle ADF source ZIP file may have a format similar to adf_vvvv_nnnn_source.zip, where vvvv is the version number and nnnn is the build number.

After you have access to the Oracle ADF source code ZIP file, extract its contents to a working directory.

42.8.2 How to Set Up the ADF Source User Library

You create a name for the source user library and then associate that name with the source ZIP file.

To add the ADF source zip file to the user library
1. In the main menu, choose Tools and then Manage Libraries.
2. In the Manage Libraries dialog, with the Libraries tab selected, click New.
3. In the Create Library window, enter a library name for the source that identifies the type of library.
4. Select the Source Path node in the tree structure. Click Add Entry.
5. In the Select Path Entry window, browse to the directory where the file was extracted and select the source ZIP file. Click Select.
6. In the Create Library window, verify that the source path entry has the correct path to the source ZIP file, and deselect Deployed by Default. Click OK.
7. Click OK.

42.8.3 How to Add the ADF Source Library to a Project

After the source library has been added to the list of available user libraries, add it to the project you want to debug.

To add the ADF source zip file to the project:
1. In the Applications window, double-click the project to which you want to add the ADF library or right-click the project and choose Project Properties.
2. In the Project Properties dialog, select Libraries and Classpaths.
3. Click Add Library.
4. In the Add Library dialog, under the Users node, select the source library you want to add and click OK.

The source library should appear in the Classpath Entries section in the Project Properties dialog.
5. Click OK.

42.8.4 How to Use the EL Expression Evaluator

When the application is paused at a breakpoint, you can use the EL expression evaluator to enter an EL expression for evaluation. You can enter arbitrary EL expressions for evaluation within the current context. If the EL expression no longer applies within the current context, the value will be evaluated to null.

The EL Evaluator is different from the Watches window in that EL evaluation occurs only when stopped at a breakpoint, not when stopped at subsequent debugging steps. The EL Evaluator is available for debugging any JSF application.

---

**Caution:** Be wary when you are evaluating EL expressions that you do not indirectly change application data and therefore the behavior of the application. For example, if you evaluate #{foo.bar}, the corresponding getBar() method modifies application data.

---

**Before you begin:**

It may be helpful to have an understanding of the ADF Declarative Debugger. For more information, see Section 42.8, "Using the ADF Declarative Debugger."

You will need to complete this task:

Set the desired breakpoints in the application, as described in Section 42.9, "Setting ADF Declarative Breakpoints." The application must be a JSF application. It does not need to be an ADF application.

**To use the EL Evaluator:**

1. Start the debugging process by using any of the following techniques.
   - In the main menu, choose Run and then Debug <project_name>.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose Debug.
   - From the task flow diagrammer, right-click an activity and choose Debug.
     Only task flows that do not use page fragments can be run.

2. When the breakpoint is reached, the EL Evaluator should appear as a tab in the debugger window area. Click the EL Evaluator tab to bring it forward. If it does not appear, in the main menu, choose Window and then Debugger > EL Evaluator.

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an Execution Point icon (red right arrow) next to the object breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

3. Enter an EL expression in the Expression input field.

When you click in the field after entering #{ or after a period, a discovery function provides a selectable list of expression items, as shown in Figure 42–13.
Auto-completion will be provided for easy entry. You can evaluate several EL expressions at the same time by separating them with semicolons.

**Figure 42–13 Using the Discovery Function of the EL Evaluator**

4. When you finish entering the EL expression, click **Evaluate** and the expression is evaluated, as shown in **Figure 42–14**.

**Figure 42–14 EL Expression Evaluated**

42.8.5 How to View and Export Stack Trace Information

If you are unable to determine what the problem is and you cannot resolve it yourself, typically your next step is to ask someone else for assistance. Whether you post a question in the OTN JDeveloper Discussion Forum or open a service request on Metalink, including the stack trace information in your posting is extremely useful to anyone who will need to assist you further to understand exactly where the problem is occurring.

JDeveloper's Stack window makes communicating this information easy. Whenever the debugger is paused, you can view the Stack window to see the program flow as a stack of method calls that got you to the current line. You can use the Preferences dialog to set the Stack window preference to include the line number information, as well as the class and method name that will be there by default. Finally, the Stack window context menu option **Export** lets you save the current stack information to an external text file whose contents you can then post or send to whomever might need to help you diagnose the problem.

**Before you begin:**

It may be helpful to have an understanding of the ADF Declarative Debugger. For more information, see Section 42.8, “Using the ADF Declarative Debugger.”

You will need to complete this task:
Set the desired breakpoints in the application, as described in Section 42.9, "Setting ADF Declarative Breakpoints." The application must be a JSF application. It does not need to be an ADF application.

**To save stack information to a text file:**

1. Start the debugging process by using any of the following techniques.
   - In the main menu, choose Run and then **Debug <project_name>**.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.

2. When the breakpoint is reached and the debugger is paused, the Stack window should appear as a window to the side of the debugger window area. Click the Stack tab to bring it forward. If the Stack window does not appear, in the main menu, choose **Window** and then **Debugger > Stack**.

3. When you want to change the Stack window preference for example to include the line number information in the export file, right-click the Stack window background and choose **Preferences**, as shown in Figure 42–15.

**Figure 42–15  Stack Window Context Menu**

4. Right-click the Stack window background and choose **Export**.

5. In the Export Stack dialog, name the file and choose the location where you want to save the file. Click **OK**.

**42.9 Setting ADF Declarative Breakpoints**

You use the ADF Declarative Debugger features in JDeveloper to declaratively set breakpoints on ADF task flow activities, page definition executables, method, action, and value bindings, ADF Lifecycle phases, and contextual events. Instead of needing to know all the internal constructs of the ADF code, such as method names and class names, you can set breakpoints at the highest level of object abstraction.

You can add breakpoints to task flow activities in the task flow diagrammer or you can launch the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window. In the task flow diagrammer, you can select a task flow activity and use the context menu to toggle or disable breakpoints on that activity, or press the F5 button. After the application pauses at the breakpoint, you can view the runtime structure of
the objects in the ADF Structure window as a tree structure. The ADF Data window displays a list of data for a given object selected in the ADF Structure window.

For example, when you set a breakpoint on a task flow call activity in the Browse Orders task flow, a red dot icon appears in the call activity, as shown in Figure 42–16.

**Figure 42–16  ADF Declarative Breakpoint on a Task Flow Activity**

![Diagram of ADF Declarative Breakpoint on a Task Flow Activity]

When the breakpoint is reached, the application is paused and the icon changes, as shown in Figure 42–17.

**Figure 42–17  Application Paused at an ADF Declarative Breakpoint**

![Diagram of Application Paused at an ADF Declarative Breakpoint]

Similarly, you can set Before and After breakpoints in the page definition file. You set breakpoints for supported value bindings (see Table 42–1 for the list of supported value binding) and for executables by clicking on the left or right margin next to the item or by selecting from the context menu. Clicking on the left margin adds a **Before page definition** breakpoint, and clicking on the right margin adds an **After page definition** breakpoint. Again, a red dot icon that indicates the breakpoint is set, as shown in Figure 42–18.
Figure 42–18  **ADF Declarative Breakpoints on ADF Bindings in the Page Definition File**

The page definition file also lets you set breakpoints on contextual events that your page or region within a page raises at runtime, as shown in Figure 42–19.

Figure 42–19  **ADF Declarative Breakpoint on a Contextual Event in the Page Definition File**

You can also set Before and After breakpoints on all the ADF lifecycle phases. You can launch the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window, as shown in Figure 42–20.

Figure 42–20  **Breakpoints Window Add Breakpoint Icon Dropdown Menu**

The Create ADF Lifecycle Phase Breakpoint dialog allows you to select different lifecycle breakpoint options, as shown in Figure 42–21.
Alternatively, you can use the ADF Lifecycle Breakpoints dialog from the ADF Structure window or the task flow diagrammer to set ADF lifecycle phase breakpoints. For more information about ADF lifecycle phases, see Chapter 27, "Understanding the Fusion Page Lifecycle."

You can define both ADF declarative breakpoints and standard Java code breakpoints when using the ADF Declarative Debugger. Depending on your debugging scenario, you may only need to use the declarative breakpoints to debug the application. Or you may find it necessary to add additional breakpoints in Java code that are not available declaratively. For information on Java code breakpoints, see Section 42.10.1, "How to Set Java Breakpoints on Classes and Methods." Table 42–1 lists the available ADF Declarative Debugger breakpoint locations.

</tbody>
</table>
The ADF Declarative Debugger uses the standard debugger icons and notations for setting, toggling, and indicating the status of ADF declarative breakpoints.

When an ADF declarative breakpoint is set, it appears as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window, as shown in Figure 42–22, Figure 42–23, Figure 42–24, and Figure 42–25.

The ADF Declarative Debugger uses the standard debugger icons and notations for setting, toggling, and indicating the status of ADF declarative breakpoints.

When an ADF declarative breakpoint is set, it appears as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window, as shown in Figure 42–22, Figure 42–23, Figure 42–24, and Figure 42–25.

<table>
<thead>
<tr>
<th>ADF Area</th>
<th>Breakpoint Type</th>
<th>Where Inserted</th>
<th>JDeveloper Context Menu Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADF page definition - contextual events</td>
<td>Break before / Break after contextual events</td>
<td>Page Definition overview editor, Contextual Events tab, Events section</td>
<td>Toggle Breakpoint or F5</td>
<td>Pauses debugging either before the event is dispatched or after the event, just before the event is consumed by a subscriber to the event.</td>
</tr>
<tr>
<td>ADF task flow</td>
<td>Break before activity</td>
<td>Task flow diagrammer, Breakpoints window Add button</td>
<td>Toggle Breakpoint or F5</td>
<td>Pauses debugging before the activity executes within the JSF Invoke Application phase. The activity where the declarative breakpoint is defined has not yet been executed. An exception are view activities; they pause within the JSF Render Response phase after the view activity is executed, but before the new page is rendered. By pausing at that point, the view activity values can be inspected using the ADF Structure and ADF Data windows.</td>
</tr>
</tbody>
</table>

The ADF Declarative Debugger uses the standard debugger icons and notations for setting, toggling, and indicating the status of ADF declarative breakpoints.

When an ADF declarative breakpoint is set, it appears as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window, as shown in Figure 42–22, Figure 42–23, Figure 42–24, and Figure 42–25.
When an ADF task flow or page definition declarative breakpoint is disabled, the red icon becomes a gray icon, as shown in Figure 42–26.

When an ADF task flow declarative breakpoint is active, the red dot icon has a green checkmark, as shown in Figure 42–27.

When the application is paused at an ADF declarative breakpoint, an Execution Point icon appears, as shown in Figure 42–28.

When the application is paused at an ADF lifecycle declarative breakpoint, an Execution Point icon appears next to the lifecycle phase in the ADF Lifecycle Breakpoints window, as shown in Figure 42–29. The name of the current ADF lifecycle phase is also displayed in the ADF Structure window.
Setting ADF Declarative Breakpoints

The Breakpoints window list all breakpoints, including ADF declarative breakpoints, as shown in Figure 42–30.

The Breakpoints window has a toolbar that includes buttons to add, edit, delete, enable, and disable breakpoints, as shown in Figure 42–30. The Add Breakpoint icon dropdown menu includes functions to create and manage ADF contextual events breakpoints, ADF lifecycle phase breakpoints, ADF page definition breakpoints (for ADF bindings and executables), ADF task flow activity breakpoints, and standard Java code breakpoints.

You can use the Breakpoints window to view the location of the ADF declarative breakpoint in its corresponding source file:

- Double-click a contextual event breakpoint to open the overview editor for the corresponding page definition file. You can then click the Contextual Events tab to view the location of the breakpoint.
- Double-click an ADF lifecycle phase breakpoint to open the ADF Lifecycle Breakpoints window which displays all ADF lifecycle execution points.
- Double-click a task flow activity breakpoint to open the task flow diagrammer for the corresponding task flow.
- Double-click an ADF binding breakpoint to open the overview editor for the corresponding page definition file.

To manage how the debugger handles a breakpoint, you can open the Edit ADF Breakpoint dialog for individual breakpoints that appear in the Breakpoints window. Or, you can select multiple ADF declarative breakpoints and customize the behavior of their common fields.

Table 42–2 lists how an ADF declarative breakpoint will appear in the Breakpoints window under the Description and Type columns.
**Table 42–2** Breakpoints Window Display of ADF Declarative Breakpoints

<tr>
<td>Step Over (F8)</td>
<td>Supported for task flow activity declarative breakpoints to step from activity to activity within a task flow. If user interaction is required (for example, page displayed), once it is received (for example, button selected), processing will resume and then will pause before the next task flow activity. supported for page definition executable breakpoints. The application will step to the next page definition executable breakpoint. Supported for ADF lifecycle phase declarative breakpoints to step to the next Before or After ADF lifecycle phase location.</td>
</tr>
<tr>
<td>Step Into (F7)</td>
<td>Supported only for task flow activity declarative breakpoints defined on task flow call activities. Task flow activity declarative breakpoints pause the application just before the activity is executed. The Step Into function provides the ability to pause debugging just prior to executing the called task flow default activity. This action would be the same as placing a task flow activity declarative breakpoint on the called task flow default activity.</td>
</tr>
</tbody>
</table>
42.9.1 How to Set and Use Task Flow Activity Breakpoints

After you have created a task flow diagram, you can set ADF declarative breakpoints on task flow activities.

Before you begin:
It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Section 42.9, “Setting ADF Declarative Breakpoints.”

To set a breakpoint on a task flow activity:
1. Open the task flow in the task flow diagrammer, or from the Breakpoints window, click the Add icon and select ADF Task Flow Activity Breakpoint.
   If the Breakpoints window is not already displayed, in the main menu, choose Window and then Breakpoints.
2. Set the task flow activity breakpoint.
   ■ If you use the task flow diagrammer, right-click and choose Toggle Breakpoint from the context menu, or press F5.
      A breakpoint icon appears on the task flow activity.
   ■ If you launched the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window, click Browse to select a task flow definition, select the task flow from the Task Flow dropdown list, select the task flow activity from the Activity dropdown list, and click OK.
3. Optionally, configure a breakpoint’s settings to manage the debugger:
   a. In the main menu, choose Window and then Breakpoints.
   b. In the Breakpoints window, select the task flow activity breakpoint you want to configure and click the Edit icon.
   c. In the Edit ADF Task Flow Activity Breakpoint dialog, click the Conditions tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the Actions tab, specify the actions that you want the debugger to take when the breakpoint occurs and click OK.

Table 42–3 (Cont.) ADF Declarative Debugger Step Commands

<table>
<thead>
<tr>
<th>ADF Debugger Step Commands</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Step Out (Shift F7)</td>
<td>Supported for task flow activity declarative breakpoints to step out of the current called task flow and back into the caller (if any). If user interaction is required (for example, page displayed) once user interaction received (for example, button selected), processing will resume and will pause before the next user interaction or activity within the calling task flow.</td>
</tr>
<tr>
<td>Continue Step (Shift F8)</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Step to End of Method</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Run to Cursor</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Pop Frame</td>
<td>Not supported for declarative breakpoints, as it is for Java code, to return to a previous point of execution.</td>
</tr>
</tbody>
</table>

42.9.1 How to Set and Use Task Flow Activity Breakpoints

After you have created a task flow diagram, you can set ADF declarative breakpoints on task flow activities.

Before you begin:
It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Section 42.9, “Setting ADF Declarative Breakpoints.”

To set a breakpoint on a task flow activity:
1. Open the task flow in the task flow diagrammer, or from the Breakpoints window, click the Add icon and select ADF Task Flow Activity Breakpoint.
   If the Breakpoints window is not already displayed, in the main menu, choose Window and then Breakpoints.
2. Set the task flow activity breakpoint.
   ■ If you use the task flow diagrammer, right-click and choose Toggle Breakpoint from the context menu, or press F5.
      A breakpoint icon appears on the task flow activity.
   ■ If you launched the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window, click Browse to select a task flow definition, select the task flow from the Task Flow dropdown list, select the task flow activity from the Activity dropdown list, and click OK.
3. Optionally, configure a breakpoint’s settings to manage the debugger:
   a. In the main menu, choose Window and then Breakpoints.
   b. In the Breakpoints window, select the task flow activity breakpoint you want to configure and click the Edit icon.
   c. In the Edit ADF Task Flow Activity Breakpoint dialog, click the Conditions tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the Actions tab, specify the actions that you want the debugger to take when the breakpoint occurs and click OK.

Table 42–3 (Cont.) ADF Declarative Debugger Step Commands

<table>
<thead>
<tr>
<th>ADF Debugger Step Commands</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Step Out (Shift F7)</td>
<td>Supported for task flow activity declarative breakpoints to step out of the current called task flow and back into the caller (if any). If user interaction is required (for example, page displayed) once user interaction received (for example, button selected), processing will resume and will pause before the next user interaction or activity within the calling task flow.</td>
</tr>
<tr>
<td>Continue Step (Shift F8)</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Step to End of Method</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Run to Cursor</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Pop Frame</td>
<td>Not supported for declarative breakpoints, as it is for Java code, to return to a previous point of execution.</td>
</tr>
</tbody>
</table>
For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.
   - In the main menu, choose Run and then Debug <project_name>.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose Debug.
   - From the task flow diagrammer, right-click an activity and choose Debug. Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an Execution Point icon (red right arrow) appears next to the breakpoint icon on the task flow activity. You can examine the application using various debugger windows.

   Task flow activity declarative breakpoints pause the application just before the task flow activity is executed (except for view activities).

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See Section 42.9.7, “How to Use the ADF Structure Window,” and Section 42.9.8, “How to Use the ADF Data Window.”

7. In the ADF Structure window, select a node and view pertinent information in the ADF Data window.

   Task flow activity declarative breakpoints pause the application just before the task flow activity is executed. You can use the Step Into (F7) function to pause the application just prior to executing the called task flow default activity.

8. Continue debugging the application as required, using the step functions as described in Table 42–3. The key step function is Step Into (F7).

   When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

42.9.2 How to Set and Use Page Definition Executable Breakpoints

   If your page definition has executables, you can set breakpoints to pause the application before or after these executables. For example, you can set breakpoints to pause the application when iterators are refreshed.
Before you begin:
It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Section 42.9, "Setting ADF Declarative Breakpoints."

To set a breakpoint on an executable in the page definition file:
1. In the Applications window, double-click the page definition file that contains the executable in which you want to set a breakpoint.

2. In the overview editor, click the Bindings and Executables tab, select an executable from the Executables list, and click in the breakpoint margin to the left of the item.
   A breakpoint icon appears in the margin next to the item.

3. Optionally, configure a breakpoint’s settings to manage the debugger:
   a. In the main menu, choose Window and then Breakpoints.
   b. In the Breakpoints window, select the executable breakpoint you want to configure and click the Edit icon.
   c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the Conditions tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the Actions tab, specify the actions that you want the debugger to take when the breakpoint occurs and click OK.

   For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.
   ■ In the main menu, choose Run and then Debug <project_name>.
   ■ From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose Debug.
   ■ From the task flow diagrammer, right-click an activity and choose Debug. Only task flows that do not use page fragments can be run.
5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears in the margin next to the breakpoint icon of the executable item. You can examine the application using several debugger windows.

The application pauses when the executable binding is refreshed. If this is a taskFlow executable, the pause occurs in the `prepareModel` and the `prepareRender` lifecycles.

---

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Executable Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

---

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See Section 42.9.7, "How to Use the ADF Structure Window," and Section 42.9.8, "How to Use the ADF Data Window."

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 42.9.3 How to Set and Use Page Definition Action Binding Breakpoints

You can set breakpoints in the page definition file on action bindings and `methodAction` bindings. The application pauses when the binding is executed.

**Before you begin:**

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Section 42.9, "Setting ADF Declarative Breakpoints."

**To set a breakpoint on an action binding in the page definition file:**

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.

2. In the overview editor, click the **Bindings and Executables** tab, select a `methodAction` binding or built-in operation item from the **Bindings** list, and click in the breakpoint margin to the left of the item.

   A breakpoint icon appears next to the item.

3. Optionally, configure a breakpoint’s settings to manage the debugger:

   a. In the main menu, choose **Window** and then **Breakpoints**.

   b. In the Breakpoints window, select the action binding breakpoint you want to configure and click the **Edit** icon.

   c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
Setting ADF Declarative Breakpoints

42.9.4 How to Set and Use Page Definition Value Binding Breakpoints

If the page definition has one of these values bindings, you can set breakpoints to pause the application:

- Attribute value binding
- Tree value binding
- Table value binding

Before you begin:
It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Section 42.9, "Setting ADF Declarative Breakpoints."

4. Start the debugging process by using any of the following techniques.

- In the main menu, choose Run and then Debug <project_name>.
- From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose Debug.
- From the task flow diagrammer, right-click an activity and choose Debug. Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an Execution Point icon (red right arrow) appears next to the breakpoint icon on the action binding item. You can examine the application using several debugger windows.

The application is paused when the binding is executed.

Note: Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an Execution Point icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See Section 42.9.7, "How to Use the ADF Structure Window," and Section 42.9.8, "How to Use the ADF Data Window."

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

d. Click the Actions tab, specify the actions that you want the debugger to take when the breakpoint occurs and click OK.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.
To set a breakpoint on a value binding in the page definition file:

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.

2. In the overview editor, click the **Bindings and Executables** tab, select an attribute, tree, or table binding from the **Bindings** list, and click in the breakpoint margin to the left of the item. A breakpoint icon appears next to the value binding.

3. Optionally, configure a breakpoint’s settings to manage the debugger:
   a. In the main menu, choose **Window** and then **Breakpoints**.
   b. In the Breakpoints window, select the binding breakpoint you want to configure and click the **Edit** icon.
   c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

   For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug <project_name>**.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**.
   Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the attribute value binding. You can examine the application using several debugger windows.

   The application pauses before an appropriate method of the ADF source code executes, as described in Table 42–1. New values will be the parameters that go into the method.

   **Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See Section 42.9.7, "How to Use the ADF Structure Window," and Section 42.9.8, "How to Use the ADF Data Window."

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.
8. Continue debugging the application as required, using the step functions as described in Table 42–3. The key step function is Step Over (F8).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 42.9.5 How to Set and Use Page Definition Contextual Event Breakpoints

If the page definition defines contextual events, you can set breakpoints on the contextual events to pause the application.

**Before you begin:**

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Section 42.9, "Setting ADF Declarative Breakpoints."

**To set a breakpoint on a contextual event in the page definition file:**

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.

2. In the overview editor, click the **Contextual Events** tab, select a contextual event from the **Events** list, and click in the breakpoint margin to the left of the item. A breakpoint icon appears next to the contextual event.

3. Optionally, configure a breakpoint’s settings to manage the debugger:
   a. In the main menu, choose **Window** and then **Breakpoints**.
   b. In the Breakpoints window, select the contextual event breakpoint you want to configure and click the **Edit** icon.
   c. In the Edit ADF Contextual Events Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

   For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug <project_name>**.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**.
     Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the contextual event. You can examine the application using several debugger windows.

The application pauses before the contextual event is raised.
6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See Section 42.9.7, "How to Use the ADF Structure Window," and Section 42.9.8, "How to Use the ADF Data Window."

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

8. Continue debugging the application as required, using the step functions as described in Table 42–3. The key step function is Step Over (F8).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

42.9.6 How to Set and Use ADF Lifecycle Phase Breakpoints

You can set both Before and After ADF lifecycle phase breakpoints on any of the ADF lifecycle phases. For each phase, you can set Before only, After only, or both. You can set breakpoints on as many phases as you want.

You can create the breakpoint and customize the options using the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window menu. Or You can create breakpoints with the default options using the ADF Lifecycle Breakpoints window. After a lifecycle breakpoint has been set, you can edit the options using the Edit ADF Lifecycle Phase Breakpoint dialog, which is also launched from the Breakpoints window.

You can set ADF lifecycle breakpoints on any of the ADF lifecycle phases:

- JSF Restore View
- Initialize Content
- Prepare Model
- JSF Apply Request Values
- JSF Process Validations
- JSF Update Model Values
- Validate Model Updates
- JSF Invoke Application
- Metadata Commit
- Prepare Render
- JSF Render Response

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an Execution Point icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.
Before you begin:
It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Section 42.9, "Setting ADF Declarative Breakpoints."

To set or manage an ADF lifecycle phase breakpoint from the Breakpoints window:
1. In the main menu, choose Window and then Breakpoints.
2. In the Breakpoints window, click Add and choose ADF Lifecycle Phase Breakpoint.
3. In the Create ADF Lifecycle Phase Breakpoint dialog Definition tab:
   ■ Select the ADF lifecycle phase where you want to set a breakpoint
   ■ Select Before Phase or After Phase breakpoint
4. In the Conditions tab, select the options you want and click OK.
5. In the Actions tab, select the options you want and click OK.

To set an ADF Lifecycle Phase Breakpoint using the breakpoint icon:
1. In the Applications window, double-click any task flow configuration file and in the overview editor click the Diagram tab.
2. In the toolbar of the task flow diagrammer or in the title bar of ADF Structure window, click the ADF Lifecycle Breakpoints icon, as shown in Figure 42–31.

Figure 42–31  ADF Lifecycle Breakpoints Icon

3. In the ADF Lifecycle Breakpoints window, click in the left margin next to the ADF lifecycle phase to set a Before breakpoint, and on the right margin to set an After breakpoint. A red dot icon appears to indicate the breakpoint is set, as shown in Figure 42–32. The breakpoint will be set with the default breakpoint options. To remove the breakpoint, click the red dot icon.

Figure 42–32  Setting Breakpoints in the ADF Lifecycle Breakpoints Window

4. If you want to edit breakpoint options, select the breakpoint in the Breakpoints window and click the Edit icon.

To debug an application using ADF Lifecycle Phase Breakpoints:
1. Start the debugging process by using any of the following techniques.
Setting ADF Declarative Breakpoints

- In the main menu, choose **Run** and then **Debug <project_name>**.
- From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
- From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.

2. When the application is paused at an ADF lifecycle phase breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon and the ADF lifecycle phase is in bold in the ADF Lifecycle Breakpoints window, as shown in **Figure 42–33**. You can examine the application using several debugger windows.

**Figure 42–33 Execution Point Displayed in the ADF Lifecycle Breakpoints Window**

![Figure 42–33 Execution Point Displayed in the ADF Lifecycle Breakpoints Window](image)

**Note:** Be sure that the application has actually hit a breakpoint by checking the Breakpoints window for a breakpoint encounter or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

3. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. The current ADF lifecycle phase is displayed at the top of the ADF Structure window. For more information, see **Section 42.9.7, “How to Use the ADF Structure Window,”** and **Section 42.9.8, “How to Use the ADF Data Window.”**

4. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

5. Continue debugging the application as required, using the step functions as described in **Table 42–3**. The key step function is **Step Over (F8)**. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

**42.9.7 How to Use the ADF Structure Window**

When the application is paused at a breakpoint, the ADF Structure window displays a tree structure of the ADF runtime objects and their relationships within the application. In particular, it shows the hierarchy of view ports, which represent either the main browser window or contained regions and portlets. When you select different items in the ADF Structure window, the data display in the accompanying ADF Data
window changes. For more information about the ADF Data window, see Section 42.9.8, "How to Use the ADF Data Window."

The ADF Structure window and the ADF Data window are shown by default during a debugging session when either of the following is true:

- The project being debugged contains a WEB-INF/afdc-config.xml file.
- The project being debugged contains any ADF Faces tag libraries.

You can launch the ADF Structure window by choosing Window > Debugger > ADF Structure in the main menu. From the ADF Structure window, you can launch the ADF Lifecycle Breakpoints window using the ADF Lifecycle Breakpoints icon.

When a breakpoint is encountered, the ADF Structure window displays the ADF lifecycle phase and a tree structure of the runtime objects, as shown in Figure 42–34.

Figure 42–34  ADF Structure Window Showing the Runtime Objects

When you select an item in the ADF Structure window, the data and values associated with that item are displayed in the ADF Data window. Figure 42–35 shows a task flow selected in the ADF Structure window, with its corresponding information displayed in the ADF Data window.

Figure 42–35  ADF Structure Window Selection and ADF Data Window Data

The roots of the hierarchy are the sibling nodes Scopes and ADF Context. The current view port where processing has stopped appears in bold. Default selections within the tree will be retained from the previous breakpoint, so you can monitor any changes.
Setting ADF Declarative Breakpoints

between breakpoints. The ADF object where the ADF declarative breakpoint was defined will be opened in the corresponding JDeveloper editor, either the task flow diagrammer or the overview editor for page definition files.

The ADF Structure tree will be rebuilt each time the application breaks and at subsequent steps to reflect the changed state of the objects. Although the entire tree hierarchy will be displayed, only items within the current view port and its parent view port(s) will be available for selection and further inspection. All other items in the tree hierarchy not in the current context will be dimmed and disabled. You can still use the hierarchy to identify runtime object relationships within the application, but it will be limited to the current context (and its parent view ports).

Table 42–4 lists the different types of items that can be displayed in the ADF Structure window hierarchy tree.

<table>
<thead>
<tr>
<th>ADF Structure Tree Item</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Scopes</td>
<td>Displayed at the top of the ADF Structure hierarchy above its sibling ADF Context node. There is only one Scopes node in the ADF Structure hierarchy. You can expand the Scopes node to show a list of child scope nodes (such as viewScope and pageFlowScope). If you select a child scope node, the ADF Data window displays the variables and values for that scope.</td>
</tr>
<tr>
<td>ADF context</td>
<td>Displayed as the root node of the ADF Structure hierarchy below its sibling Scopes node. There will only be one ADF Context within the ADF Structure hierarchy.</td>
</tr>
<tr>
<td>View port</td>
<td>View ports are an ADF Controller concept. For this reason, view ports appear within the ADF Structure hierarchy only when the application being debugged utilizes ADF Controller. View ports can represent one of the following:</td>
</tr>
<tr>
<td></td>
<td>- Browser: Main browser view ports, also known as root view ports, appear as children of the root ADF Context. If multiple browser windows are open during the debugging runtime session, multiple browser view ports are presented within the hierarchy. The label of each browser view port displays the text &quot;Browser&quot;. The view port also provides a tooltip for the view port ID similar to the following example: &quot;Root View Port: 999999&quot;.</td>
</tr>
<tr>
<td></td>
<td>- Region: Region view ports appear as the children of page or page fragments. They are also known as child view ports. The label of each region view port displays the text &quot;Region&quot;. The region also provides a tooltip for the view port ID similar to the following example: &quot;Child View Port: 999999&quot;.</td>
</tr>
<tr>
<td>ADF task flows</td>
<td>The page flow stack corresponding to each view port appears as a hierarchy of ADF task flows. The initial ADF task flow called for the stack is a direct child of its corresponding view port. The label of each ADF task flow reflects the corresponding ADF task flow display name (if any) or its task flow ID. Region view ports will not display the item in their page flow stack hierarchy for their implied unbounded task flow. The task flow also provides a tooltip displaying the ADF task flow path, and a context menu item to open to the corresponding ADF task flow within the editor workspace. If ADF Controller is not utilized in the application (or if the page is run outside the context of an ADF task flow), ADF task flows will not appear within the hierarchy.</td>
</tr>
<tr>
<td>Page</td>
<td>Represents the page (view) currently displayed within a browser view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, pages will be children of each browser view port. The label of each page reflects its corresponding runtime view ID. The page also provides a tooltip displaying the page path, and a context menu item to open to the corresponding page within the editor workspace. If a visual user interface is not implemented for the application, the page will not appear within the hierarchy.</td>
</tr>
</tbody>
</table>
When an application is paused at an ADF declarative breakpoint, the ADF Data window displays relevant data based on the selection in the ADF Structure window. You can launch the ADF Data window by choosing Window > Debugger > ADF Data in the main menu. The content of the ADF Data window based on the selection in the ADF Structure window is summarized in Table 42–5.

### Table 42–4 (Cont.) ADF Structure Window Items

<table>
<thead>
<tr>
<th>ADF Structure Tree Item</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Page fragment</td>
<td>Represents the page fragment currently displayed within a region view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, page fragments will be children of each region view port. The label of each page fragment node reflects its corresponding runtime view ID. The page fragment also provides a tooltip displaying the source file page definition path, and a context menu item to open to the corresponding page fragment within the editor workspace.</td>
</tr>
<tr>
<td>Binding container</td>
<td>Represents the binding container for the corresponding page or page fragment. The label of each binding container reflects its corresponding file name (page definition file) without the extension. The binding container node will also provide a tooltip displaying the page fragment path. The binding container also appears under current task flows when used to represent task flow activity bindings (for example, method call activity bindings). If ADF Model is not utilized for the application, binding containers will not appear.</td>
</tr>
<tr>
<td>Application data</td>
<td>Represents the application data objects (for example, ADF Business Components objects or ADF Business Components business service objects) instantiated within the data control frame for the corresponding view port (or binding container if ADF Controller is not used). Application data objects don’t need to be currently instantiated for the Application Data node to appear.</td>
</tr>
</tbody>
</table>

### 42.9.8 How to Use the ADF Data Window

When an application is paused at an ADF declarative breakpoint, the ADF Data window displays relevant data based on the selection in the ADF Structure window. You can launch the ADF Data window by choosing Window > Debugger > ADF Data in the main menu. The content of the ADF Data window based on the selection in the ADF Structure window is summarized in Table 42–5.

### Table 42–5 ADF Data Window Content for an ADF Structure Window Selection

<table>
<thead>
<tr>
<th>ADF Structure Window</th>
<th>ADF Data Content</th>
</tr>
</thead>
<tbody>
<tr>
<td>Scopes</td>
<td>Displays memory scope values based on the current context. pageFlowScope will also appear within ADF task flow content for the pageFlowScope values specific to a selected ADF task flow (not necessarily the current context). viewScope will also appear within the view port content for the viewScope values specific to a selected view port (not necessarily the current context).</td>
</tr>
<tr>
<td>ADF context</td>
<td>Displays the ADF context variables and values hierarchy. ADF context variables and values can be inspected by evaluating the #(data.adfContext) EL expression in the EL Evaluator.</td>
</tr>
<tr>
<td>View port</td>
<td>Displays view port details, including the viewScope contents.</td>
</tr>
<tr>
<td>Page flow stack entry</td>
<td>Displays information for the selected page flow stack entry, including current transaction status and ADF Model save point status.</td>
</tr>
<tr>
<td>Page/page fragment</td>
<td>Displays the page or page fragment UI component tree hierarchy for the selected page or page fragment if the page or page fragment has been rendered.</td>
</tr>
<tr>
<td>Binding container</td>
<td>Displays the binding container runtime values, including parameters, bindings, and executables.</td>
</tr>
<tr>
<td>Application data</td>
<td>Displays application data objects (for example, ADF Business Components objects) instantiated within the current binding context. If the business service layer is implemented with a technology other than ADF Business Components objects (for example, EJB) the application data objects will be displayed in a more generic form.</td>
</tr>
</tbody>
</table>
The **Scopes** node in the ADF Structure window can be expanded to show a list of child scope nodes. When a child scope node is selected in the ADF Structure window, the ADF Data window displays the current context values for the selected memory scope, as shown in **Figure 42–36**.

**Figure 42–36  Child Scope Selected in the ADF Structure Window**

If the **Scopes** node itself is selected, then the full list of memory scopes appears also in the ADF Data windows, which can also be expanded for inspection. **Figure 42–37** shows the **Scopes** node selected in the ADF Structure window, and the **viewScope** child node being selected with its values displayed in the ADF Data window. You can inspect the values of **requestScope**, **viewScope**, **pageFlowScope**, **applicationScope**, and **sessionScope** by expanding each corresponding node. **pageFlowScope** will also appear within the ADF Task Flow content to reflect the values of the specific ADF task flow currently selected in the ADF Structure window. **viewScope** will also appear within the view port content to reflect the values of the specific view port currently selected in the ADF Structure window.

**Figure 42–37  Scopes Node Selected in the ADF Structure Window**

When the ADF context is selected in the ADF Structure window, as shown in **Figure 42–38**, the current value of the ADF context variables will be displayed in the ADF Data window. You can also inspect ADF context variables and values by evaluating the `#{data.adfContext}` EL expression in the EL Evaluator. For more information, see Section 42.8.4, "How to Use the EL Expression Evaluator."

---

42-54  Developing Fusion Web Applications with Oracle Application Development Framework
Selecting a view port within the ADF Structure hierarchy will display the view port's current view port details in the ADF Data window, as shown in Figure 42–39. Values displayed for each view port are summarized in Table 42–6.

### Figure 42–39  View Port Selected for the ADF Data Window

<td>Displayed for bounded task flows and not displayed for unbounded task flows. Current ADF task flow on the view port’s page flow stack. Appears as a link to open the corresponding task flow definition in the editor workspace.</td>
</tr>
<tr>
<td>View activity ID</td>
<td>Current ADF task flow view activity ID. Applicable only if the current ADF task flow activity is a view activity.</td>
</tr>
<tr>
<td>Submitted activity ID</td>
<td>ADF task flow activity submitting the current request.</td>
</tr>
<tr>
<td>Final activity ID</td>
<td>ADF task flow activity receiving the current request.</td>
</tr>
</tbody>
</table>
In the ADF Structure window, each individual ADF task flow within a page flow stack hierarchy is selectable. An ADF task flow selected in the ADF Structure window will display the current task flow information in the ADF Data window, as shown in Figure 42–40. Task flow templates utilized by the selected ADF task flow will be determined by manually navigating to the ADF task flow source file. This is the same way similar functionalities are handled for Java source files. Current information for a selected ADF task flow is summarized in Table 42–7.

Figure 42–40 Task Flow Selected for the ADF Data Window

</tbody>
</table>
When you select a page or page fragment node in the ADF Structure hierarchy, the corresponding UI component tree is displayed within the ADF Data window, as shown in Figure 42–41. If a page or page fragment is based on a page template, you can include the content coming from the page template outside any facet reference elements by selecting the Include Page Template Content checkbox at the top of the ADF Data window. If the page template content is not included, the page or page fragment UI component tree will appear structurally similar to its source file.

Table 42–8  ADF Data Window Content for Binding Container

<table>
<thead>
<tr>
<th>Binding Container</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Page definition link</td>
<td>Navigates to the corresponding page definition source file and opens it within the editor workspace.</td>
</tr>
</tbody>
</table>
Setting ADF Declarative Breakpoints

Data Controls Displays the binding container’s data controls.

Data controls implemented by ADF Business Components objects and non-ADF Business Components objects will be presented slightly different. ADF Business Components-based data controls will appear similar to the actual business service implementation using row collections. Non-ADF Business Components-based data controls will typically appear as raw member variables similar to what is displayed in the ADF Declarative Debugger Data window. The ADF Data window shows only cached information such as member variables and arrays. Standard debugger functionality can also be used to customize each element.

Each ADF Business Components data control will display the following information:

- Row collections
- Query string for each row collection
- Query string with variable substitution for each row collection
- Application data rows
- Current row indicator
- Change indicator
- Current and original values (if changed within the same request)

Parameters Current values of all binding container parameters.

Executables Displays executables showing current row indicators, and current and original values (if changed within the same request). This includes the following types of executables:

- Iterator - presents corresponding attribute bindings along with their Refresh and RefreshCondition properties.
- task flow - current value of the task flow ID assigned to the task flow binding and all of its associated parameter values. Task flow IDs will appear as links navigating to open the corresponding task flow definition source file within the editor workspace. Link text consists of `<task flow source document>=<task flow id>`.
- Search region - presented similar to iterators, but also displays criteria and criteria with substitution information.

Bindings Displays value, table, tree, and method bindings. Each binding will display the following information:

- Associated executables
- Change indicator
- Current and original values (if changed within the same request)

Binding container of page template If the corresponding page or page fragment utilized a page template, the binding container of the page template will appear as a child of page or page fragment binding container content.

<table>

<td>Binding container of page template</td>
<td>If the corresponding page or page fragment utilized a page template, the binding container of the page template will appear as a child of page or page fragment binding container content.</td>
</tr>
</tbody>
</table>
When you select a binding container for an application based on non-ADF Business Components objects, the ADF Data window displays the binding container content, as shown in Figure 42–1.

*Figure 42–42  Binding Container (Non-Business Components) Selected for the ADF Data Window*

When you select a binding container for an application based on ADF Business Components objects, the ADF Data window displays standard row collection icons, as shown in Figure 42–2.

*Figure 42–43  Binding Container (Business Components) Selected for the ADF Data Window*

Expanding the Parameters node in the ADF Data window displays information similar to that shown in Figure 42–44.
Expanding the Executables node in the ADF Data window displays information similar to that shown in Figure 42–45.

If a value has changed, the changed item will be marked with a blue dot to its left and the previous value is displayed in parenthesis. For instance, suppose the OrderTotal value has changed from 7895.81 to 7670.11. The ADF Data window places a blue dot next to OrderTotal and its parent OrdersView1Iterator and displays the current and previous values in the Value column, as shown in Figure 42–46.
Setting ADF Declarative Breakpoints

Testing and Debugging ADF Components

Figure 42–46  A Value Change Is Indicated by a Blue Dot in the ADF Data Window

Method binding information is displayed in the ADF Data window similar to what is shown in Figure 42–47.

Figure 42–47  Method Bindings Selected for the ADF Data Window

When you select an Application Data node from the ADF Structure window, the ADF Data window displays the application objects, such as ADF Business Components objects, instantiated within the current data control frame for the corresponding view port (or binding context if ADF Controller is not used).

Business services implemented by ADF Business Components objects display the application data content, as shown in Figure 42–48 and described in Table 42–9.
Figure 42–48  Application Data for ADF Business Components Business Services

</tbody>
</table>
Setting ADF Declarative Breakpoints

42.9.9 What Happens When You Set an ADF Declarative Breakpoint

When you set an ADF declarative breakpoint, JDeveloper adds the breakpoint to the appropriate class, method, or other construct in the ADF source Java code that

---

**Table 42–9 (Cont.) ADF Data Window Content for Application Data**

<table>
<thead>
<tr>
<th>Binding Container</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>View object</td>
<td>View objects instantiated within the corresponding view port data control frame will appear underneath the corresponding application module root node as subordinate nodes. Design time icons will be used to identify them. Child view objects will appear subordinate to their parent view objects within the hierarchy. Named row sets will appear similar to view objects. Named iterators for a view object will appear similar to child view objects. Each view object node will provide the following information:</td>
</tr>
<tr>
<td></td>
<td>■ View object link - link to open the corresponding view object source file within the editor workspace.</td>
</tr>
<tr>
<td></td>
<td>■ Query - last executed view object SQL statement. Displays bind variables without value substitution.</td>
</tr>
<tr>
<td></td>
<td>■ Query with substitution - last executed view object SQL statement. Displays bind variables with value substitution.</td>
</tr>
<tr>
<td></td>
<td>■ Bind variables - last executed view object SQL statement bind variables and their values.</td>
</tr>
<tr>
<td></td>
<td>■ View object rows - each row displayed will be identified by its concatenated key values. The current row will be identified with a special icon.</td>
</tr>
<tr>
<td></td>
<td>■ Attributes - attributes contained on each row will display their current values along with their originating entity object. Transient attributes will also be displayed.</td>
</tr>
<tr>
<td></td>
<td>■ Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and view objects node labels. Both the old and new value of the modification will be displayed.</td>
</tr>
</tbody>
</table>

| Entity object     | Entity objects instantiated within the corresponding view port data control frame will appear underneath the application module root node as subordinate nodes. Design time icons will be used to identify them. Each entity object node will provide the following information: |
|                   | ■ Entity object link - link to open the corresponding entity object source file within the editor workspace. |
|                   | ■ Entity object rows - each row displayed will be identified by its concatenated key values. The current entity-state and post-state of the row (e.g., STATUS_MODIFIED) will also be presented. |
|                   | ■ Attributes - attributes contained on each row will display their current values. |
|                   | ■ Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and entity objects node labels. Both the old and new value of the modification will be displayed. |

Business services implemented by non-ADF Business Components objects display application data content using raw member variables. The format is similar to the display of non-ADF Business Components content for the binding container, as shown in Figure 42–42.
corresponds to the breakpoint. Once the breakpoint is set in the code, the standard Java debugger mechanism pauses application execution when the breakpoint is reached. When the breakpoint is reached, it will be identified by a red dot icon in the Breakpoints window. Depending on the type of declarative breakpoint that was reached, it will also appear as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window.

For task flow activity breakpoints, the debugger pauses the application within the JSF Invoke Application phase before the activity where the breakpoint is set. In other words, the activity where the breakpoint is set is not executed.

For task flow view activities, however, the application is paused within the JSF Render Response phase after the view activity is executed, but before the new page is rendered.

For a page definition Before executable breakpoint, the debugger pauses the application when the executable is refreshed. For a page definition Before action binding breakpoint, the debugger pauses the application when the binding is executed. For a page definition Before attribute value binding breakpoint, the debugger pauses the application before the attribute's `setInputValue()` method in the ADF source code is executed.

For a Before lifecycle breakpoint, the debugger pauses the application before it enters the next lifecycle phase. For an After lifecycle breakpoint, the debugger pauses the application after the lifecycle phase and before the next phase.

### 42.10 Setting Java Code Breakpoints

You can use the ADF Declarative Debugger to set breakpoints on Java classes and methods, as in any standard Java code debugger. You can use Java code breakpoints in combination with ADF declarative breakpoints or by themselves. For most ADF applications, ADF declarative breakpoints will provide enough debugging information to troubleshoot the application. For information about using ADF declarative breakpoints, see Section 42.9, "Setting ADF Declarative Breakpoints." However, you may need to set breakpoints on specific classes or methods for further inspection. Or, you may be debugging a non-ADF application, in which case, you can use Java code breakpoints.

JDeveloper provides a class locator feature that assists you in finding the class you want to break on. If you can obtain Oracle ADF source code, you can enhance your debugging by having access to various ADF classes and methods. For more information about getting ADF source code, see Section 42.8.1, "Using ADF Source Code with the Debugger." If you obtained the ADF source, you can further enhance the debugging experience by using the debug library version of the ADF source, as described in Section 42.10.4, "How to Use Debug Libraries for Symbolic Debugging."

### 42.10.1 How to Set Java Breakpoints on Classes and Methods

You can set Java breakpoints on your classes and methods. If you have ADF source code, you can set Java breakpoints in the source as well. If you are debugging an ADF application, you should check to see whether ADF declarative breakpoints can be used instead of Java code breakpoints. For more information, see Section 42.9, "Setting ADF Declarative Breakpoints."
Before you begin:
It may be helpful to have an understanding of when to use Java code breakpoints instead of ADF declarative breakpoints. For more information, see Section 42.10, "Setting Java Code Breakpoints."

You will need to complete this task:

Before you attempt to use breakpoints, you should try to run the application and look for missing or incomplete data, actions and methods that are ignored or incorrectly executed, or other unexpected results. If you did not find the problem, create a debugging configuration that will enable the ADF Log and send Oracle ADF messages to the Log window. For more information, see Section 42.6.2, "How to Create an Oracle ADF Debugging Configuration."

To set Java breakpoints to debug an application:

1. In the main menu, choose Navigate and then Go To Java Type (or press Ctrl+Minus) and use the dialog to locate the Oracle ADF class that represents the entry point for the processing failure.

   **Note:** JDeveloper will locate the class from the user interface project with current focus in the Applications window. If your workspace contains more than one user interface project, be sure that the one with the current focus is the one you want to debug.

2. Open the class file in the source editor and find the Oracle ADF method call that will enable you to step into the statements of the method.

3. Set a breakpoint on the desired method and run the debugger.

4. When the application stops on the breakpoint, use the Data window to examine the local variables and arguments of the current context.

   **Tip:** If you are using the Go to source context menu command in the Data, Watches, or Smart Data window, you can go back to the execution point by using the back button. You can also access the back button through the Navigate menu.

Once you have set breakpoints to pause the application at key points, you can proceed to view data in the Data window. To effectively debug your web page’s interaction with the ADF Model layer, you need to understand:

- The ADF page lifecycle and the method calls that get invoked
- The local variables and arguments that the ADF Model layer should contain during the course of application processing

Awareness of Oracle ADF processing will give you the means to selectively set breakpoints, examine the data loaded by the application, and isolate the contributing factors.

**Note:** JSF web pages may also use backing beans to manage the interaction between the page’s components and the data. Debug backing beans by setting breakpoints for them as you would with any other Java class file.
42.10.2 How to Optimize Use of the Source Editor

Once you have added the ADF source library to your project, you have access to the helpful Quick Javadoc feature (Ctrl+D) that the source editor makes available. Figure 42-49 shows Quick Javadoc for a method like findSessionCookie().

Figure 42-49 Using Quick Javadoc on ADF API in the Source Editor

42.10.3 How to Set Breakpoints and Debug Using ADF Source Code

After loading the ADF source code, you can debug any Oracle ADF code for the current project the same way that you do your own Java code. This means that you can press Ctrl+Minus to type in any class name in Oracle ADF, and JDeveloper will open its source file automatically so that you can set breakpoints as desired.

42.10.4 How to Use Debug Libraries for Symbolic Debugging

When debugging Oracle ADF source code, by default you will not see symbol information for parameters or member variables of the currently executing method.

For example, in a debugging session without ADF source code debug libraries, you may see unrecognizable names such as "_slot", as shown in Figure 42-50.

Figure 42-50 Local Symbols Are Hard to Understand Without Debug Libraries
These names are hard to decipher and make debugging more difficult. You can make debugging easier by using the debug versions of the ADF JAR files supplied along with the source while debugging in your development environment.

**Note:** The supplied debug libraries should not be used in a test or production environment, since they typically have slightly slower runtime performance than the optimized JAR files shipped with JDeveloper.

The debug library JARs are versions of Oracle ADF JARs that have been compiled with additional debug information. When you use these debug JAR files instead of the default optimized JARs, you will see all of the information in the debugger. For example, the variable evid is now identified by its name in the debugger, as shown in Figure 42–51.

![Figure 42–51 Symbol Information Displayed in the Debugger](image)

Before you begin:
It may be helpful to have an understanding of when to use Java code breakpoints instead of ADF declarative breakpoints. For more information, see Section 42.10, "Setting Java Code Breakpoints."

You will need to complete this task:

Before you replace the standard library JAR, make sure that JDeveloper is not running. If it's currently running, exit from the product before proceeding.

**To replace the standard library JARs with the debug library JARs:**

1. With JDeveloper closed, make a backup subdirectory of all existing optimized JAR files in the ./BC4J/lib directory of your JDeveloper installation. For example, assuming jdev11 is the JDeveloper home directory:

   ```
   C:\jdev11\BC4J\lib> mkdir backup
   C:\jdev11\BC4J\lib> copy *.jar backup
   ```

2. For each ADF library that you want debug symbols for while debugging, copy the _g.jar version of the matching library over the existing, corresponding library in the C:\jdev11\BC4J\lib directory.

   This is safe to do since you made a backup of the optimized JAR files in the backup directory in Step 2.
Since debug libraries typically run a little slower than libraries compiled without debug information, this diagnostic message is to remind you not to use debug libraries for performance timing:

**************************************************************************
*** WARNING: Oracle BC4J debug build executing - do not use for timing ***
**************************************************************************

3. To change back to the optimized libraries, simply copy the JAR file(s) in question from the ./BC4J/lib/backup directory back to the ./BC4J/lib directory.

42.10.5 How to Use Different Kinds of Java Code Breakpoints

You first need to understand the different kinds of Java code breakpoints and where to create them.

To see the debugger Breakpoints window, choose Window and then Breakpoints in the main menu (or press Ctrl+Shift+R).

You can create a new Java code breakpoint by choosing Create Breakpoint from the context menu in the Breakpoints window. The Breakpoint Type dropdown list controls what kind of breakpoint you will create, as shown in Table 42–10.

**Note:** You can also use the Create Breakpoint dialog to create an ADF lifecycle phase declarative breakpoint. For information about creating ADF declarative breakpoints, see Section 42.9.6, “How to Set and Use ADF Lifecycle Phase Breakpoints.”

<table>
<thead>
<tr>
<th>Breakpoint Type</th>
<th>The Breakpoint Occurs Whenever</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exception</td>
<td>An exception of this class (or a subclass) is thrown.</td>
<td>An Exception breakpoint is useful when you don't know where the exception occurs, but you know what kind of exception it is (for example, java.lang.NullPointerException, java.lang.ArrayIndexOutOfBoundsException, oracle.jbo.JboException). The checkbox options allow you to control whether to break on caught or uncaught exceptions of this class. The Browse button helps you find the fully qualified class name of the exception. The Exception Class combobox remembers the most recently used exception breakpoint classes. Note that this is the default breakpoint type when you create a breakpoint in the breakpoints window.</td>
</tr>
<tr>
<td>Source</td>
<td>A particular source line in a particular class in a particular package is run.</td>
<td>You rarely create a source breakpoint in the Create Breakpoint dialog, because it's much easier to create it by first using the Navigate &gt; Go to Java Type menu (accelerator Ctrl+Minus), then scrolling to the line number you want — or using Navigate &gt; Go to Line (accelerator Ctrl+G) — and finally clicking in the breakpoint margin at the left of the line you want to break on. This is equivalent to creating a new source breakpoint, but it means you don't have to type in the package, class, and line number by hand.</td>
</tr>
</tbody>
</table>

42-68 Developing Fusion Web Applications with Oracle Application Development Framework
42.10.6 How to Edit Breakpoints for Improved Control

After creating a Java code breakpoint you can edit the breakpoint in the Breakpoints window by right-clicking it and choosing Edit in the context menu.

Note: You can use the Edit Breakpoint dialog to edit an ADF declarative breakpoint. However, you cannot edit some of the other information such as the information in the Definition tab. You can launch the Edit Breakpoint dialog by choosing Edit from the context menu in the Breakpoints window. For information about creating ADF declarative breakpoints, see Section 42.9, "Setting ADF Declarative Breakpoints."

Some of the features you can use by editing your breakpoint are:

- Associate a logical "breakpoint group" name to group this breakpoint with others of the same group name. Breakpoint groups make it easy to enable/disable an entire set of breakpoints in one operation.

- Associate a debugger action to a breakpoint when the breakpoint is hit. The default action is to stop the debugger so that you can inspect the application states, but you can add a sound alert, write information to a log file, and enable or disable group of breakpoints.

- Associate a conditional expression with the breakpoint so that the debugger stops only when that condition is met. The expressions can be virtually any boolean expression, including:

  - expr == value

---

### Table 42–10 (Cont.) Different Types of Java Breakpoints

<table>
<thead>
<tr>
<th>Breakpoint Type</th>
<th>The Breakpoint Occurs Whenever</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Method</td>
<td>A method in a given class is invoked.</td>
<td>The Method breakpoint is useful for setting breakpoints on a particular method you might have seen in the call stack while debugging a problem. If you have the source, you can set a source breakpoint wherever you want in that class, but this kind of breakpoint lets you stop in the debugger even when you don’t have source for a class.</td>
</tr>
<tr>
<td>Class</td>
<td>Any method in a given class is invoked.</td>
<td>The Class breakpoint can be used when you might know the class involved in the problem, but not the exact method you want to stop on. This kind of breakpoint does not require source. The Browse button helps you quickly find the fully qualified class name you want to break on.</td>
</tr>
<tr>
<td>Watchpoint</td>
<td>A given field is accessed or modified.</td>
<td>The Watchpoint breakpoint can be used to find a problem if the code inside a class modifies a member field directly from several different places (instead of going through setter or getter methods each time). You can pause the debugger when any field is modified. You can create a breakpoint of this type by using the Toggle Watchpoint menu item on the context menu when pointing at a member field in your class’s source.</td>
</tr>
</tbody>
</table>
Setting Java Code Breakpoints

- expr.equals("value")
- expr instanceof fully.qualified.ClassName

**Note:** Use the debugger Watches window to evaluate the expression first to make sure it’s valid.

### 42.10.7 How to Filter Your View of Class Members

You can use the debugger to filter the members that are displayed in the debugger window for any class. In the debugger’s Data window, selecting any item and choosing **Preferences** from the context menu brings up a dialog that lets you customize which members appear in the debugger and (more importantly sometimes) which members *don’t* appear. You can filter by class type to simplify the amount of scrolling you need to do in the debugger Data window. This is especially useful when you might be interested only in a handful of a class’s members.

### 42.10.8 How to Use Common Oracle ADF Breakpoints

If you loaded Oracle ADF source code, you can use the breakpoints listed in Table 42–11 to debug your application.

By looking at the Stack window when you hit these breakpoints, and stepping through the source, you can get a better idea of what’s going on.

**Table 42–11 Commonly Used ADF Breakpoints**

<table>
<thead>
<tr>
<th>Breakpoint</th>
<th>Breakpoint Type</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>oracle.jbo.JboException</td>
<td>Exception</td>
<td>This breakpoint useful for setting a breakpoint on the base class of all ADF Business Components runtime exceptions.</td>
</tr>
<tr>
<td>oracle.jbo.DMLException</td>
<td>Exception</td>
<td>This is the base class for exceptions originating from the database, like a failed DML operation due to an exception raised by a trigger or by a constraint violation.</td>
</tr>
<tr>
<td>doIt()</td>
<td>Method</td>
<td>You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition action binding. See Section 42.9.3, “How to Set and Use Page Definition Action Binding Breakpoints.”</td>
</tr>
<tr>
<td></td>
<td></td>
<td>If you prefer to use this Java breakpoint, you can find it in the JUCtrlActionBinding class (oracle.jbo.uicli.binding package).</td>
</tr>
<tr>
<td></td>
<td></td>
<td>This is the method that will execute when any ADF action binding is invoked, and you can step into the logic and look at parameters if relevant.</td>
</tr>
</tbody>
</table>
Testing your business services is an important part of your application development process. By creating a set of JUnit regression tests that exercise the functionality provided by your application module, you can ensure that new features, bug fixes, or refactorings do not destabilize your application. JDeveloper’s integrated support for creating JUnit regression tests makes it easy test your application. Its integrated support for running JUnit tests means that any developer on the team can run the test suite with a single mouse click, greatly increasing the chances that every team member can run the tests to verify their own changes to the system. Furthermore, by using JDeveloper’s integrated support for creating and running Apache Ant build scripts, you can easily incorporate running the tests into your automated build process as well. You can create a JUnit test for your application module, run it, and integrate the tests into an Ant build script.

JDeveloper provides the ability to generate JUnit test cases, test fixtures, and test suites. You can create test cases to test individual Java files containing single or multiple Java classes. You can create JUnit test fixtures that can be reused by JUnit test cases. You can group all these test cases into a JUnit test suite, which you can run together as a unit.

You can also use the JUnit BC4J Test Suite wizard to generate a test suite when there is an application module in the project. The wizard generates a test suite, test fixture, and a test case for each view object in the application module.

You can create a separate project to contain your regression tests or to integrate the test files into an existing project. If you are creating an ADF Business Components test, you should create a separate project for testing.

Creating separate projects for testing has the following advantages:

- The ability to compile the base project without having a dependency on JUnit
- The ability to package the base project for deployment without having to exclude the test classes.

If you are creating separate projects for JUnit testing, you should create directory structures that mirror the structure of the packages being tested. You may want to name the test classes using a naming convention that can easily identify the package being tested. For example, if you are testing myClass.java, you can name the test class myClassTest.java.

**42.11 Regression Testing with JUnit**

Testing your business services is an important part of your application development process. By creating a set of JUnit regression tests that exercise the functionality provided by your application module, you can ensure that new features, bug fixes, or refactorings do not destabilize your application. JDeveloper’s integrated support for creating JUnit regression tests makes it easy test your application. Its integrated support for running JUnit tests means that any developer on the team can run the test suite with a single mouse click, greatly increasing the chances that every team member can run the tests to verify their own changes to the system. Furthermore, by using JDeveloper’s integrated support for creating and running Apache Ant build scripts, you can easily incorporate running the tests into your automated build process as well. You can create a JUnit test for your application module, run it, and integrate the tests into an Ant build script.

JDeveloper provides the ability to generate JUnit test cases, test fixtures, and test suites. You can create test cases to test individual Java files containing single or multiple Java classes. You can create JUnit test fixtures that can be reused by JUnit test cases. You can group all these test cases into a JUnit test suite, which you can run together as a unit.

You can also use the JUnit BC4J Test Suite wizard to generate a test suite when there is an application module in the project. The wizard generates a test suite, test fixture, and a test case for each view object in the application module.

You can create a separate project to contain your regression tests or to integrate the test files into an existing project. If you are creating an ADF Business Components test, you should create a separate project for testing.

Creating separate projects for testing has the following advantages:

- The ability to compile the base project without having a dependency on JUnit
- The ability to package the base project for deployment without having to exclude the test classes.

If you are creating separate projects for JUnit testing, you should create directory structures that mirror the structure of the packages being tested. You may want to name the test classes using a naming convention that can easily identify the package being tested. For example, if you are testing myClass.java, you can name the test class myClassTest.java.
Although having separate projects has many advantages, in certain cases it may be easier to include the tests within the project.

You can use the Create Test wizards in the context of the project to create a JUnit test case, test fixture, or test suite. However, if you do not want to include these tests as part of the deployment, you may want to separate the tests out in their own project.

**Tip:** If you don’t see the Create Test wizards, use JDeveloper’s Help > Check for Updates feature to install the JUnit Integration extension before continuing.

Each test case class contains a `setUp()` and `tearDown()` method that JUnit invokes to allow initializing resources required by the test case and to later clean them up. These test case methods invoke the corresponding `setUp()` and `tearDown()` methods to prepare and clean up the test fixture for each test case execution. Any time a test in the test case needs access to the application module, it uses the test fixture’s `getApplicationModule()` method. The method returns the same application module instance, saved in a member field of the test fixture class, between the initial call to `setUp()` and the final call to `tearDown()` at the end of the test case.

JDeveloper supports JUnit 4, which allows annotations to be used instead of explicitly having to name the methods `setUp()` and `tearDown()`. These annotations — `@Before`, `@After` — allow you to have multiple setup and teardown methods, including inherited ones if required.

The generated `ExampleModuleConnectFixture` is a JUnit test fixture that encapsulates the details of acquiring and releasing an application. It contains a `setUp()` method that uses the `createRootApplicationModule()` method of the `Configuration` class to create an instance of an application module. Its `tearDown()` method calls the matching `releaseRootApplicationModule()` method to release the application module instance.

Your own testing methods can use any of the programmatic APIs available in the `oracle.jbo` package to work with the application module and view object instances in its data model. You can also cast the `ApplicationModule` interface to a custom interface to have your tests invoke your custom service methods as part of their job. During each test, you will call one or more `assertXxx()` methods provided by the JUnit framework to assert what the expected outcome of a particular expression should be. When you run the test suite, if any of the tests in any of the test cases contains assertions that fail, the JUnit Test Runner window displays the failing tests with a red failure icon.

The JUnit test generation wizard generates skeleton test case classes for each view object instance in the data model, each of which contains a single test method named `testAccess()`. This method contains a call to the `assertNotNull()` method to test that the view object instance exists.

```java
// In ViewInstanceNameTest.java test case class
public void testSomeMeaningfulName() {
    // test assertions here
}
```

Each generated test case can contain one or more test methods that the JUnit framework will execute as part of executing that test case. You can add a test to the test case simply by creating a public void method in the class whose name begins with the prefix `test` or use the annotation `@Test`. 
42.11.1 How to Obtain the JUnit Extension

JUnit must be loaded as an extension to JDeveloper before it becomes available and appears in the menu system.

**Before you begin:**
It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Section 42.11, "Regression Testing with JUnit.”

**To load the JUnit extension:**
1. In the main menu, choose **Help** and then **Check For Updates**.
2. In the Source page of the Check for Updates dialog, select **Search Update Centers** and **Official Oracle Extensions and Updates** and click **Next**.
   
   If you have the JUnit zip file or if the JUnit selection does not appear in the **Available Updates** list, select **Install From Local File** to load the JUnit zip file.
3. In the Updates page, select **JUnit Integration** and click **Next**, as shown in **Figure 42–52**.

![](Figure 42–52  Check for Updates Wizard for Adding JUnit Extension)

4. On the License Agreements page, click **I Accept** and click **Finish**.

42.11.2 How to Create a JUnit Test Case

Before you create a JUnit test case, you must have created a project that is to be tested.
Before you begin:
It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Section 42.11, "Regression Testing with JUnit.”

To generate a JUnit test case:
1. In the Applications window, right-click the project in which want to create a test case and choose New and then From Gallery.
2. In the New Gallery, expand General, select Unit Tests and then Test Case, and click OK.
3. In the Select the Class to Test page of the Create Test Case dialog, enter the class under test or click Browse.
4. In the Class Browser dialog, locate the class you want to test or enter the beginning letters in the Match Class Name field. The Match Class list will be filtered for easier identification.

For example, entering Summit filters the list down to four items, as shown in Figure 42–53.

Figure 42–53 Class Browser for Selecting Class Files to Test

Select the class and click OK to close the dialog. Click Next.
5. Select the individual methods you want to test, and click Next.

For example, in Figure 42–54, the four methods that are checked are to be tested.
6. In the Setup Test Case Class page, enter the name of the test case, the package, and the class it extends and select the list of built-in functions JUnit will create stubs for. Click Next.

For example, in Figure 42–55, JUnit will create a stub for the `setUp()` method for the `SummitViewObjectImplTest` test case in the `oracle.summit.base` package of the Summit sample application for Oracle ADF.

Figure 42–55 Create Test Case Dialog for Setting Up Classes to Test

7. In the Select Test Fixtures page, select any test fixtures you want to add to the test case or click Browse.
8. Make sure that all the test fixtures you want to add to the test case are selected in the list and click Finish.

42.11.3 How to Create a JUnit Test Fixture

You should create a JUnit test fixture if you require more than one test for a class or method. A JUnit test fixture allows you to avoid duplicating test code that is needed to initialize testing.

Before you begin:
It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Section 42.11, “Regression Testing with JUnit.”

To generate a JUnit test fixture:
1. In the Applications window, right-click the project in which you want to create a test fixture and choose New and then From Gallery.
2. In the New Gallery, expand General, select Unit Tests and then Test Fixture, and click OK.
3. In the Create Test Fixture dialog, enter the name of the test fixture, the package, and any class it extends.
4. Click OK.

42.11.4 How to Create a JUnit Test Suite

Before you create a JUnit test suite, you should have already created JUnit test cases that can be added to the test suite.

Before you begin:
It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Section 42.11, “Regression Testing with JUnit.”

To generate a JUnit test suite:
1. In the Applications window, right-click the project in which you want to create a test suite and choose New and then From Gallery.
2. In the New Gallery, expand General, select Unit Test and then Test Suite, and click OK.
3. In the Setup Test Suite Class page of the Create Test Suite dialog, enter the name of the test suite, the package, and the class it extends. Click Next.
   For example, in Figure 42–56, an AllTests test suite is created that extends the java.lang.Object class.
4. In the Select Test Cases page of the Create Test Suite dialog, check that all the test cases you want included in the test suite have been selected. The test cases you have created will populate the list. Deselect any test cases that you do not want included. Click Finish.

**42.11.5 How to Create a Business Components Test Suite**

The test fixture that is created is a singleton class to reduce the number of connections. If you want to connect or disconnect for each test case, customize the test case using the JUnit 4 annotations @Before and @After.

The JUnit BC4J Test Suite wizard will generate tests for each view object in the application module. If the application module does not have exported methods, the wizard will also generate a test for the application module itself. A generated view object class has the format `view_objectVOTest.java` and is placed into a package with the format `package.view.viewobjectVO`, where `package` is the application module package. A generated application module test has the format `application_moduleAMTest.java` and is placed into a package with the format `package.applicationModule`. A generated test fixture class has the format `applicationmoduleAMFixture.java` and is placed in the same package as the application module test.

The generated all test suite class has the format `AllapplicationmoduleTest.java` and is placed into the package with the same name as the application module package name.

A test case XML file is also generated for each application module or view object test. The XML file contains test methods defined in the application module or view object test cases. It does not include the test methods from the base classes (if any) because there may be too many duplicates.

For instance, after you created a test suite for an application module named `StoreAAppModule` with view objects `Employees1View1` and `Employees1View2` in the package `StoreAPack`, the Applications window displays the test hierarchy as shown in Figure 42–20.
Before you begin:
It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Section 42.11, "Regression Testing with JUnit."

You will need to complete this task:

Create the application modules in the data model project, as described in Chapter 13, "Implementing Business Services with Application Modules."

To create a business components test suite:
1. In the main menu, choose File and then New and then From Gallery.
   You will create a separate project for the business components tests.

2. In the New Gallery, expand General, select Projects and then Java Application Project, and click OK.

3. In the Project Name page of the Create Java Project wizard, enter a name and the directory path for the test project, and click Next.

4. In the Project Java Settings page, enter the package name, the directory of the Java source code in your project, and output directory where output class files will be placed, and click Finish.

5. In the Applications window, double-click the application module you want to test.

6. In the overview editor, click the Java navigation tab.

7. In the Java page of the overview editor, click the Edit icon for the Java Class section.

8. In the Select Java Options dialog, select Generate Application Module Class and click OK.

9. In the Java page of the overview editor, click the Edit icon for the Class Interface section.

10. In the Edit Client Interface dialog, shuttle the methods you want to test to the Selected pane, and click OK.

11. In the Applications window, right-click the test project you have created and choose New and then From Gallery.

12. In the New Gallery, expand General, select Unit Tests and then Business Components Test Suite, and click OK.

13. In the Configure Tests page of the JUnit BC4J Test Suite wizard, select values for the following and click Next:
Regression Testing with JUnit

- **Business Component Project**: Select the project that has the application module you want to test.
- **Application Module**: Select the application module you want to test.
- **Configuration**: Choose a local or shared application module.
- **Test Base Class-Application Module Extends**: You can specify different base cases. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.
- **Test Base Class-View Object Extends**: You can specify which class the view object extends. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.

14. In the Summary page, verify the selections and click **Finish**.

42.11.6 How to Create Business Components Test Fixture

When you create a business components test suite, a business components test fixture is created with it. You can also create Business Components test fixtures independently.

A generated test fixture class has the format `applicationmoduleAMFixture.java` and put into a package with the format `package.applicationModule`, where `package` is the application module package.

**Before you begin:**

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Section 42.11, "Regression Testing with JUnit."

You will need to complete this task:

Create the application modules in the data model project, as described in Chapter 13, "Implementing Business Services with Application Modules."

**To create a business components test fixture:**

1. In the main menu, choose **File** and then **New** and then **From Gallery**.

You will create a separate project for the business components tests.

2. In the New Gallery, expand **General**, select **Projects** and then **Java Application Project**, and click **OK**.

3. In the Project Name page of the Create Java Project dialog, enter a name and the directory path for the test project, and click **Next**.

4. In the Project Java Settings page, enter the package name and the source and output directories, and click **Finish**.

5. In the Applications window, double-click the application module you want to test.

6. In the overview editor, click the **Java** navigation tab and then click the **Edit** icon for the **Java Class** section.

7. In the Select Java Options dialog, select **Generate Application Module Class**, and click **OK**.

8. In the Java page of the overview editor, click the **Edit** icon for the **Class Interface** section.
9. In the Edit Client Interface dialog, shuttle the methods you want to test to the Selected pane, and click OK.

10. In the Applications window, right-click the test project you have created and choose New and then From Gallery.

11. In the New Gallery, expand General, select Unit Tests and then Business Components Test Fixture, and click OK.

12. In the Configure Tests page of the JUnit BC4J Test Fixture wizard, select values for the following and click Next:
   - Business Component Project: Select the project that has the application module you want to test.
   - Application Module: Select the application module you want to test.
   - Configuration: Choose a local or shared application module.

13. In the Summary page, verify the test fixture class and click Finish.

42.11.7 How to Run a JUnit Test Suite as Part of an Ant Build Script

Apache Ant is a popular, cross-platform build utility for which JDeveloper offers design time support. You can incorporate the automatic execution of JUnit tests and test output report generation by using Ant's built-in junit and junitreport tasks. Example 42–3 shows a task called tests from an Ant build.xml file. It depends on the build and buildTests targets that Ant ensures have been executed before running the tests target.

Example 42–3 Ant Build Target Runs JUnit Test Suite

```xml
<target name="testCustomizations" depends="compileExtensionClasses">
  <junit printsummary="yes" haltonfailure="yes">
    <classpath refid="customization.classpath">
      <pathelement location="${customization.build.dir}"/>
    </classpath>
    <formatter type="plain"/>
    <test name="oracle.customization.tests.AllTests"/>
  </junit>
</target>
```

The junit tag contains a nested test tag that identifies the test suite class to execute and specifies a directory in which to report the results. The junitreport tag allows you to format the test results into a collection of HTML pages that resemble the format of Javadoc.

To try running the JUnit test from Ant, select the build.xml file in the Applications window, and choose Run Ant Target > tests from the context menu.
This chapter describes considerations for renaming, moving, and deleting source files, configuration files, objects, attributes, and elements in a Fusion web application. In most cases, JDeveloper can perform the complete refactoring. However, in some cases, you might need to complete some manual steps to refactor.

This chapter includes the following sections:

- Section 43.1, "About Refactoring a Fusion Web Application"
- Section 43.2, "Renaming Files"
- Section 43.3, "Moving JSF Pages"
- Section 43.4, "Refactoring pagedef.xml Bindings Objects"
- Section 43.5, "Refactoring ADF Business Components"
- Section 43.6, "Refactoring ADF Business Component Object Attributes"
- Section 43.7, "Refactoring Named Elements"
- Section 43.8, "Refactoring ADF Task Flows"
- Section 43.9, "Refactoring the DataBindings.cpx File"
- Section 43.10, "Refactoring Limitations"
- Section 43.11, "Moving the ADF Business Components Project Configuration File (.jpx)"

### 43.1 About Refactoring a Fusion Web Application

JDeveloper provides refactoring options that allow you to make changes to the name and location attributes, named elements, files, and ADF Business Components objects that your application uses. These refactoring options synchronize your changes with other parts of the application that are dependent on the changes. For example, renaming an ADF Business Components object such as a view object using the Rename option renames any references to it in other XML source files.

In a Fusion Web Application, you can use the refactoring actions (move, rename, and delete) in JDeveloper to make changes to the names and locations of objects. These actions are available from the main menu under Refactor, as well as the context menu for each type of object in the Applications window.

#### 43.1.1 Refactoring Use Cases and Examples

During the course of development, you will create objects such as entity objects, as needed, to satisfy the needs of the application. Then you might find that you need to
subsequently need to delete an object that is no longer used, rename an object to fit a naming convention, or move a set of objects into a different package to consolidate their location. Using JDeveloper, you can refactor these objects so that they are updated and the references to these objects in other objects are also updated to maintain the integrity of the whole application.

43.1.2 Additional Functionality for Refactoring
You may find it helpful to understand other refactoring features available from JDeveloper. Following are links to other functionality that may be of interest.

- For additional information about using JDeveloper features for refactoring Java code, see the “Refactoring Java Projects” section of Developing Applications with Oracle JDeveloper.

43.2 Renaming Files
You can rename files, such as configuration files, using the following methods:

- In the Applications window, select the file and choose File > Rename from the main menu.
- In the Applications window, right-click the file and choose Refactor > Rename.
- In the source editor, select a class name, right-click it, and choose Rename.

To move a file between directories, use the Move menu item.

When you rename or move a file, all references to the file are updated as well. For example when you rename a page definition file, its entry in the DataBindings.cpx file is updated accordingly.

You cannot rename the XML file or Java files associated with an ADF Business Components object independently of the object, as these files must be kept in sync. For more information, see Section 43.5, "Refactoring ADF Business Components."

43.3 Moving JSF Pages
In addition to the other refactoring operations, you can change the package of a JSF page. In the Applications window, right-click a JSF page and choose Refactor > Move to move the page to another package.

Moving the JSF page to another package updates:

- faces-config.xml files that reference the page and its package
- ADF task flows containing views associated with the page
- DataBindings.cpx mappings to the page

43.4 Refactoring pagedef.xml Bindings Objects
The pagedef.xml binding objects that you can refactor include bindings and executables. For more information, see Section 17.7, "Working with Page Definition Files."

Before you begin:
It may be helpful to have an understanding of the options you have for refactoring. For more information, see Section 43.1, "About Refactoring a Fusion Web Application."
In JDeveloper, open the application that contains the objects you want to refactor.

To refactor pagedef.xml binding objects:
1. In the Applications window, select the page node on which you have added a bound object such as an ADF Form or selection list.
2. Right-click the page node and choose Go to Page Definition.
   If the page does not already have a page definition, the Create Page Definition dialog appears. Click OK to create a page definition for the page.
3. In the overview editor, click the Bindings and Executables tab.
   Data bindings such as list bindings and iterator bindings defined for the page display under Bindings and Executables, as shown in Figure 43–1.

Figure 43–1 Page Data Binding Definition Overview Tab

4. In the Structure window, right-click a data binding or executable, choose Refactor and a refactoring option, such as Rename or Delete.
5. To display the usages between bindings, executables, and data controls, right-click a binding or executable and choose Find Usages.

43.5 Refactoring ADF Business Components

ADF Business Components includes objects such as view objects and entity objects. Table 43–1 shows support for refactoring ADF Business Components.

<table>
<thead>
<tr>
<th>Action</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Move</td>
<td>Moves the object to a different package or directory and updates all references.</td>
</tr>
<tr>
<td>Delete</td>
<td>JDeveloper shows all dependencies on the object and permits a forced delete. The application may not work at this point. You may need to resolve broken references.</td>
</tr>
</tbody>
</table>
Refactoring ADF Business Components

Table 43–1  (Cont.) Refactoring ADF Business Components

<table>
<thead>
<tr>
<th>Action</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Rename</td>
<td>ADF Business Components objects are defined by an XML file. The XML file has a file name identical to the object name. For example, the name of the XML file for a view object named Persons1View is Persons1View.xml. Renaming results in changing the Name attribute, renaming the XML file, and updating all references. For example, the name of an entity (Customer) is stored as an attribute in the XML file (name=Customer). The XML file has the same name the entity name (Customer.xml).</td>
</tr>
<tr>
<td>Find Usages</td>
<td>JDeveloper shows all dependencies on the object.</td>
</tr>
</tbody>
</table>

**Note:** Refactoring does not cross abstraction layers. For example, when a view object is created based on the Dept entity object, it is named DeptView by default. Renaming the Dept entity object updates the entity usage in DeptView, but does not change the name of the view object.

**Before you begin:**

It may be helpful to have an understanding of the options you have for refactoring. For more information, see Section 43.1, "About Refactoring a Fusion Web Application."

In JDeveloper, open the application that contains the object you want to refactor.

**To refactor ADF Business Components objects:**

1. In the Applications window, expand the project and then the Application Sources node and then the package containing the object you want to refactor.

2. Right-click the object and choose Refactor and a refactoring option.
   - To change the name of the object, choose Rename.
     The Rename dialog displays the current name of the object. Enter the new object name and click OK to proceed with the refactoring or Cancel to cancel.
     You can optionally select Preview and click OK to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.
     When you click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.
   - To change the location of the object, choose Move.
     The Move dialog displays the current location of the object. Enter the new package name, or click Browse to navigate to it. Click OK to proceed with the refactoring or Cancel to cancel.
   - To remove the object, choose Delete.
     The Confirm Delete dialog displays the name of the object and searches for usages. Click Show Usages to display where the object is used. Click Yes to proceed with the refactoring or No to cancel. Click Preview to display the results in the Log window, which allows you to proceed with the refactoring or cancel. When you click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.
By default JDeveloper searches in the current application for usages of the object. You can change the scope of the search by choosing from the Finding Usages In dropdown list, or by clicking the Manage Working Sets icon.

### 43.6 Refactoring ADF Business Component Object Attributes

Table 43–1 shows support for refactoring attributes of ADF Business Component entity objects and view objects.

<table>
<thead>
<tr>
<th>Action</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Move</td>
<td>Not supported.</td>
</tr>
<tr>
<td>Delete</td>
<td>JDeveloper shows all dependencies on the attribute and permits a forced delete. The application may not work at this point. You may need to resolve broken references.</td>
</tr>
<tr>
<td>Rename</td>
<td>Attributes share data elements represented in entity and view objects (see Section 4.1, “About Entity Objects” for more information). References to the attribute are updated when you rename the attribute. Renaming results in changing the Name attribute and updating all references. This includes updating the service implementation of view attributes used in an application module’s generated service. Renaming an attribute does not change the data it represents, nor does it rename the underlying table column.</td>
</tr>
<tr>
<td>Find Usages</td>
<td>JDeveloper shows all dependencies on the attribute.</td>
</tr>
</tbody>
</table>

**Before you begin:**

It may be helpful to have an understanding of the options you have for refactoring. For more information, see Section 43.1, “About Refactoring a Fusion Web Application.”

In JDeveloper, open the application that contains the attribute you want to refactor.

**To refactor attributes:**

1. In the Applications window, double-click the entity object or view object that contains the attribute you want to refactor.
2. In the overview editor, click the Attributes navigation tab.
3. In the Name column, right-click the attribute and choose a refactoring option.
   - To change the name of the attribute, choose **Rename**.
     The Rename dialog displays the current name of the attribute. Enter the new attribute name and click **OK** to proceed with the refactoring or **Cancel** to cancel.
     You can optionally select **Preview** and click **OK** to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.
   - To see where the attribute is used, choose **Find Usages**.
     The Log window displays usages of the attribute. When you click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.
   - To remove the attribute, choose **Delete**.
In the Confirm Delete dialog, click **Show Usages** to display where the attribute is used. Click **Yes** to proceed with the refactoring or **No** to cancel. Click **Preview** to display the results in the Log window, which allows you to proceed with the refactoring or cancel.

- To change the type of the attribute, choose **Change Type**.

  In the Change Type dialog, choose the new type from the **Type** dropdown list, or click **Browse** to find the type. Click **OK** to proceed with the refactoring or **Cancel** to cancel.

  You can optionally select **Preview** and click **OK** to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.

### 43.7 Refactoring Named Elements

Named elements are any elements in the XML schema that can be referenced by a **Name** attribute. A named element is not an object or an attribute. **Table 43–3** shows support for refactoring named elements in an XML schema.

**Table 43–3  Refactoring Named Elements**

<table>
<thead>
<tr>
<th>Action</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Move</td>
<td>Not supported.</td>
</tr>
<tr>
<td>Delete</td>
<td>Not supported.</td>
</tr>
<tr>
<td>Rename</td>
<td>One exception to the definition of named elements is the design time element <strong>Attr</strong>, which does have a <strong>Name</strong> attribute. <strong>Attr</strong> is a name-value pair, is not accessible from the code editor, and should not be renamed.</td>
</tr>
<tr>
<td>Find Usages</td>
<td><strong>JDeveloper</strong> shows all dependencies on the named element.</td>
</tr>
</tbody>
</table>

**Before you begin:**

It may be helpful to have an understanding of the options you have for refactoring. For more information, see Section 43.1, “About Refactoring a Fusion Web Application.”

In JDeveloper, open the application that contains the named element you want to refactor.

**To refactor named elements:**

1. In the Applications window, double-click the entity object or view object that contains the named element you want to refactor.

2. In the editor window, click the **Source** tab, and search or scroll to find the named element.

   Named elements are indicated by **Name=**"<element>" in the source code, for example:

   ```xml
   <Key Name="PersonsAffContactChk">
   ```

   A named element is not an object or attribute.

3. Right-click the named element you want to refactor and choose **Refactor** and a refactoring option.

   - To change the name of the element, choose **Rename**.
The Rename dialog displays the current name of the element. Enter the new element name and click **OK** to proceed with the refactoring or **Cancel** to cancel.

You can optionally select **Preview** and click **OK** to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.

- To remove the element, choose **Delete**.

  In the Confirm Delete dialog, click **Show Usages** to display where the element is used. Click **Yes** to proceed with the refactoring or **No** to cancel. Click **Preview** to display the results in the Log window, which allows you to proceed with the refactoring or cancel.

### 43.8 Refactoring ADF Task Flows

For more information, see Section 20.6, "Refactoring to Create New Task Flows and Task Flow Templates."

### 43.9 Refactoring the DataBindings.cpx File

The DataBindings.cpx file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime (see Section A.7.1, "DataBindings.cpx Syntax" for more information). This file is a registry used to quickly find all .cpx, .dcx, .jpx, and .xcfg files, which are themselves registries of metadata.

If you rename the DataBindings.cpx file to a new name, such as DataBindingsNew.cpx, the change is added to the adfm.xml file.

**Example 43–1** shows the contents of the adfm.xml file after DataBindings.cpx is refactored to DataBindingsNew.cpx.

**Example 43–1 Renamed DataBindings.cpx file in adfm.xml**

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<MetadataDirectory xmlns="http://xmlns.oracle.com/adfm/metainf"
  version="11.1.1.0.0">
  <DataBindingRegistry path="adf/sample/view/DataBindingsNew.cpx"/>
</MetadataDirectory>
```

Additionally, to enable the application to access the correct bindings file, the ID value is changed to an ID similar to the one shown in **Example 43–2**.

**Example 43–2 Updated DataBindingsNew.cpx ID**

```xml
<Application xmlns="http://xmlns.oracle.com/adfm/application"
  version="11.1.1.49.28" id="DataBindingsNew" SeparateXMLFiles="false"
  Package="adf.sample.view" ClientType="Generic"/>
```

### 43.10 Refactoring Limitations

**Table 43–4** summarizes the limitations of JDeveloper’s refactoring support.
Table 43–4 Refactoring Limitations

<table>
<thead>
<tr>
<th>Area</th>
<th>Limitation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Database</td>
<td>When a database artifact used in an ADF Business Components object is renamed, the object needs to be updated. This type of refactoring is currently not supported.</td>
</tr>
<tr>
<td>Service interface</td>
<td>A service interface defines a contract between two separate pieces of software. For example, the ADF Business Components service interface is responsible for exposing business components to the view and model layers. Changing the name of a service interface can cause a conflict. While developing the application, consider removing the service interface, refactoring the object, and regenerating the service interface. Additionally, if your service interface defines a find operation based on a view criteria that specifies bind variables, changing the number or order of the bind variables in the underlying view criteria will require that you regenerate the service interface. For more information, see Chapter 15, “Integrating Service-Enabled Application Modules.”</td>
</tr>
<tr>
<td>Java literal references</td>
<td>The Java code generated by ADF Business Components has literal references to the XML metadata. These literal references are updated during refactoring operations. Generated (type safe) methods are also updated. Also, the refactor delete operation is available for local Java variables. However, if the application code directly refers to the metadata, these references are not updated.</td>
</tr>
<tr>
<td>Domain</td>
<td>If a domain needs to be renamed or moved, you must create the new domain, then change the type of existing domain usages. For example, you might rename a domain called EmployeeID to EmployeeNumber. In addition, the entity Emp has an attribute called Empno that is of type EmployeeID. After creating the new domain EmployeeNumber, go to the attributes page for the entity, right-click Empno and choose Change Type. This switches Empno from EmployeeID to EmployeeNumber.</td>
</tr>
<tr>
<td>Security</td>
<td>Security policies in the policy store may reference the name of an entity object, attribute, page, or task flow. These policy definitions are not updated in response to the refactoring of the object itself.</td>
</tr>
<tr>
<td>Resource Bundles</td>
<td>Entity object definitions can reference a resource in one or more arbitrary resource bundle (.properties) files that you create. You can use this file to define labels for the attributes of entity objects. However, if you rename the .properties file you created, JDeveloper will not update the entity object definitions to reflect the new file name. As an alternative to resource bundle files that you create, you can specify a project setting to generate a single, default resource bundle file for the data model project. In this case, JDeveloper will not allow you to rename this generated file. However, if you attempt to change the project-level default resource bundle file, JDeveloper will warn you about the change. The data model project will honor the new ADF Business Components project-level setting for any objects that have not yet been linked to the default resource bundle file; all existing Business Components that have already been linked to the original default file will continue to use it instead.</td>
</tr>
</tbody>
</table>
43.11 Moving the ADF Business Components Project Configuration File (.jpx)

Although refactoring the ADF Business Components project configuration file (.jpx) is not supported, you may need to change its name or location to avoid conflicts when sharing your project contents as an ADF library. The .jpx file contains configuration information that JDeveloper uses in the design time to allow you to create the data model project with ADF Business Components. If you need to refactor this file, you must do so manually.

Before you begin:
It may be helpful to have an understanding of the options you have for refactoring. For more information, see Section 43.1, "About Refactoring a Fusion Web Application."

To manually move the ADF Business Components project configuration file (.jpx):

1. Move the .jpx file to the new source tree location.
   
   For example, you can move the Model.jpx file from src/Model.jpx to src/newpackage/name/here/Model.jpx.

2. Change the .jpx file contents. The PackageName attribute of the root element JboProject needs to have the correct value.
   
   For example, you can specify PackageName="newpackage.name.here".

3. Change the jbo.project attributes in all common/bc4j.xcfg files that contain elements referred to in the .jpx file to include the new package name.
   
   For example:
   ```xml
   < AppModuleConfig name="ScottDeptAMLocal"
   ApplicationName="newpackage.name.here.ScottDeptAM"
   DeployPlatform="LOCAL" JDBCName="scottdb"
   jbo.project="newpackage.name.here.Model">
   ```

4. Change the contents of the JDeveloper project file (the .jpr file):
   - Set the new .jpx package location. If you later change the default package in the project properties, you will again raise a NotFound error for the .jpx file.
     
     For example:
     ```xml
     <value n="defaultPackage" v="newpackage.name.here"/>
     ```

---

**Table 43–4 (Cont.) Refactoring Limitations**

<table>
<thead>
<tr>
<th>Area</th>
<th>Limitation</th>
</tr>
</thead>
<tbody>
<tr>
<td>.jpx project configuration file</td>
<td>Renaming the ADF Business Components project configuration file (.jpx) is not supported.</td>
</tr>
</tbody>
</table>

In previous versions of JDeveloper, ADF Business Components project configuration .jpx files were created only in the root package of the src directory of a project and were named with the same base name as the project. The ADF Business Components objects (entity objects, view objects, and application modules) were all created in the model package (for example, /model/AppModule.xml), but the /Model.jpx is not. This may cause a reusability problem when attempting to package them in ADF JAR files for use on the class path. There may be name conflicts because several projects are named Model.
Fix any ownerURL elements in the ownerMap that contain references to the old location of the .jpx file.

For example:

```xml
<url n="ownerURL"
    path="src/newpackage/name/here/Model.jpx"/>
```
Reusing Application Components

This chapter describes how to package certain Oracle ADF components into the ADF Library for reuse in Fusion web applications. Reusable ADF components are application modules, business components (entity objects, view objects, associations), data controls, task flows, page templates, and declarative components.

This chapter includes the following sections:

- Section 44.1, "About Reusable Components"
- Section 44.2, "Packaging a Reusable ADF Component into an ADF Library"
- Section 44.3, "Adding ADF Library Components into Projects"
- Section 44.4, "Removing an ADF Library JAR from a Project"

44.1 About Reusable Components

In the course of application development, certain components will often be used more than once. Whether the reuse happens within the same application, or across different applications, it is often advantageous to package these reusable components into a library that can be shared between different developers, across different teams, and even across departments within an organization.

In the world of Java object-oriented programming, reusing classes and objects is just standard procedure. With the introduction of the model-view-controller (MVC) architecture, applications can be further modularized into separate model, view, and controller layers. By separating the data (model and business services layers) from the presentation (view and controller layers), you ensure that changes to any one layer do not affect the integrity of the other layers. You can change business logic without having to change the UI, or redesign the web pages or front end without having to recode domain logic.

Oracle ADF and JDeveloper support the MVC design pattern. When you create an application in JDeveloper, you can choose many application templates that automatically set up data model and user interface projects. Because the different MVC layers are decoupled from each other, development can proceed on different projects in parallel and with a certain amount of independence.

ADF Library further extends this modularity of design by providing a convenient and practical way to create, deploy, and reuse high-level components. When you first design your application, you design it with component reusability in mind. If you created components that can be reused, you can package them into JAR files and add them to a reusable component repository. If you need a component, you may look into the repository for those components and then add them into your project or application.
For example, you can create an application module for a domain and package it to be used as the data model project in several different applications. Or, if your application will be consuming components, you may be able to load a page template component from a repository of ADF Library JARs to create common look and feel pages. Then you can put your page flow together by stringing together several task flow components pulled from the library.

An ADF Library JAR contains ADF components and does not, and cannot, contain other JARs. It should not be confused with the JDeveloper library, Java EE library, or Oracle WebLogic shared library.

Table 44–1 lists the reusable components supported by ADF.

<table>
<thead>
<tr>
<th>Reusable Component</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Data control</td>
<td>Any data control can be packaged into an ADF Library JAR. Some of the data controls supported by Oracle ADF include application modules, Enterprise JavaBeans, web services, URL services, JavaBeans, and placeholder data controls.</td>
</tr>
<tr>
<td>Application module</td>
<td>When you are using ADF Business Components and you generate an application module, an associated application module data control is also generated. When you package an application module data control, you also package up the ADF Business Components associated with that application module. The relevant entity objects, view objects, and associations will be a part of the ADF Library JAR and available for reuse.</td>
</tr>
<tr>
<td>Business components</td>
<td>Business components are the entity objects, view objects, and associations used in the ADF Business Components data model project. You can package business components by themselves or together with an application module.</td>
</tr>
<tr>
<td>Task flows and taskflow templates</td>
<td>Task flows can be packaged into an ADF Library JAR for reuse. If you drop a bounded task flow that uses page fragments, JDeveloper adds a region to the page and binds it to the dropped task flow. ADF bounded task flows built using pages can be dropped onto pages. The drop will create a link to call the bounded task flow. A task flow call activity and control flow will automatically be added to the task flow, with the view activity referencing the page. If there is more than one existing task flow with a view activity referencing the page, it will prompt you to select the one to automatically add a task flow call activity and control flow. If an ADF task flow template was created in the same project as the task flow, the ADF task flow template will be included in the ADF Library JAR and will be reusable.</td>
</tr>
<tr>
<td>Page templates</td>
<td>You can package a page template and its artifacts into an ADF Library JAR. If the template uses image files and they are included in a directory within your project, these files will also be available for the template during reuse.</td>
</tr>
<tr>
<td>Declarative components</td>
<td>You can create declarative components and package them for reuse. The tag libraries associated with the component will be included and loaded into the consuming project.</td>
</tr>
</tbody>
</table>

You can also package up projects that have several different reusable components if you expect that more than one component will be consumed. For example, you can create a project that has both an application module and a bounded task flow. When this ADF Library JAR file is consumed, the application will have both the application module and the task flow available for use. You can package multiple components into one JAR file, or you can package a single component into a JAR file. Oracle ADF and JDeveloper give you the option and flexibility to create reusable components that best suit you and your organization.
You create a reusable component by using JDeveloper to package and deploy the project that contains the components into an ADF Library JAR file. You use the components by adding that JAR to the consuming project. At design time, the JAR is added to the consuming project's class path and so is available for reuse. At runtime, the reused component runs from the JAR file by reference. For the procedure to add the JAR manually, see Section 44.3.2, "How to Add an ADF Library JAR into a Project Manually." For the procedure to add the JAR using the JDeveloper Resource Catalog, see Section 44.3.1, "How to Add an ADF Library JAR into a Project using the Resources Window."

Before you proceed to create reusable components, you should review the guidelines for creating reusable components.

44.1.1 Creating Reusable Components

Creating and consuming reusable components should be included in the early design and architectural phases of software projects. You and your development team should consider which components are candidates for reuse, not only in the current applications but also for future applications and including those applications being developed in other departments.

You and your team should decide on the type of repository needed to store the library JARs, where to store them, and how to access them. You should consider how to organize and group the library JARs in a structure that fits your organizational needs. You should also consider creating standardized naming conventions so that both creators and consumers of ADF Library JARs can readily identify the component functionality.

Tip: If, in the midst of development, you and your team find a module that would be a good candidate for reuse, you can use the extensive refactoring capabilities of JDeveloper to help eliminate possible naming conflicts and adhere to reusable component naming conventions.

### 44.1.1.1 Naming Conventions

When you create reusable components, you should try to create unique and relevant names for the application, project, application module, task flow, connection, or any other file or component. Do not accept the JDeveloper wizard default names such as Application, Project, ViewController, AppModule, task-flow-definition.xml, or Connection. You want to try to have unique names to avoid naming conflicts with other projects, components, or connections in the application. Naming conflicts could arise from components created in the consuming application and those loaded from other JAR files. Table 44–2 lists the objects that you may be required to rename.

<table>
<thead>
<tr>
<th>Type</th>
<th>JDeveloper Default</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Application</td>
<td>Application</td>
<td>SummitADF</td>
</tr>
<tr>
<td>Project</td>
<td>Model</td>
<td>BackOfficeService</td>
</tr>
<tr>
<td></td>
<td>ViewController</td>
<td>OrderTrackingUI</td>
</tr>
<tr>
<td></td>
<td>Project</td>
<td></td>
</tr>
<tr>
<td>Package</td>
<td>Various possibilities. For more information, see Section 44.1.1.1.1.</td>
<td>oracle.summit</td>
</tr>
</tbody>
</table>
Be aware that some components use the default package name of the project without allowing the name to be explicitly set. In this situation, you must take extra care to avoid package name collisions. You can set the package name in the application creation wizard and you should check the names in the Project Properties dialog afterwards. If you don’t set the package name, it will default to a variant of the project name, typically with the first letter being lowercase. For example, a project with the name Project1 will have a default package name of project1. You should manually change the package name to a more unique name before you proceed to build the project.

When you are creating a reusable component’s web resource files (such as JSPs, HTMLs, and task flows), you should create them in their own relative directories. When the JAR is deployed into another application, there will be less chance for conflict between the reusable component’s files and the consuming application’s files.

### 44.1.1.1 Naming Considerations for Connections

Often, several modules in an application will connect to the same data source. You should standardize the connection name to the same data source to avoid confusion because there is only one namespace for connections across the application. This would require coordination with other developers, component producers, and
component consumers. For example, if customers and suppliers both have a connection to the same database, the connection name should be standardized to an agreed upon name, such as orders_db.

ADF Library JARs (with connections) may be used in different applications with different connection requirements. ADF Library JAR producers should choose connection names that are at least representative of the connection source, if not the actual standardized connection name. Be aware that consumers of the JAR that was created with connections will be required to satisfy the connection requirements when they add the component to the application.

For example, for a database connection, choosing an endpoint host name is usually not appropriate. The most appropriate name is a complete representative for the schema. Acceptable example names for connections are oracle-appsdb and oracle-customersdb. You should realize that if many reusable components use different names for the same logical connection, then the consumer of the component will have to satisfy each one individually with duplicate information. The consumer will have to supply connection details for several different connection names, when in fact they all refer to the same instance.

### 44.1.1.1.3 Naming Considerations for Applications with EJB Projects

If an application has both EJB projects and a web application project with data binding, you should check to see that the EJB component names are not in conflict with any other web application project component names. The EJB project components may have global scope because the project is automatically added to the global class path of all web projects in the application. The web application project may mistakenly access a component with the same name in the EJB project rather than within its own project.

For example, if both an EJB project and a web-based project have a test1.jspx page, when the web-based project is run, it may try to run the EJB project test1.jspx page.

At runtime, JDeveloper detects if there are EJB projects and web application projects with data binding in the same application. If there are both types in the application, when the project is run and the server starts up, a warning message will appear in the Log window.

### 44.1.1.2 The Naming Process for the ADF Library JAR Deployment Profile

Before you package the project, you must create a deployment profile with the name and path for the JAR file. You should choose a name that follows you and your development team’s naming convention and that is descriptive of the function of the component. You should realize that the consuming project may also include other JAR files from other software authors.

For example, if the component is a task flow for self-service paying, you might name it mycompany.hcm.pay.selfservice.taskflows.jar. Other examples are oracle.apps.hcm.pay.model.jar and mycompany.hcm.pay.model.overrides.jar.

When you create the deployment profile, JDeveloper will present a default name with the following format:

```
adflibidentifierN
```

Where identifier is random number up to three-digits and N is a number that starts with 1 and increments by 1 for each iteration of the profile.
For example, the default name for a profile may be \texttt{adflib7491} (random number is 749 and suffix is 1). The default name for the another profile may be \texttt{adflib51} (random number is 5 and suffix is 1).

You can change this default name to a name of your choice.

44.1.1.3 Keeping the Relevant Project

When you are creating reusable components, you should eliminate any projects that are not relevant to the reusable component. For example, if you want to create a reusable application module, you would need a data model project, but you would not need a user interface project. In this instance, if you had created an application with both a data model and a user interface project, you could delete the user interface project. Of course, you should rename the default name \texttt{Model} to something more relevant, such as \texttt{BackOfficeService}. Similarly, if you are creating a reusable task flow that is not databound, you can delete any data model project from the application.

44.1.1.4 Selecting the Relevant Feature

If you know the technology scope of your consuming projects, you can design your component with technologies that will be compatible. For example, if the consuming application uses only standard JSF Faces, then it may not be compatible with a declarative component that is built with ADF Faces.

When you create your application, you can define the features using the Create Application Wizard by selecting from the application template.

After the project has been created, you can define the technology using the Features page of the Project Properties dialog.

44.1.1.5 Selecting Paths and Folders

If you are using the file system to store your ADF Library JARs, you should select file system locations that can function as repositories. You may want to put groups of JARs into a common directory folder, for example, \texttt{C:\ADF\jdev\DevTeamADFRepository}. If your team or organization plans to share ADF Library JARs, you should consider setting up network-accessible repository folders, directories, or services. The Resources window has provisions to connect to different repository sources and make multiple connections. For more information about accessing ADF Library JARs using the Resources window, see Section 44.1.4.2, “Using the Resources Window.”

44.1.1.6 Including Connections Within Reusable Components

If the project you are packaging into an ADF Library JAR includes a connection, that information can be included in the JAR and may be available to the consuming project. Oracle ADF uses connection architecture which defines a connection as two parts, the connection name and the connection details (or endpoint definition). JDeveloper will present the producer of the JAR the option to package the connection name only or to include connection details with the connection name.

If a connection is present in the project, the packaged ADF Library JAR will contain a \texttt{jar-connections.xml} file and a \texttt{jar-adf-config.xml} file. They will be added to the \texttt{META-INF} directory. The \texttt{jar-connections.xml} file contains the connection name and other relevant connection information. The \texttt{jar-adf-config.xml} file stores the information about the credentials used for the connections. If connection credentials were also specified, then a \texttt{jar-credential-jazn-data.xml} will also be included for the credential store. You can select the individual connections or
connection types that you want to be packaged with the ADF Library JAR when you create the ADF Library JAR deployment profile. You make connection selections in the Create or Edit ADF Library Deployment Profile Properties dialog Connections page, as described in Section 44.2.1, "How to Package a Component into an ADF Library JAR."

When an ADF Library JAR is being added to a project, JDeveloper checks for conflicts between the application’s connections and the JAR’s connections. A dialog will be presented to allow you to decide whether to proceed with adding the JAR to the project. Connections defined in the ADF Library JAR may be added to the consuming project, depending on the following conditions:

- If the connection defined in the JAR is fully configured and there are no connection name conflicts with the consuming project, a new connection will be added.
- If the connection defined in the JAR is partially configured, a new connection will be added to the consuming project but it must be configured before use. Connection dialogs may appear to allow the user to enter connection information. This partially configured connection may be indicated by an incomplete icon.
- If the connection defined in the JAR has the same name as the application’s connection, it will not be added to the project. The application’s existing connection will be used.
- If the connection defined in the JAR has the same name as the application’s connection but is of different type, the JAR’s connection will not be added to the project. For example, if a database connection in the JAR and a URL connection in the application have the same name, the database connection will not be added to the application.

For instructions on how to add an ADF Library to a project that includes connections, see Section 44.3.1, "How to Add an ADF Library JAR into a Project using the Resources Window."

---

**Note:** In the process of adding the ADF Library to a project, you will see one message displayed in the Log window for each connection defined in the JAR. The messages indicate the merge action taking place in the project.

### 44.1.2 Reusable ADF Components Use Cases and Examples

Packaging projects into ADF Library JARs allows components to be reused multiple times in the same or in different applications. Different development teams can create and consume projects and create libraries of reusable modules. ADF Library JARs support the M-V-C design pattern. You can create ADF Libraries and access them using drag and drop from the Resources window.

For instance, you can package up an application module into an ADF Library JAR and place it in a public folder for other team to use. Different implementation teams may access that JAR to create their applications. They may use the application module to create different pages for their use instead on having to create their own application modules. When there is a change in the model, the original developer can repackage the application module and republish the ADF Library JAR. The other implementation teams can update their application using the updated ADF Library.
44.1.3 Additional Functionality for Reusable ADF Components

You may find it helpful to understand other ADF features before you work with reusable ADF components. Following are links to other functionality that may be of interest.

- You can package business components for reuse. For more information on application modules, see Chapter 3, "Getting Started with ADF Business Components."
- You can package application modules for reuse. For more information on application modules, see Chapter 13, "Implementing Business Services with Application Modules."
- You can package task flows for reuse. For more information on task flows, see Chapter 20, "Getting Started with ADF Task Flows."
- You can package page templates for reuse. For more information on task flows, see Chapter 26, "Getting Started with Your Web Interface."
- You can package page templates for reuse. For more information, see the "Using Declarative Components" section of the Developing Web User Interfaces with Oracle ADF Faces.

44.1.4 Common Functionality of Reusable ADF Components

When you package or consume an ADF Library JAR, you also include and consume the extension libraries that are associated with the project. When you consume an ADF Library, you can use the Resources window.

44.1.4.1 Using Extension Libraries

An ADF project usually includes a list of extension libraries that it needs to run. These libraries are loaded in the class path of the project. You can view a project’s dependent libraries by selecting the Libraries and Classpath node of the Project Properties dialog. Some of the libraries that may appear are JSP Runtime, ADF Page Flow Runtime, Connection Manager, and Oracle JDBC.

When a project is packaged into an ADF Library JAR, its extension libraries are packaged with it. And when an ADF Library JAR is being consumed by another project, JDeveloper automatically resolves any extension library conflicts between them. During the consuming process, JDeveloper checks to see whether the consuming project already has the extension libraries of the ADF Library JAR in its class path and loads only those libraries that it does not have. For example, if JSP Runtime already exists in the consuming project, it will not be loaded again if the ADF Library JAR also includes it. The consuming project’s extension libraries will be a union of its own libraries and the libraries in the ADF Library JAR.

If the project you want to package into an ADF Library has a dependent project, you can include the dependent project’s extension libraries directly in the JAR or, if the dependent project has a deployment profile, you can add the dependent project’s JAR to the ADF Library. For more information about setting up the deployment process, see Section 44.2.1, "How to Package a Component into an ADF Library JAR."

For example, suppose that project View is being packaged into ADF Library adflibView1.jar and that has a dependency on the Model project. For project View, the Model project is a dependent project with the deployment profile option (adflibmodell) selected, as shown in Figure 44–1.
When the deployment profile is selected, the dependent project’s JAR file will be added to the ADF Library JAR. As a result, the extension libraries of the dependent project will also be made available to any consuming project. In Figure 44–2, the ADF Library being packaged, adflibView1.jar, includes the dependent adflibModel.jar as listed under the Library Dependencies node.

Alternately, you can include the dependent project’s artifacts and extension libraries directly into the ADF Library JAR.
For example, project View can also be packaged into ADF Library adflibView2.jar. It also has a dependency on the Model project. But in this second deployment profile, the Model project is a dependent project with the Build Output option selected (as opposed to the deployment profile (adflibmodel1) being selected), as shown in Figure 44–3.

Figure 44–3  Edit Dependencies Dialog Used to Built adflibview2.jar

When Build Output is selected, the dependent project’s classes and extension libraries will be added directly to the ADF Library JAR. Figure 44–4 shows the ADF Library adflibView2.jar, which includes artifacts of the Model project and its extension libraries. Note that the extension libraries under the adflibView2.jar Library Dependencies node are the same as the combined extension libraries under the adflibView1.jar and adflibModel.jar shown in Figure 44–2.

Figure 44–4  Resources Window Showing adflibView2.jar Extension Libraries
About Reusable Components

How you decide to package the dependent project depends on how you intend the ADF Library to be used. Including the dependent project as a JAR may be advantageous when the dependent project is itself a reusable component, or when it is a dependent project for several projects that will be packaged into an ADF Library JAR. In the example, the dependent project Model may be a dependent project for several view projects. On the other hand, packaging the dependent project as Build Output is straightforward and eliminates the need for multiple JARs.

---

**Note:** If you are creating an ADF Library JAR that is included in a JDeveloper extension library, you should include the additional manifest JDevLibrary: extension_library_name entry in the JAR. When you use Add to Project from the Resources window to add a ADF Library JAR that has a JDevLibrary manifest entry, the JDeveloper extension library containing this JAR will be added instead of the ADF Library JAR itself.

---

### 44.1.4.2 Using the Resources Window

ADF Library JARs can be packaged, deployed, discovered, and consumed like any other Oracle Library component. Creating an ADF Library JAR is the action of packaging all the artifacts (and additional control files) of a project into a JAR. Consuming a reusable component from an ADF Library JAR is the action of loading that ADF Library JAR into the project’s set of libraries.

However, the easiest way to manage and use ADF Library JAR components is by using JDeveloper’s Resources window. With the Resources window, developers who want to consume reusable components can easily find and discover available components and add them to their projects. The Resources window provides search and browse functions across different data management systems to locate the component. It provides multiple connections to access different sources. It has a structure tree view for displaying different connections and the ADF Library JAR component types. Figure 44-5 shows the Resources window with several file system connections.

The Resources window tree structure displays each JAR as subcategories. Separate nodes are created for each type of reusable component. For example, application modules are under the Data Controls node, and task flows are under the ADF Task Flows node.

The tree structure for the ADF Library JAR lists any connection information under a Library Connections node and lists all the producing project’s extension libraries under the Library Dependencies node.
Packaging a Reusable ADF Component into an ADF Library

44.2 Packaging a Reusable ADF Component into an ADF Library

Once you have decided that a certain component or components can be reused, create an application and a project to develop that component. Follow the guidelines in Section 44.1.1, "Creating Reusable Components" to name your application, project, package, and other objects and files. A project corresponds to one ADF Library JAR. If you create multiple projects and want to reuse components from each of the projects, you may need to create an ADF Library JAR for each project. In other situations, you may be able to involve multiple components under one project to create a single ADF Library JAR. For example, you may be able to create application modules, business components (entity object, view objects, associations), task flows, and page templates all under one project and create one ADF Library JAR.

Creating an ADF Library JAR involves compiling the project and validating the components, creating a resource service file, control files, an adflibREADME.txt, and adding the relevant project files into a JAR. For more information about the ADF Library JAR, see Section 44.2.2, "What Happens When You Package a Project to an ADF Library JAR."

If you are packaging a component that itself uses another ADF Library component, the final consuming project must have both ADF Library JARs added to the project. For example, say you created a reusable task flow that contains tables dropped from a data control in another ADF Library JAR. When you add the task flow from an ADF Library JAR into a consuming project, that project will also require the data control ADF Library JAR.

If you are packaging a component that has dependent JARs, such as third-party JARs, you have two options:

- If the consuming environment has control over the placement of JARs, you can place the ADF Library JAR and its dependent JARs in a JDeveloper Extension.
Library. The advantage of using a JDeveloper Extension Library is that it does not clutter the consuming project with specific references to the dependent JARs.

- If using JDeveloper Extension Library is not possible, you can place the dependent JARs in the same location as the ADF Library JAR and include a manifest classpath entry for each dependent JAR.

### 44.2.1 How to Package a Component into an ADF Library JAR

To package up a reusable component, you first create a deployment profile that specifies the archive type, the name of the JAR file, and the directory path where the JAR will be created. Then you deploy the project using the deployment profile.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Section 44.2, "Packaging a Reusable ADF Component into an ADF Library.”

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Section 44.1.3, "Additional Functionality for Reusable ADF Components.”

You will need to complete this task:

Create a project and determine whether it has dependent projects and JAR that need to be packaged. For more information, see Section 44.2, "Packaging a Reusable ADF Component into an ADF Library.”

**To package and deploy a project into the ADF Library JAR:**

1. In the Applications window, double-click the project that contains the component you want to make reusable.
2. In the Project Properties dialog, select **Deployment** and then click **New**.
3. In the Create Deployment Profile dialog, select **ADF Library JAR file** for **Profile Type**, enter a name or accept the default name for **Deployment Profile Name**, and click **OK**.

**Figure 44–6 Create Deployment Profile Dialog with Default Name**

4. In the Project Properties dialog, select the deployment profile and click **Edit**.
5. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Library Dependencies** node, as shown in **Figure 44–7**.
The Library Dependencies pane shows a list of dependent projects for the project being packaged. You can add the dependent project’s build output directly into the packaging project’s library, or you can add selected deployment profile archives to the class path.

1. To add dependent projects, click the **Edit** icon to bring up the Edit Dependencies dialog, as shown in **Figure 44–8**.

   If you select **Build Output**, the dependent project’s extension libraries will be added directly to the ADF Library JAR. If you select deployment profile, the dependent project’s JAR file (which includes its own extension libraries) will be added to the ADF Library JAR. For more information about library dependencies, see Section 44.1.4.1, “Using Extension Libraries.”

In this example, the **Model** project can be set as a dependency only as **Build Output**. However, the **ViewController** project can be set as a dependency either as **Build Output**, or as a deployment profile (SummitADF_Controller_webapp).
b. For each dependent project, select the Build Output node for the project or select the dependent profile and click OK.

6. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the Connections node, as shown in Figure 44–9.

You can select:

- **Connection Details (excluding secure content):** If the project has a connection, select this checkbox if you want to include any available connection details in addition to the connection name. Connection details include hostname, port number, sid, driver type, and user name. For more information, see Section 44.1.1.6, “Including Connections Within Reusable Components.”

- **Connection Name Only:** Select this checkbox if you want to add the connection name without any connection details.

**Note:** The connection options available depends on the JDeveloper role. **Connection Details (excluding secure content)** and **Connection Name Only** are the selections available for the Studio Developer role. If your JDeveloper is set to a different role, you may have different options and defaults.

In the Applications Connections tree structure, select the checkbox for the level of connection you want to include.

![Figure 44–9 Connections Page of the Edit ADF Library JAR Deployment Profile Properties Dialog](image)

7. Select the JAR Options node, as shown in Figure 44–10, verify the default directory path or enter a new path to store your ADF Library JAR file.

If the ADF Library JAR is to be included in a JDeveloper extension library, create a text file with a JDevLibrary: extension_library_name entry and place the
file in the project root directory. Click **Add** to locate and merge that file into the Manifest.mf file.

When you create your manifest text file, make sure the JDevLibrary entry starts in column 1 with a space after the colon, and that there is a blank line at the end of the file.

**Figure 44–10  ADF Library JAR Deployment Profile Properties Dialog JAR Option**

8. Select the **ADF Validation** node.

You can select:

- **Ignore Errors**: To create the JAR file even when validation fails. This is the default option.
- **Stop Processing**: To stop processing when validation fails.
9. Click OK to finish setting up the deployment profile.

10. In the Applications window, right-click the project and choose Deploy > deployment, where deployment is the name of the deployment profile.

11. In the Deploy dialog Deployment Action page, click Next and then click Finish. JDeveloper will create the ADF Library JAR in the directory specified in Step 7. You can check that directory to see whether the JAR was created.

44.2.2 What Happens When You Package a Project to an ADF Library JAR

When you deploy the library JAR, JDeveloper packages up all the necessary artifacts, adds the appropriate control files, generates the JAR file, and places it in the directory specified in the deployment profile. During deployment, you will see compilation messages in the Log window.

When you deploy a project into an ADF Library JAR, JDeveloper performs the following actions:

- Package the HTML root directory artifacts into the JAR. When the JAR is added to the consuming project, JDeveloper will make the reusable component’s public_html resources available by adding it to the class path.

- Add the adfm.xml file to the JAR. If there are multiple META-INF/adfm.xml files in the workspace, only the adfm.xml in the project being deployed is added. JDeveloper modifies this file to include relevant content from any dependent project’s adfm.xml file.

- Add a service resources file, oracle.adf.common.services.ResourceService.sva, into the META-INF directory of the JAR. The addition of this file differentiates an ADF Library JAR file from standard JAR files. This file defines the service strategies of the JAR and allows the Resources window to properly discover and display the contents of the JAR.
Add a `Manifest.mf` file to the JAR. The `Manifest.mf` file is used to specify dependencies between JAR files, and to determine whether to copy and include the contents of a JAR file or to reference it. JDeveloper will create a default manifest file. For example:

```
Manifest-Version: 1.0
```

Add a `jar-connections.xml` file to the JAR for components that require a connection and that use the connections architecture. Note that in the consuming application, connection information in configuration files that are defined in the class path and accessible at runtime may be merged together. If the same connection is named multiple times in the class path, the connection in the main application will be given priority.

Different types of reusable components have different artifact files and different entries in the service resource file.

### 44.2.2.1 Application Modules Files Packaged into a JAR

For application modules, JDeveloper adds these control files to the JAR:

```
```

The service resource file for an application module includes entries for the business components associated with the application module, as well as an entry for the application module data control.

The `jar-connections.xml` file may appear for components that use the connection architecture and that contain connection information regarding the data source.

### 44.2.2.2 Data Controls Files Packaged into a JAR

For data controls such as placeholder data controls, JDeveloper includes three control files in the JAR:

```
oracle.adf.common.services.ResourceService.sva, Manifest.mf, and DataControl.dcx file.
```

Data controls are used when the data source is not based on ADF Business Components, and so business components are not included in the JAR file, as is the case in an application module JAR file. The service resource file for a standard data control has an entry for the data control.

The JAR also includes the `Datacontrol.dcx` file from the project to describe the data control type.

### 44.2.2.3 Task Flows Files Packaged into a JAR

For task flows, JDeveloper includes three control files in the JAR:

```
oracle.adf.common.services.ResourceService.sva, Manifest.mf, and task-flow-registry.xml.
```

The service resource file for a task flow includes an entry that indicates that one or more task flows are in the JAR.

### 44.2.2.4 Page Templates Files Packaged into a JAR

For page templates, JDeveloper includes two control files in the JAR:

```
oracle.adf.common.services.ResourceService.sva and Manifest.mf.
```

### 44.2.2.5 Declarative Components Files Packaged into a JAR

For declarative components, JDeveloper includes two control files in the JAR:

```
oracle.adf.common.services.ResourceService.sva and Manifest.mf.
```
44.2.3 How to Place and Access JDeveloper JAR Files

If you have JAR files that can be reused by other projects, such as third-party JAR files, you can use JDeveloper to place them in an accessible location and create a library file (.library) to designate them. The consumer can use JDeveloper to navigate to this location and add the JAR to the project.

An ADF Library JAR contains ADF components and does not and cannot contain other JARs.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Section 44.2, "Packaging a Reusable ADF Component into an ADF Library."

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Section 44.1.3, "Additional Functionality for Reusable ADF Components."

You will need to complete this task:

Place the JAR files in a accessible location for both the producer and the consumer of these JAR files. For example, the directory may be on a network drive where other shared files are located. For more information, see Section 44.2, "Packaging a Reusable ADF Component into an ADF Library."

To place and access a JDeveloper Library JAR:
1. From the main menu, choose Tools > Manage Libraries.
2. In the Manage Libraries dialog, click Load Dir.
3. In the Load Directory dialog, select the directory where the secondary JAR files are located.
4. In the Manage Libraries dialog, click New.
5. In the Create Library dialog, enter a library name and click Add Entry.
   You have created a library file (with a .library extension). You should place library files in source control systems.
6. In the Select Path Entry dialog, select the JARs you want to add and click OK.
7. In the Create Library dialog, be sure that the Deployed by Default option is set correctly for your JAR, click OK and then click OK again.
8. In the consuming project.
   a. From the main menu, choose Tools > Manage Libraries.
   b. In the Manage Libraries dialog, click Load Dir.
   c. In the Load Directory dialog, select the directory where the secondary JAR files are located and click Select. This should be the same location specified in Step 3.
   d. Right-click the project and select Project Properties.
   e. In the Project Properties window, select Libraries and Classpath and click Add Library.
   f. In the Add Library dialog, select the library, click OK and then click OK again.
Adding ADF Library Components into Projects

44.3 Adding ADF Library Components into Projects

After ADF Library JARs are created, they must be distributed to the developers who will use these JARs. Distributing the ADF Library JARs may include putting the JARs into a network file system to be searched, browsed, and discovered. It may include using other forms of data store or services to access and retrieve these JARs. Since ADF Library JARs are simply binary files, they can distributed like any other file such as ftp and email.

Once you have access to the ADF Library JARs, you can use JDeveloper to access them and add them to your consuming projects. Using the JDeveloper Resources window is the easiest and most efficient way. You can also use JDeveloper to manually add the JARs into the project by entering them into the class path.

When a project is packaged into an ADF Library JAR, it captures the list of dependent JARs the project needs for deployment and runtime. This list is based on the project’s dependent profiles and the information in the project’s Libraries and Classpath with Deployed By Default selected. When the ADF Library JAR is added to the consuming project, this list of dependent JARs is placed in a library called ADF Library Dependencies. This is a locked library in the consuming project and its content will not be shown in the Data Controls panel, Components window, or other places in JDeveloper. The library is maintained and updated as different ADF Library JARs are added and deleted from the project. If the dependencies have changed (for example, the producer project was rebuilt), then you can refresh the dependencies in the consuming project using a JDeveloper menu command.

Once reusable components have been added, how they are used depends on the type of component.

44.3.1 How to Add an ADF Library JAR into a Project using the Resources Window

You can use the Resources window to search, discover, and add the ADF Library JAR to your project.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Section 44.3, "Adding ADF Library Components into Projects."

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Section 44.1.3, "Additional Functionality for Reusable ADF Components."

You will need to complete this task:

Create an ADF Library JAR in a repository folder. If you do not already have a Resources window connection to this repository, you must know the location of this folder. For more information, see Section 44.3, "Adding ADF Library Components into Projects."

To add a component to the project using the Resources Window:

1. From the main menu, choose Window > Resources.
2. In the Resources window, click the New icon, and then choose IDE Connections > File System.
3. In the Create File System Connection dialog, enter a name and the path of the folder that contains the JAR.
For file path guidelines, see Section 44.1.1.5, “Selecting Paths and Folders.”

4. Click OK.

The new ADF Library JAR appears under the connection name in the Resources window.

5. To examine each item in the JAR structure tree, use tooltips. The tooltip shows pertinent information such as the source of the selected item.

Figure 44–12 shows a Resources window with a tooltip message that shows package information for a business component.

![Figure 44–12 ToolTip Message for a Connection in the Resources Window](image)

6. To add the ADF Library JAR or one of its items to the project, right-click the item and choose Add to Project. In the confirmation dialog that appears, click Add Library, as shown in Figure 44–13.

![Figure 44–13 Confirm Add ADF Library Dialog](image)

If you had previously added that library JAR, you will get a Confirm Refresh ADF Library dialog asking you whether you want to refresh the library.

7. If the ADF Library JAR has changes to its dependencies, you can refresh the project with the new changes. From the Applications window, right-click the project and select Refresh ADF Library Dependencies in `project.jpr`. 
For application modules and data controls, you have the option to drag and drop the application module or data control from the Resources window into the Data Controls panel.

**Note:** JDeveloper will load whichever ADF Library JAR extension libraries are not already in the consuming project. Extension libraries from the ADF Library’s dependent JARs will also be checked and loaded if not already part of the consuming project. For more information, see Section 44.1.4.1, "Using Extension Libraries"

### 44.3.2 How to Add an ADF Library JAR into a Project Manually

You can add an ADF Library JAR in the same way as you would other library JARs.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Section 44.3, "Adding ADF Library Components into Projects."

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Section 44.1.3, "Additional Functionality for Reusable ADF Components."

You will need to complete this task:

Create an ADF Library JAR. For more information, see Section 44.3, "Adding ADF Library Components into Projects."

**To add a component to a project manually:**

1. In the Applications window, double-click the project to which the component is to be added.
2. In the Project Properties dialog, select the Libraries and Classpath node and then click Add Library.
3. In the Add Library dialog, click New.
4. In the Create Library dialog, in the Location dropdown list, select Project and enter a name for the ADF Library. The preferable name is "ADF Library". Select Deploy by Default, and click Add Entry.
5. In the Select Path Entry dialog, enter or browse to the ADF Library JAR file and click Open.
6. The Create Library dialog reappears with the path of the JAR file filled in under the Class Path node. Click OK.
7. The Add Library dialog reappears with the ADF Library entry filled in under the Project node. Click OK.
8. The Project Properties dialog reappears with the JAR file added to the list of libraries. Click OK.

44.3.3 What Happens When You Add an ADF Library JAR to a Project

When you add an ADF Library JAR to a project, either by using the Resources window or by manually adding the JAR, an ADF Library definition is created in the project. The ADF Library JAR file will be added to the class path of the project. The project will access and consume the components in the JAR by reference.

By default, the ADF Library Deployed by Default option in the Create Library dialog is set to true. If this option is set, when the application or module is further archived or built into a WAR file, the contents of the ADF Library JAR will be copied to that archive or WAR file. If the Deploy by Default option is not set, then the JARs in the ADF Library must be loaded in some other way, such as by deploying them in a shared library.

Figure 44–15 shows the empty Data Controls panel for a consuming project before the ADF Library was added.
Figure 44–15  Data Controls Panel of the Consuming Project

Figure 44–16 shows the adflibview1 ADF Library being added to the consuming project.

Figure 44–16  Adding the ADF Library JAR to the Project

Figure 44–17 shows several data controls from the ADF Library added to the Data Controls panel in the consuming project.

Figure 44–17  Consuming Project Data Controls Panel with Added Application Modules
After adding the ADF Library JAR, you may notice some changes to some of the JDeveloper windows. These changes are different depending on the type of components being added. Table 44–3 lists the effects on several JDeveloper windows.

#### 44.3.4 What You May Need to Know About Using ADF Library Components

Although the procedure to add an ADF Library JAR to a project is standardized, the component type determines where it appears in JDeveloper and how it can be reused.

##### 44.3.4.1 Using Data Controls

When you add a data control to a project, the data control appears in the Data Controls panel. If you are using the Resources window, you have the option of dragging and dropping the data control from the Resources window onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

##### 44.3.4.2 Using Application Modules

When you add an application module to a project, the application module appears in the Data Controls panel. If you are using the Resources window, you have the option of dragging and dropping the application module item from the Resources window onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.
Application modules are associated with business components. When the reusable application module was packaged, the JAR includes the business components used to create the application module. These components will be available for reuse.

### 44.3.4.3 Using Business Components

Business components can also be packaged and reused. The entity objects, view objects, and associations can be packaged together and added to a consuming project. By default, packaged application modules will include the business components in the JAR, but business components can be reused by themselves without the accompanying application module.

One way to reuse business components is to create new view objects using the entity objects from an ADF Library JAR. When you add view objects using the wizard, the entity objects will become available within the wizard to support view object generation. For instructions on creating view objects, see Section 5.2.1, "How to Create an Entity-Based View Object." When the wizard presents a screen for entity objects used to create view objects, the entity objects from the ADF Library will be available in the shuttle window, as shown in Figure 44–18.

![Figure 44–18 Creating View Object Using Entity Objects from ADF Library](image)

If the consuming project has the Initialize Project for Business Component option selected (in the Project Properties dialog Business Components page) before the ADF Library JAR is added, the business components within the JAR will automatically be made available to the project.

If you add the ADF Library JAR first, and then select Initialize Project for Business Component, JDeveloper will automatically load the business components.

### 44.3.4.4 Using Task Flows

Task flows added to a project will appear in the Components window when you are adding components to a JSF page. If you are using the Resources window, you can
also drag and drop the task flow directly from the Resources window onto another task flow or page, as shown in Figure 44–19.

**Figure 44–19 Using the Resources Window to Drag and Drop Task Flows**

![Resource Palette](image)

For more information about creating task flows, see Chapter 20, "Getting Started with ADF Task Flows."

### 44.3.4.5 Using Page Templates

When you add a page template to a project, the template will not be exposed in the Applications window. You will not have direct access to individual supporting files, such as image files. However, the template retains its access to its supporting files inside the JAR and is fully reusable within the project. When you apply the template, it will retain all the images that were loaded with the template.

The page template is exposed and accessible when you create a new JSF page using the wizard. When the wizard presents you with the option to use a page template, the ADF Library template will appear in the dropdown list. For example, if you loaded a page template called `SummitTemplate` from an ADF Library, when you use the wizard to create a JSF page, `SummitTemplate` will appear in the wizard, as shown in Figure 44–20. For information on how to use page templates and create a JSF page, see Section 26.2, "Using Page Templates" and the Developing Web User Interfaces with Oracle ADF Faces.
44.3.4.6 Using Declarative Components

When you add a declarative component to a project, the JSP tag libraries that contain the component will be added to the project. The tag libraries will appear in the Components window, and the declarative components will be available for selection. For information about creating and using declarative components, see the Developing Web User Interfaces with Oracle ADF Faces.

44.3.5 What You May Need to Know About Differentiating ADF Library Components

If you mix components created during application development with components imported from the ADF Library, you may be able to differentiate between them by using the tooltips feature of JDeveloper.

Move the cursor over an application module or data control and you will see the full path of the source. If you see the ADF Library JAR file in the path, that means the component source is the ADF Library.

*Note:* The tooltip for items in the Data Controls panel varies depending on whether or not the node has ever been opened in this session. To ensure that you are seeing the most complete tooltip, you should expand the item.

44.3.6 What Happens at Runtime: How ADF Libraries are Added to a Project

After an ADF Library JAR has been added to a project and to the class path, it behaves like any other library file. During runtime, any component that uses the component in the ADF Library JAR will reference that object. The process is transparent and there is no need to distinguish between components that were developed for the project and those that are in ADF Library JARs. Figure 44–21 shows the ADF Library and the path to the JAR as defined for a project.
44.4 Removing an ADF Library JAR from a Project

You can use the Resources window to remove an ADF Library JAR from a project, or you can manually remove the JAR using the Project Properties dialog. You can remove an ADF Library JAR only if the components in the project do not have any dependencies on the components in the ADF Library JAR.

When you remove a JAR, it will no longer be in the project class path and its components will no longer be available for use.

44.4.1 How to Remove an ADF Library JAR from a Project Using the Resources Window

The Resources window allows you to remove previously added ADF Library JARs from a project using a simple command.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Section 44.4, "Removing an ADF Library JAR from a Project."
You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Section 44.1.3, "Additional Functionality for Reusable ADF Components."

You will need to complete this task:

Add the ADF Library JAR using the Resources window. For more information, see Section 44.3, "Adding ADF Library Components into Projects."

To remove an ADF Library JAR from the project using the Resources Window:
1. From the main menu, choose Window > Resources.
2. In the Applications window, select the project that has the ADF Library JAR you want to remove.
3. In the Resources window, locate the ADF Library JAR you want to remove from the current project.
4. Right-click the JAR and choose Remove from Project.

44.4.2 How to Remove an ADF Library JAR from a Project Manually

When you remove an ADF Library JAR manually, be sure to remove the correct library. Be aware of other libraries that are critical to the operation of the project.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Section 44.4, "Removing an ADF Library JAR from a Project."

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Section 44.1.3, "Additional Functionality for Reusable ADF Components."

You will need to complete this task:

Add the ADF Library JAR manually. For more information, see Section 44.3, "Adding ADF Library Components into Projects."

To remove an ADF Library JAR from the project manually:
1. In the Applications window, double-click the project.
2. In the Project Properties dialog, select the Libraries and Classpath node.
3. In the Classpath Entries list, select ADF Library and click Edit.
4. In the Edit Library Definition dialog, select the ADF Library JAR you want to remove under the Class Path node, and click Remove.
5. Click OK to accept the deletion, and click OK again to exit the dialog.
This chapter describes how to develop Fusion web applications that can be customized and subsequently deployed by a customer, using the customization features provided by Oracle Metadata Services (MDS) framework. It also covers how to implement customizations on such applications.

This chapter includes the following sections:

- Section 45.1, "About Customization and MDS"
- Section 45.2, "Developing a Customizable Application"
- Section 45.3, "Customizing an Application"
- Section 45.4, "How to Package and Deploy Customized Applications"
- Section 45.5, "Extended Metadata Properties"
- Section 45.6, "Enabling Runtime Modification of Customization Configuration"

For information on how to deploy customized applications, see Section 48.4, "Deploying the Application."

### 45.1 About Customization and MDS

Using the customization features provided by MDS, you can create applications that fall into the following customization patterns:

- **Seeded customization**
  
  Seeded customization of an application is the process of taking a generalized application and making modifications to suit the needs of a particular group, such as a specific industry or site. Seeded customizations exist as part of the deployed application, and endure for the life of a given deployment. This chapter describes how to create a customizable application, and then customize the application using JDeveloper.

- **User customization (change persistence)**
  
  User customization allows an end user to change the content of the application at runtime to suit individual preferences (for example, which columns are visible in a table), and have those changes "remembered" the next time the user opens the application. For information about user customization, see Chapter 46, "Allowing User Customizations at Runtime."

For more information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), refer to the section about managing the MDS repository in *Administering Oracle Fusion Middleware*. 
45.1.1 Customization and Layers: Use Cases and Examples

A customized application contains a base application and one or more layers containing customizations. MDS stores the customizations in a metadata repository and retrieves them at runtime to merge the customizations with the base metadata to reveal the customized application. Since the customizations are saved separately from the base, the customizations are upgrade safe; a new patch to base can be applied without breaking customizations. When a customized application is launched, the customization content is applied over the base application.

For example, say you have a generalized payroll application with a validation rule that limits the salary field to 4000. Then you create a customization of that validation rule that limits the salary field to 3300. At runtime, the customization is applied to the base application and the validation rule for the salary field limits it to 3300.

A customizable application can have multiple customization layers. Examples of customization layers are industry and site. Each layer can have multiple customization layer values, but typically only one such layer value from each layer is applied at runtime. For example, the industry layer for a customizable application can contain values for healthcare and financial industries; but in the deployed customized application, only one of the values from this layer is used at a time.

Layer values from multiple customization layers can be applied, in a specified order of precedence, on top of the base metadata. For example, a customized application can contain customizations in the financial layer value of the industry layer and the Financial Company #1 layer value of the site layer. Each customization layer corresponds to a customization document that contains a set of instructions that change the underlying metadata.

The customization context of a customized application is defined by the set of customization layer values applied to it.

Figure 45–1 illustrates how layers are applied in a customized application.

Figure 45–1 Example of Layered Customization

To support this, you use JDeveloper to create customization classes, define layers and values, and specify the order of precedence. These processes are described in Section 45.2, "Developing a Customizable Application."
45.1.2 Static and Dynamic Customization Content

Customizations can be categorized as either static or dynamic. Static customizations have only one layer value in effect for all executions of the application, while dynamic customizations can have values that vary based on the execution context of the application. If a customization can vary for different users executing the application, then it is dynamic. If a customization has the same value for all users executing the application then it is static.

When you implement customizations in ADF Business Components objects, the customizations remain the same for entire runtime of the application. This is because these objects are loaded only once for an application and reused for the duration of the application. For example, you can have a customized validation rule in the Healthcare Company #1 value of the site layer that limits salaries for that site to 3300. This is static customization content.

However, you can also implement customizations at the controller or view level that allow the layer value to be determined at runtime, based on user roles (responsibilities) or other application-specific criteria. For example, you can design an application so that users from different organizations see different sets of fields on a given screen. This is dynamic customization content.

The determination of whether a customization is static or dynamic is made in the customization class. In the customization class, if the `getCacheHint()` method returns `ALL_USERS`, then the customization layer is static. For more information about `CacheHint` values, see Section 45.2.2, "What You May Need to Know About Customization Classes."

All objects could have a static customization layer, depending on how the customization classes are implemented. But for ADF Business Components objects, customizations can only be static.

45.1.3 Additional Functionality for Customization

You may find it helpful to understand other features before you start working with customization. Following are links to other functionality that may be of interest.

- For information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see the section about managing the MDS repository in Administering Oracle Fusion Middleware.
- You can use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime. For information, see Chapter 46, "Allowing User Customizations at Runtime."

45.2 Developing a Customizable Application

To create a customizable application, create the base application and perform the following procedures:

**To prepare an application for customization:**

1. Create the customization classes that will be used, as described in Section 45.2.1, "How to Create Customization Classes."
2. Enable seeded customization in the application, as described in Section 45.2.4, "How to Enable Seeded Customizations for User Interface Projects."
3. Specify the customization classes in the `adf-config.xml` file, as described in Section 45.2.7, "How to Configure the `adf-config.xml` File."
4. You can optionally restrict runtime customizations on the application, as described in Section 45.5.1, "How to Edit Extended Metadata Properties."

5. After you have prepared the application for customization, you must prepare JDeveloper so you can use it to implement the customizations, as described in Section 45.3.4, "How to Configure Customization Layers."

45.2.1 How to Create Customization Classes

A customization class is the interface that MDS uses to define which customization applies to the base definition metadata. Each customization class defines a customization layer (for example, industry or site) and can contain multiple layer values. The customization classes that are used in the application must be available to JDeveloper when customizing the application, and included in the deployed application.

45.2.1.1 Customization Classes

A customization class evaluates the current context and returns a String result. This String result is used to locate the customization layer.

The customization class provides the following information:

- A name, that represents the name of the layer.
- An array of values, that represent the customization layer values. Typically, each layer returns a single value. If multiple values are returned, the customizations available in the MDS repository for those values are applied in the order in which they appear in the array. A null value or an array containing an empty string ("") indicates there is no customization layer to apply. For more information, see Section 45.2.1.2, "Implementing the getValue() Method in Your Customization Class."
- An IDPrefix, for objects created in the layer. When new objects are created in a customization layer they need a unique ID. The IDPrefix is added to the autogenerated identifier for the object to create an ID for the newly added object. Each layer needs a unique IDPrefix so that objects created at different customization layers will have unique IDs.
- A cache hint, for the layer defined by the customization class. The cache hint defines whether a layer is static or dynamic. If the getCacheHint() method returns ALL_USERS, then the customization layer is static. For more information about dynamic customizations, see Section 45.1.2, "Static and Dynamic Customization Content." For more information about CacheHint values, see Section 45.2.2, "What You May Need to Know About Customization Classes."

Customizations can be used to tailor an application to suit a specific industry domain (verticalization). Each such domain denotes a customization layer and is depicted using a customization class.

To implement seeded customizations using your customization classes:

- The cust-config section (under mds-config) in the adf-config.xml must contain a reference to the customization classes (as shown in Example 45–6). The customization configuration (cust-config) section provides the customization classes and their precedence for a customized application. See Section 45.2.7, "How to Configure the adf-config.xml File."
- The customization classes must be included in the application to support seeded customizations.
Developing a Customizable Application

For more information, see Section 45.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time." At runtime, your customization classes must be available in the EAR-level application class loader.

- The layer values must be listed in the `CustomizationLayerValues.xml` file.

  This file is located in the `jdev_install\jdev` directory. The names of the layers in this file must be consistent with the customization classes. (For more information, see Section 45.3.4, "How to Configure Customization Layers.") JDeveloper uses this file to retrieve layer values at design time.

When JDeveloper is launched in the Customization Developer role, the Customization Context window displays the available customization layers and layer values. You can select the layer and value to which you want to apply customizations in the Customization Context window. For more information about working in the Customization Developer role, see Section 45.3.1, "Introducing the Customization Developer Role." The layer you choose to customize is called the tip layer. For more information, see Section 45.3.3, "Introducing the Tip Layer."

Example 45–1 shows a sample customization class. Note that all customization classes should have a single, no-argument constructor.

**Example 45–1 Sample IndustryCC customization class in the mycompany package**

```java
package mycompany;

import java.io.IOException;
import java.io.InputStream;
import java.util.Properties;
import oracle.mds.core.MetadataObject;
import oracle.mds.core.RestrictedSession;
import oracle.mds.cust.CacheHint;
import oracle.mds.cust.CustomizationClass;

public class IndustryCC extends CustomizationClass {

    private static final String DEFAULT_LAYER_NAME = "industry";
    private String mLayerName = DEFAULT_LAYER_NAME;

    public IndustryCC() {
    }

    public CacheHint getCacheHint() {
        return CacheHint.ALL_USERS;
    }

    public String getName() {
        return mLayerName;
    }

    public String generateIDPrefix(RestrictedSession sess, MetadataObject mo) {
        return 'I';
    }

    public String[] getValue(RestrictedSession sess, MetadataObject mo) {
        // This needs to return the appropriate value at runtime.
        return new String[] {"financial"};
    }
}
```

This example shows the four methods that define how the customization class will work: `getCacheHint()`, `getName()`, `generateIDPrefix()`, and `getValue()`. Today, the methods `generateIDPrefix()` and `getValue()` are used to define the layer and its values.
The return value for `getCacheHint()` indicates to MDS how widely visible a metadata object with this customization is, and therefore its likely duration in memory. It also defines whether or not a layer is static or dynamic. In this example, the `getCacheHint()` method returns `ALL_USERS`, which means the customization layer is static. For more information about CacheHint values, see Section 45.2.2, "What You May Need to Know About Customization Classes."

The `getName()` method returns the name of the customization layer. A SiteCC customization class, for example, might return "site." In this example, the `getName()` method returns "industry."

The `generateIDPrefix()` method creates an IDPrefix. The IDPrefix is a unique, abbreviated string that identifies the name and value of the layer. It is used as the prefix of the ID for objects created in the customization layer. The default implementation (if no IDPrefix is specified) returns name of the layer concatenated with customization value. For performance reasons, the IDPrefix should be kept short (4 characters or less). Therefore, the default implementation should be overridden. The related `getIDPrefix()` method returns the IDPrefix of the customization layer. In this example, the `getIDPrefix()` method would return "I" (for "industry").

The `getValue()` method returns the customization value (or values) for the customization class. In this example, the `getValue()` method returns a single value, "financial," that defines the customization context when combined with the layer name. There are additional techniques for using the `getValue()` method described in Section 45.2.1.2, "Implementing the `getValue()` Method in Your Customization Class."

```
45.2.1.2 Implementing the `getValue()` Method in Your Customization Class
The `getValue()` method is used to retrieve the layer value(s) of the customization class based on the application context and the metadata. For example, calling `getValue()` on a SiteCC customization class might return an array with single entry "headquarters." Typically, the `getValue()` method returns an array with a single value, as shown in Example 45–1.

You can also return multiple values from the `getValue()` method, as shown in Example 45–2.

**Example 45–2 The `getValue()` Method Returning Multiple Values**
```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
   return new String[] {"North America", "US", "CA"}
}
```

When multiple values are returned, customizations applicable to all values are applied. Customizations are applied in the order in which they appear in the array. In this example, `North America` customizations are applied over the base application, then `US` customizations are applied, and finally `CA`. Note: The possible layer values corresponding to a layer name are retrieved by JDeveloper in the Customization Developer role from the `CustomizationLayerValues.xml` file. The precedence of layers is defined by the order of the customization classes specified in the `adf-config.xml` file. The names of the layers must be consistent in these files and in the customization classes.
Developing a Customizable Application

Customizing Applications with MDS

The `getValue()` method can return a layer value based on the current execution context for the current user, pulled either from static or thread local state maintained by the client, or from properties set by the client on the MDS session and based on the metadata object name. **Example 45–3** shows this type of implementation.

**Example 45–3  The getValue() Method Returning a Layer Value Based on the Current Execution Context**

```java
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    if (mo.getName().equals("/sample/abc.jspx")) {
        return new String[]{"Headquarters"};
    } else {
        return new String[]{"RemoteSite"};
    }
}
```

In this example, the `getValue()` method uses the `getName()` method on the metadata object to determine if the name of the metadata document is "/sample/abc.jspx". If so, `getValue()` returns Headquarters to apply headquarters customizations. If not, it returns RemoteSite to apply customizations for remote sites.

**Note:** Returning multiple values for a customization layer is an advanced concept that is typically unnecessary.

An additional technique that can be useful during the development cycle is to use an external properties file to specify layer values. **Example 45–4** references a properties file (`customization.properties`) that stores the layer values.

**Example 45–4  The getValue() Method Using a Properties File to Specify Layer Values**

```java
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    Properties properties = new Properties();
    String configuredValue = null;
    Class clazz = IndustryCC.class;
    InputStream is = clazz.getResourceAsStream("/customization.properties");
    if (is != null) {
        try {
            properties.load(is);
            String propValue = properties.getProperty(mLayerName);
            if (propValue != null) {
                configuredValue = propValue;
            }
        } catch (IOException e) {
            e.printStackTrace();
        }
    }
    return new String[] {configuredValue};
}
```

**Note:** Coding the `getValue()` method to return a value based on the metadata object is an advanced concept that is typically unnecessary. Customization context for dynamic layers is typically determined through facets of the application context, such as user name or responsibility.
try {
    is.close();
} catch (IOException e) {
    e.printStackTrace();
}

return new String[] {configuredValue};

When an application using this technique is run in JDeveloper, you can change the layer value in the properties file and refresh the browser to see new customizations being applied. This customization class and properties file combination allows you to maintain the layer value in a separate file so you don’t need to modify and recompile Java code to change it for a particular deployment. If you use a customization.properties file, it must be packaged with the customization classes so that they are loaded from the same class loader.

Example 45–5 shows a sample customization.properties file. When the IndustryCC class is loaded with this properties file, the layer value healthcare is applied.

Example 45–5  Sample Contents of a customization.properties File

#Configured values for the default layer values
industry=healthcare
site=headquarters

45.2.1.3 Creating a Customization Class

When creating customization classes, put them in a separate project. This allows you to deploy them to a JAR and to import the JAR into your lowest level project (which is typically the data model project). This approach increases modularity, making it easier to include the customization classes in multiple applications across your company, and easier to patch them centrally. For more information about this approach, see Section 45.2.3, "How to Consume Customization Classes."

Alternatively, you can put the customization classes in the data model project if you are creating customization classes that will be used in a single application only, or if you have no need to use the Customization Developer role and want simply to run the application locally from JDeveloper or to deploy remotely with MDS configuration.

Make sure that there is only one copy of the customization classes in the application and that they are packaged in a JAR file so that they are loaded at the EAR-level application class loader. By default, adding project dependencies will add the customization classes to the WAR profile, which will not work correctly after the application is packaged and deployed. For more information about packaging your application for deployment, see Section 48.3.2, "How to Create Deployment Profiles."

Use the following procedure to create a customization class.

Before you begin:

It may be helpful to have an understanding of the features of customization classes. For more information, see Section 45.2.1.1, "Customization Classes."
You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will need to launch JDeveloper using the Studio Developer role, and open (or create) the application that will hold the customization classes.

**To create a customization class:**

1. From the main menu, choose File and then From Gallery.
2. In the New Gallery, expand General, select Projects and then Java Application Project, and click OK.
3. In the Create Java Project dialog, specify the appropriate settings for your project, and click Finish.

   ---
   **Note:** You should use a single project to hold all of your customization classes.
   ---

4. For more information about the options in the Create Java Project dialog, see the online help.
5. In the Applications window, right-click your project and choose Project Properties.
6. In the Project Properties dialog, select Libraries and Classpath, and then click Add Library.
7. In the Add Library dialog, select MDS Runtime, and click OK, and then click OK to close the Project Properties dialog.
8. In the Applications window, right-click the project and choose New and then Java Class.
9. In the Create Java Class dialog, enter a name for the class and the appropriate package.

   ---
   **Note:** Customization classes are typically named for the layer name they return. For example, a customization class that returns the layer name industry would be named IndustryCC.
   ---

10. In the Extends field, enter oracle.mds.cust.CustomizationClass. For more information about this class, refer to the Javadoc.
11. Make sure that Implement Abstract Methods is selected and click OK.
12. Replace the code in the generated file with code like that shown in Example 45–1.
13. Save your changes and rebuild the project.

This creates the customization class. The sample code uses the package name mycompany and the class name IndustryCC. You will need to change these as appropriate for your application.

### 45.2.2 What You May Need to Know About Customization Classes

As described in Section 45.2.1.1, "Customization Classes," the customization class defines a CacheHint which specifies the visibility of metadata objects in a
customization layer, and therefore its likely duration in memory. This information is used by MDS to decide whether or not to cache a customization, and where to cache it. Any customization layers constructed using this customization class have this cache hint.

The following constants are supported values of CacheHint:

- **ALL_USERS** — The customization is applied globally (unconditionally) for a given deployment. This constant is used for static customization layers.
- **MULTI_USER** — The customization is applied to multiple users.
- **REQUEST** — The customization is applied for the duration of the request only.
- **USER** — The customization is applied for a single user to documents which are accessed throughout the user’s application session. (In web applications the application session is typically a servlet session.)

**Note:** Customization classes are likely to be executed frequently, once for each document being accessed to get the layer name and layer value, so take care to ensure their efficiency.

### 45.2.3 How to Consume Customization Classes

After you have created your customization classes, you can use them at design time in the *Customization Developer* role, and at runtime in the application. To be consumed in an application or in JDeveloper, the classes must be packaged appropriately.

#### 45.2.3.1 Making Customization Classes Available to JDeveloper at Design Time

After you create the customization classes, you must make them available to JDeveloper so that you can use them when implementing customizations while working in the *Customization Developer* role.

Because the customization classes are reusable components, you can create a separate project to contain them, and package them into their own JAR file. You can then import the JAR into the consuming application, which makes the customization classes available to JDeveloper. For more information about creating the customization classes in a separate project, see Section 45.2.1.3, "Creating a Customization Class." For more information about packaging the customization classes into a JAR file, see Section 48.3.2.4, "Adding Customization Classes into a JAR."

**Note:** This procedure is not required if you created your customization classes in the data model project of the consuming application.

Use the following procedure to make the customization classes visible to the application, and then add the customization classes to the `cust-config` section of the `adf-config.xml` file, as described in Section 45.2.7, "How to Configure the `adf-config.xml` File."

**Before you begin:**

It may be helpful to have an understanding of how customization classes are packaged. For more information, see Section 45.2.1.1, "Customization Classes."
You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customization classes in an external project, as described in Section 45.2.1.3, "Creating a Customization Class."
- Create a JAR using the procedure described in Section 48.3.2.4, "Adding Customization Classes into a JAR."
- Launch JDeveloper using the Studio Developer role, and open the application that you want to customize.

**To use customization classes from an external project:**

1. In the Applications window, right-click the data model project and choose Project Properties.
2. In the Project Properties dialog, select Libraries and Classpath, and click Add JAR/Directory.
3. In the Add Archive or Directory dialog, select the JAR file you created that contains the customization classes, and click Select.
4. Click OK.

Now the customization classes are available to JDeveloper for customization, and for running your project locally in JDeveloper.

### 45.2.3.2 Making Customization Classes Available to the Application at Runtime

When you package and deploy your customized application, the customization classes must be available at the application level on the application’s class path.

When you define the deployment profiles for your application, you need to add the customization classes JAR file to the EAR assembly, and to avoid duplication, you need to make sure that the WAR profile does not include the customization classes JAR file. For more information, see Section 48.3.2.3, "Creating an Application Level EAR Deployment Profile."

### 45.2.4 How to Enable Seeded Customizations for User Interface Projects

Like all customizable components, the XML elements of a customizable metadata object must be uniquely identifiable by MDS, and therefore must have a unique, non-null identifier. The component’s identifier is used to refer to the element in the customization instructions in the customization layer. The ID property is the identifier for each type of component in an ADF Faces .jspx or .jsff file.

To allow for customizations on your JSF and JSP pages, you must enable seeded customizations in the application's user interface project, which drives some defaults for your pages. This is not necessary for your model and controller projects.

---

**Note:** MDS requires that pages be XML-based to be customized. Therefore, customizations are not allowed on .jsp files; use .jspx files instead.

Additionally, facelets files must have a .jsf extension to be customizable. MDS uses this extension to recognize it as a Facelets file.
Before you begin:

It may be helpful to have an understanding of how seeded customization works. For more information, see Section 45.1.1, "Customization and Layers: Use Cases and Examples."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to launch JDeveloper using the Studio Developer role, and open the application that you want to make customizable.

To enable seeded customizations in your user interface project:

1. In the Applications window, right-click the user interface project and choose Project Properties.

2. In the Project Properties dialog, select ADF View and then select the Enable Seeded Customizations checkbox, as shown in Figure 45–2.

3. Click OK.

4. Save the changes to your project.

Figure 45–2 Project Properties - Enable Seeded Customizations

45.2.5 How to Enable Seeded Customizations in Existing Pages

If you have pages in your project that were created in an earlier version of JDeveloper, you must make sure that these preexisting pages are also enabled for seeded customizations. This is only necessary if you migrated the application from an earlier version of JDeveloper and did not generate IDs during migration.
Before you begin:
It may be helpful to have an understanding of how seeded customization works. For more information, see Section 45.1.1, "Customization and Layers: Use Cases and Examples."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to launch JDeveloper using the Studio Developer role, and open the application that you want to make customizable.

To enable seeded customizations in an existing page:
1. Create an audit profile to implement ID tokens for all XML objects in your page:
   a. From the main menu, choose Tools > Preferences.
   b. In the Preferences dialog, select Audit > Profiles.
   c. On the Profiles page, click Rules and deselect all rules.
   d. Expand Application Development > ADF Faces > Component ID Rules.
   e. Select the rule Check for ID When ADF Faces is Present.
   f. From the Default Fix dropdown list, select Generate a unique ID.
   g. Click Save As, then enter an identifiable name for the profile (such as Generate Unique IDs). and click Save.
   h. Click OK to close the Preferences dialog.
2. In the Applications window, select the page for which you want to enable seeded customizations. Alternatively, you can select a project to run the audit on all the files it contains.
3. From the main menu, choose Build > Audit.
4. In the Audit dialog, select the profile you created to generate IDs and click Run.
5. Use the Log window to review issues and apply fixes.
6. When the audit is complete, save your changes.

45.2.6 How to Enable Customizations in Resource Bundles
If you plan to create new resource keys when implementing customizations, you can specify the affected resource bundles using the Application Properties dialog.

Before you begin:
It may be helpful to have an understanding of how seeded customization works. For more information, see Section 45.1.1, "Customization and Layers: Use Cases and Examples."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to launch JDeveloper using the Studio Developer role, and open the application that you want to make customizable.

To enable customizations in resource bundles:
1. From the Applications window context menu, choose Application Properties.
2. In the Application Properties dialog, click Resource Bundles, and then click Add.

3. In the Select Resource Bundle dialog, navigate to and select the resource bundles for which you want to enable customization.

4. Click Open.

5. In the Application Properties dialog, select the checkbox in the Overridden column of the Bundle table.

6. Click OK.

### 45.2.7 How to Configure the adf-config.xml File

The application's adf-config.xml file must have an appropriate cust-config element in the mds-config section. The cust-config element allows clients to define an ordered and named list of customization classes. You use the overview editor for the adf-config.xml file to add customization classes (see Figure 45–3).

**Before you begin:**

Before you begin:

It may be helpful to have an understanding of how customization classes are created and packaged. For more information, see Section 45.2.1.1, "Customization Classes."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customization classes, as described in Section 45.2.1.3, "Creating a Customization Class."
- Create a JAR using the procedure described in Section 48.3.2.4, "Adding Customization Classes into a JAR."
- Make your classes available to JDeveloper, as described in Section 45.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."
- Launch JDeveloper using the Studio Developer role, and open the application that you want to customize.

**To identify customization classes in the adf-config.xml file:**

1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click adf-config.xml.

2. In the overview editor, click the MDS Configuration navigation tab and then click the Add icon.

3. In the Edit Customization Class dialog, search for or navigate to the customization classes you have already created.

4. Select the appropriate classes and click OK.

5. After you have added all of the customization classes, you can use the arrow icons to put them in the appropriate order.

Figure 45–3 shows the overview editor for the adf-config.xml file with two customization classes added.
The order of the customization-class elements defines the precedence of customization layers. For example, in the code shown in Example 45–6, the IndustryCC class is listed before the SiteCC class. This means that customizations at the industry layer are applied to the base application, and then customizations at the site layer are applied.

Example 45–6  Customization Class Order in the adf-config.xml File

```xml
<adf-config xmlns="http://xmlns.oracle.com/adf/config">
  <adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
    <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
      <cust-config>
        <match path="/">
          <customization-class name="com.mycompany.IndustryCC"/>
          <customization-class name="com.mycompany.SiteCC"/>
        </match>
      </cust-config>
    </mds-config>
  </adf-mds-config>
</adf-config>
```

45.2.8  What Happens When You Create a Customizable Application

When you create a customizable application, you have a base application that includes the pieces necessary for you or someone else to use as the basis for a customized application.

To perform the customization, you must open the application in JDeveloper using the Customization Developer role, as described in Section 45.3, "Customizing an Application."

45.2.9  What You May Need to Know About Customizable Objects and Applications

Oracle ADF components (such as controller, model, and business components objects) must have a unique identifier so that they can be customized. ADF components generated by JDeveloper are created with identifiers by default, with the exception of JSP and JSF pages in your user interface projects. To cause JDeveloper to generate identifiers for components on pages in your user interface projects, you must explicitly specify this at the project level (as explained in Section 45.2.4, "How to Enable Seeded Customizations for User Interface Projects").
Before you implement customizations in an application, make sure that all objects that you intend to customize have the necessary identifiers. In many cases, you can run an audit rule to catch and fix any omissions (as explained in Section 45.2.5, "How to Enable Seeded Customizations in Existing Pages").

Also, take care to ensure the efficiency of your customization classes, because they can be executed frequently, once for each document being accessed to get the layer name and layer value.

### 45.3 Customizing an Application

Using the **Customization Developer** role, you can create customizations in a customizable application.

#### 45.3.1 Introducing the Customization Developer Role

The **Customization Developer** role is used to customize the metadata in a project. Customization features are available only in this role. When you are in the **Customization Developer** role, you can do the following:

- Create and update customizations
- Select and edit the tip layer of a customized application
- Remove existing customizations

When you are in the **Customization Developer** role, the source editor is read-only and the following JDeveloper features are disabled:

- Workspace migration
- Creation, deletion, and modification of application and IDE connections. You must configure connections in Default role before opening an application in Customization Developer role.

When working with an application in the **Customization Developer** role, new objects cannot be created, and noncustomizable objects cannot be modified. However, the following content types are customizable:

- Portal modules
- ADF modules, including ADF Faces, ADF Model, ADF Business Components, and ADF Controller

**Note:** ADF Business Components objects are customizable only if a static customization class is selected in the Customization Context window. Otherwise, business components objects are read-only.

When working in the **Customization Developer** role, you cannot edit noncustomizable files, such as Java classes, resource bundles, security policies, deployment descriptors, and configuration files. Noncustomizable files are indicated by a lock icon when you are working in the **Customization Developer** role.

**Note:** Facelets files must have a `.jsf` extension to be customizable. MDS uses this extension to recognize it as a Facelets file.
You are also restricted from modifying project settings and customizing certain ADF Business Components features, including service interfaces and business event definitions. Additionally, you cannot refactor, or make changes to customizable files that would, in turn, necessitate changes in noncustomizable files.

### 45.3.2 How to Switch to the Customization Developer Role in JDeveloper

The customization features of JDeveloper are available to you in the **Customization Developer** role. To work in this role, you can either choose it when you start JDeveloper or, if JDeveloper is already running, you can use the **Switch Roles** menu to switch to the **Customization Developer** role.

#### Before you begin:

It may be helpful to have an understanding of the features of the **Customization Developer** role. For more information, see Section 45.3.1, "Introducing the Customization Developer Role."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to launch JDeveloper.

#### To switch to the Customization Developer role in JDeveloper:

1. From the main menu, choose **Tools > Switch Roles > Customization Developer**.

   **Note:** You can optionally toggle the **Tools > Switch Roles > Always Prompt for Role Selection at Startup** menu item, to specify whether or not you want to choose the role when JDeveloper is launched. If deselected, JDeveloper launches in the role it was in when you last closed it.

### 45.3.3 Introducing the Tip Layer

When working in the **Customization Developer** role, the layer and layer value combination that is selected in the Customization Context window is called the **tip layer**. The changes you make while in the **Customization Developer** role are applied to this layer.

**Note:** When working in the **Customization Developer** role, if the Customization Context window is not displayed, you can access it from the **Window** menu.

The metadata displayed in the JDeveloper editors is a combination of the base metadata and the customization layers up to and including the tip layer, according to the precedence set in `adf-config.xml`, with the values specified in the Customization Context window for each layer.

When working in the **Customization Developer** role, you can also see the noncustomized state of the application. When you select **View without Customizations** in the Customization Context window, there is no current tip layer. Therefore, what you see is the noncustomized state. While you are in this view, all customizable files show the lock icon (in the Applications window), indicating that these files are read-only.
When you make customizations in a tip layer, these customizations are indicated by an orange icon in the Properties window. A green icon indicates non-tip layer customizations. When you see an orange icon beside a property, you have the option of deleting that customization by choosing Remove Customization from the dropdown menu for that property.

### 45.3.4 How to Configure Customization Layers

To customize an application, you must specify the customization layers and their values in the CustomizationLayerValues.xml file so that they are recognized by JDeveloper.

When you open a customizable application in the Customization Developer role, JDeveloper reads the adf-config.xml file to determine the customization classes to use and their order of precedence. JDeveloper also reads the CustomizationLayerValues.xml file to determine the layer values to make available in the Customization Context window. If there are layer values defined in the CustomizationLayerValues.xml file that are not defined in the customization classes listed in the adf-config.xml file, they are not displayed in the Customization Context window.

Therefore, you can have a comprehensive list of layer values for all of your customization projects in the CustomizationLayerValues.xml file, and only those appropriate for the current application are available in the Customization Context window. Conversely, you could have a comprehensive list of customization classes for an application in the adf-config.xml file, and only the subset of layer values that you will work on in your CustomizationLayerValues.xml file.

---

**Note:** At design time, JDeveloper retrieves customization layer values from the CustomizationLayerValues.xml file. But at runtime, the layer values are retrieved from the customization class.

---

The names of the layers and layer values that you enter in the CustomizationLayerValues.xml file must be consistent with those specified in your customization classes. Example 45–7 shows the contents of a sample CustomizationLayerValues.xml file.

**Example 45–7   Layers and Layer Values Defined in CustomizationLayerValues.xml**

```xml
<cust-layers xmlns="http://xmlns.oracle.com/mds/dt">
  <cust-layer name="industry" id-prefix="i">
    <cust-layer-value value="financial" display-name="Financial" id-prefix="f"/>
    <cust-layer-value value="healthcare" display-name="Healthcare" id-prefix="h"/>
  </cust-layer>
  <cust-layer name="site" id-prefix="s">
    <cust-layer-value value="headquarters" display-name="HQ" id-prefix="hq"/>
    <cust-layer-value value="remoteoffices" display-name="Remote" id-prefix="rm"/>
  </cust-layer>
</cust-layers>
```

For each layer and layer value, you can add an id-prefix token. This helps to ensure the uniqueness of the id, so that customizations are applied accurately. When you add a new element (such as a command button) to a page during customization, JDeveloper adds the id-prefix of the layer and layer value (determined by the selected tip layer) to the autogenerated identifier for the element to create an id for the newly added element in the customization metadata file. For example, in
Example 45–7, the site layer has an id-prefix of "s" and the headquarters layer value has an id-prefix of "hq". So, when you select site/headquarters as the tip layer and add a command button to a page, the command button will have an id of "shqcb1" in the metadata customization file.

For each layer value, you can also add a display-name token to provide a human-readable name for the layer value. When you are working in the Customization Developer role, the value of the display-name token is shown in the Customization Context window for that layer value.

For each layer, you can optionally provide a value-set-size token that defines the size of the value set for the customization layer. This can be useful, for example, when using a design-time, application-specific CustomizationLayerValues.xml file. By setting value-set-size to "no_values" you can exclude runtime-only layers at design time.

```
<cust-layer name="runtime_only_layer" value-set-size="no_values"/>
```

You can define the customization layer values either globally for JDeveloper or in an application-specific file. If you use an application-specific file, it takes precedence over the global file. For more information on configuring layer values globally for JDeveloper, see Section 45.3.4.1, "Configuring Layer Values Globally." For more information on configuring application-specific layer values, see Section 45.3.4.2, "Configuring Workspace-Level Layer Values from the Studio Developer Role."

45.3.4.1 Configuring Layer Values Globally

The following procedure describes how to configure the CustomizationLayerValues.xml file globally for JDeveloper.

Before you begin:

It may be helpful to have an understanding of layers and layer values. For more information, see Section 45.3.4, "How to Configure Customization Layers."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customization classes, as described in Section 45.2.1.3, "Creating a Customization Class."
- Make your classes available to JDeveloper, as described in Section 45.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."

To configure design time customization layer values globally for JDeveloper:

1. Locate and open the CustomizationLayerValues.xml file.
   You can find this file in the jdev subdirectory of your JDeveloper installation directory (jdev_install\jdev\CustomizationLayerValues.xml).
2. For each layer, enter a cust-layer element, as shown in Example 45–7.
3. For each layer value, enter a cust-layer-value element, as shown in Example 45–7.
4. Save and close the CustomizationLayerValues.xml file.
5. After you have made changes to the global CustomizationLayerValues.xml file, you must restart JDeveloper.
45.3.4.2 Configuring Workspace-Level Layer Values from the Studio Developer Role

When configuring layer values for an application, you can use either the Studio Developer role or the Customization Developer role. Note that when you configure an application-specific CustomizationLayerValues.xml file, you can create and modify layer values, but you cannot create additional customization layers. It is not necessary to restart JDeveloper to pick up changes made to the application-specific layer values.

When you create an application-specific CustomizationLayerValues.xml file, JDeveloper stores it in an application-level directory (for example, workspace-directory\.mds\dt\customizationLayerValues\CustomizationLayerValues.xml). You can access this file in the Application Resources panel of the Applications window, under the MDS DT node.

The following procedure describes how to configure the CustomizationLayerValues.xml file for a specific application from the Studio Developer role. This procedure can also be used from the Customization Developer role.

Before you begin:

It may be helpful to have an understanding of layers and layer values. For more information, see Section 45.3.4, "How to Configure Customization Layers."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customization classes, as described in Section 45.2.1.3, "Creating a Customization Class."
- Make your classes available to JDeveloper, as described in Section 45.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."
- Launch JDeveloper using the Studio Developer role, and open the application that you want to customize.

To configure design time customization layer values at the workspace level from the Studio Developer role:

1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click adf-config.xml.

2. In the overview editor, click the MDS Configuration navigation tab.

3. On the MDS Configuration page, below the table of customization classes, click the Configure Design Time Customization Layer Values link to open the workspace-level CustomizationLayerValues.xml file.

   When you click the link, the file opens in the source editor. If the override file doesn’t already exist, JDeveloper displays a confirmation dialog. Click Yes to create and open a copy of the global file.

4. In the file, specify layer values as necessary, as described in Section 45.3.4, "How to Configure Customization Layers."

5. Save your changes.
45.3.4.3 Configuring Workspace-Level Layer Values from the Customization Developer Role

You can also configure layer values for an application from the Customization Developer role. Note that when you configure an application-specific CustomizationLayerValues.xml file, you can create and modify layer values, but you cannot create additional customization layers. It is not necessary to restart JDeveloper to pick up changes made to the application-specific layer values.

When you create an application-specific CustomizationLayerValues.xml file, JDeveloper stores it in an application-level directory (for example, workspace-directory\mds\dt\customizationLayerValues\CustomizationLayerValues.xml). You can access this file in the Application Resources panel of the Applications window, under the MDS DT node.

The following procedure describes how to configure the CustomizationLayerValues.xml file for a specific application from the Customization Developer role.

Before you begin:
It may be helpful to have an understanding of layers and layer values. For more information, see Section 45.3.4, "How to Configure Customization Layers."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customization classes, as described in Section 45.2.1.3, "Creating a Customization Class."
- Make your classes available to JDeveloper, as described in Section 45.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."
- Launch JDeveloper using the Customization Developer role, and open the application that you want to customize.

To configure design time customization layer values at the workspace level from the Customization Developer role:

1. In the Customization Context window, click the Configure application layer values link.

   When you click the link, the CustomizationLayerValues.xml file opens in the source editor. If the override file doesn't already exist, JDeveloper displays a confirmation dialog. Click Yes to create and open a copy of the global file.

2. Specify layer values as necessary, as described in Section 45.3.4, "How to Configure Customization Layers."

3. Save your changes.

   After you make changes to the application-specific CustomizationLayerValues.xml file while you are in the Customization Developer role, any tip layer you have selected in the Customization Context window is deselected. You can then select the desired tip layer.

45.3.5 How to Customize Metadata in JDeveloper

You use the same development procedures and techniques to customize metadata that you use when developing the base application. To implement customizations,
however, you must be working in the **Customization Developer** role and specify the customization context by selecting a tip layer and layer value before editing the metadata. For an application to be customizable, customizations must be enabled in your project. For more information, see Section 45.2, "Developing a Customizable Application."

**Before you begin:**

It may be helpful to have an understanding of how customization works. For more information, see Section 45.1.1, "Customization and Layers: Use Cases and Examples," and Section 45.3, "Customizing an Application."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customization classes, as described in Section 45.2.1.3, "Creating a Customization Class."
- Create a JAR using the procedure described in Section 48.3.2.4, "Adding Customization Classes into a JAR."
- Make your classes available to JDeveloper, as described in Section 45.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."
- Update the `adf-config.xml` file, as described in Section 45.2.7, "How to Configure the `adf-config.xml` File."
- Enable seeded customizations in your application, as described in Section 45.2.4, "How to Enable Seeded Customizations for User Interface Projects," and Section 45.2.5, "How to Enable Seeded Customizations in Existing Pages."
- Configure the applications customization layers, as described in Section 45.3.4, "How to Configure Customization Layers."
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

**To customize metadata in JDeveloper:**

1. In the Customization Context window, select the layer and value for which you want to implement customizations.

   The **Customization Context** (displayed at the bottom of the Customization Context window) changes to reflect your selection, as shown in Figure 45–4.
Customizing Applications with MDS

Customizing an Application

Figure 45–4  Customization Context Window with site/headquarters Selected as the Tip Layer

2. Edit the metadata as you typically would during development. For example, double-click an entity object. Then edit the object using the overview editor.

   While you use the same techniques for editing metadata during customization that you would during development, certain restrictions apply. For example, some string properties, such as button labels, cannot be edited directly in the Properties window: they must be edited using the Select Text Resource dialog or the Expression Builder. For more information about restrictions to editing during customization, see Section 45.3.1, "Introducing the Customization Developer Role."

   For information about using the Expression Builder, see Section 17.8.1.1, "Opening the Expression Builder from the Properties Window."

   Even though you use the overview editor to implement customizations, you do not make changes to the base metadata file. Your changes are stored separately in a customization metadata file.

   **Note:** The selection you make in the Customization Context window indicates the context for the customizations that you will implement in JDeveloper. This selection does not directly impact the runtime for the application. At runtime, the customization context is returned from your customization classes. For more information, see Section 45.2.1, "How to Create Customization Classes."

3. You can optionally choose Remove Customization from the dropdown menu for a property (in the Properties window) to clear the existing customization.

   **Note:** In the Properties window, tip layer customizations are indicated by an orange icon, while properties that are not customized in the current tip layer are indicated by a green icon. A customization can only be removed in the context in which it was added. So you can remove only those customizations that have an orange indicator in the Properties window.

4. From the main menu, choose File > Save to save your changes.
45.3.6 What Happens When You Customize an Application

When you implement customizations in an application, JDeveloper creates a metadata file for the customizations and a subpackage to store them in.

The metadata file contains the customizations for the customized object, which are applied over the base metadata at runtime. The new metadata file is named the same as the base file for the object with an additional .xml extension. For example, if you implement customizations for the browseOrders.jsff page, the customization metadata file is named browseOrders.jsff.xml. Or if you implement customizations on the OrderItems entity object, the base metadata file is named OrderItems.xml and the customization metadata file is named OrderItems.xml.xml.

The customization metadata files are stored in a subpackage hierarchy that is created at the same level as the object you customize. The first-level package is named mdssys, and it contains a package named cust. The cust package contains a package for each customization layer for which you have implemented customizations.

For example, say you have a base application that has a package called oracle.summit.model.entities containing your entity objects, and you have a customization layer named site with two layer values: headquarters and remoteoffices. Then you implement customizations for the OrderItems entity object at the headquarters layer value. When you implement these customizations, JDeveloper creates the subpackage hierarchy oracle.summit.model.entities.mdssys.cust.site.headquarters and stores the customization metadata files there.

Similarly, for pages in your user interface project, JDeveloper creates a directory structure to store the customization metadata files. For example, if you customize the BrowseOrders.jsff page in the Web Content node of your user interface project, JDeveloper creates the directory structure mdssys/cust/site/headquarters under Web Content and stores the customization metadata file there.

45.3.7 How to Customize ADF Library Artifacts in JDeveloper

In the Customization Developer role, you can use JDeveloper to customize artifacts in an ADF library. This need can arise when, for example, one development team produces task flows as part of a framework service and makes them available to other teams as an ADF library. Then another development team uses one of the task flows in a consuming application, and needs to fine-tune it to fit the requirements of the application.

45.3.7.1 Customizing an ADF Library Artifact

You can add an ADF library to your project in the Customization Developer role just as you would add it in the Studio Developer role. However, in the Customization Developer role, content from an ADF library appears as editable to allow you to implement customizations, whereas in the Studio Developer role it is read-only. For more information about working with ADF libraries, see Chapter 44, "Reusing Application Components."
Before you begin:

It may be helpful to have an understanding of how customization works. For more information, see Section 45.1.1, "Customization and Layers: Use Cases and Examples," and Section 45.3, "Customizing an Application."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customization classes, as described in Section 45.2.1.3, "Creating a Customization Class."
- Create a JAR using the procedure described in Section 48.3.2.4, "Adding Customization Classes into a JAR."
- Make your classes available to JDeveloper, as described in Section 45.2.3.1, "Making Customization Classes Available to JDeveloper at Design Time."
- Update the adf-config.xml file, as described in Section 45.2.7, "How to Configure the adf-config.xml File."
- Enable seeded customizations in your application, as described in Section 45.2.4, "How to Enable Seeded Customizations for User Interface Projects," and Section 45.2.5, "How to Enable Seeded Customizations in Existing Pages."
- Configure the applications customization layers, as described in Section 45.3.4, "How to Configure Customization Layers."
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

To customize an ADF library artifact:

1. In the Applications window, click the Applications Window Options icon and choose Show Libraries.

   This displays the libraries in the Applications window, so that you can explore them and access their artifacts.

2. Add the desired library to your project if it is not already shown among the libraries in the Applications window.

   For information about how to do this, see Section 44.3, "Adding ADF Library Components into Projects."

3. Customize the artifacts just as you would customize other content in your project.

   For example, you can drag and drop taskflows from a library to .jspx or .jsff pages in a consuming project, drag and drop taskflows from a library to a page or fragment in another library, drag and drop library content or taskflows from the Resource catalog, drag and drop data controls from Data Controls panel to .jspx or .jsff pages in a library, edit business components, and drag and drop a data control from a library to the Data Controls panel and then drop to a page in another palette. All of these actions result in customizations of the library.

**45.3.7.2 Specifying a Location for ADF Library Customizations**

The location where ADF library customizations are stored is `project-dir\libraryCustomizations` by default. If your workspace contains multiple projects, you should change this to a workspace-level location for each project (for example, `workspace-dir\.mds\ADFLibraryCustomizations`).
You can change the location of ADF library customizations on the **Project Source Paths > ADF Library Customizations** page of the Project Properties dialog. If you change this location after you have implemented customizations on an ADF library, you must move the customization metadata files to the new location. To do this, use the file system to move the customization metadata (XML) files from the old directory to the new one.

If you have more than one project in the workspace with existing ADF library customizations that need to be moved to the common location, move the customizations to the new location one project at a time. For each project, change the location of ADF library customizations in the Project Properties dialog, and then move the customization metadata files from the old location to the new location. To mitigate conflicts where an ADF library artifact has customizations in more than one project, you have following options:

- From both projects, open the ADF Library artifact for which there are conflicting customizations, and decide upon which customizations you want. Preserve the customizations you want to keep and delete the others.
- If both customizations are important, open the ADF library artifact from the first project and implement the customizations that were previously done in second project. Then save the customizations in the first project and remove the customizations from the second project.

Do not open ADF library customization metadata files from multiple projects in a text editor and merge their contents. This can corrupt the customization metadata file.

Additionally, the location where ADF library customizations are stored is automatically included when you create a MAR deployment profile. If you change this location after you have created a MAR profile, you must also change the corresponding entry in the contributors list on the User Metadata file group page of the Edit MAR Deployment Profile Properties dialog before packaging. Alternatively, you can re-create the MAR profile to pick up this change. For more information about creating a MAR deployment profile, see Section 48.3.2, "How to Create Deployment Profiles."

### 45.3.8 How to View ADF Library Runtime Customizations from Exported JARs

When working in the JDeveloper Customization Developer role, you can view runtime customizations implemented on ADF library artifacts contained in an exported JAR.

**Before you begin:**

It may be helpful to have an understanding of how customization works. For more information, see Section 45.1.1, "Customization and Layers: Use Cases and Examples,” and Section 45.3, "Customizing an Application."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customizable application, as described in Section 45.2, "Developing a Customizable Application."
- Deploy the application and implement runtime customizations on it, then export the runtime customizations to a JAR file.
- Launch JDeveloper using the **Customization Developer** role, and open the customizable application.
To make runtime customizations viewable from JDeveloper:
1. From the Applications window context menu, choose **Application Properties**.
2. In the Application Properties dialog, select **Customization Libraries**.
3. Click **Browse**, and navigate to the location of the exported JAR file.
4. Select the JAR file and click **Select**.
5. Click **OK**.

Now the JAR is available so that JDeveloper can look up customizations on ADF library artifacts. When you open an object that contains ADF library artifacts, JDeveloper looks for customizations in this JAR file and displays them if appropriate. JDeveloper decides what to display for a given artifact in a given customization context as follows:

- If the artifact has *neither* runtime customizations *nor* seeded customizations associated with it, the artifact from the ADF library is displayed.
- If the artifact has only *either* runtime customizations *or* seeded customizations associated with it (but not both), the customized artifact is displayed.
- If the artifact has *both* runtime customizations *and* seeded customizations associated with it, the seeded customization takes precedence and is displayed.

Additionally, when you run the application locally from JDeveloper, the runtime customizations are displayed. However, the runtime customizations are not included in any packaging of the application for deployment.

### 45.3.9 What Happens When You Customize ADF Library Artifacts

During the development of enterprise applications, there might be artifacts (such as task flows) that can be reused in multiple applications. To facilitate reuse of these common artifacts, they can be packaged into an ADF library and distributed. This allows you to add the ADF library to the list of libraries that the consuming application depends on. Then when the application is packaged, the customizations from all such ADF libraries are included in the MAR, which is later deployed to the MDS repository. Note, however, that ADF library customizations are added to the MAR deployment profile when you create the profile, which is not automatically updated when customizations are implemented after creating the profile. To pick up these subsequent customizations, use the **Update Profile** button on the MAR Options page of the Edit MAR Deployment Profile Properties dialog.

**Note:** The ADF library provider should take care to ensure that no name conflicts arise due to customizations in the library. In the event that name conflicts arise between customizations packaged in an ADF library and the customizations from the consuming project, the customizations from the ADF library are ignored.

When you implement customizations on objects from an ADF library, the customization metadata is stored by default in a subdirectory of the project called `libraryCustomizations`. And although you create ADF library customizations at the project level, they are merged together during packaging to be available at the application level at runtime. Essentially, ADF libraries are JARs that are added at the project level, which map to library customizations being created at the project level. However, although projects map to web applications at runtime, the MAR (which
contains the library customizations) is at the EAR level, so the library customizations are seen from all web applications.

Therefore, you can customize an ADF library artifact in only one place in an application for a given customization context (customization layer and layer value). Customizing the same library content in different projects for the same customization context would result in duplication in MAR packaging. To avoid duplicates that would cause packaging to fail, implement customizations for a given library in only one project in your application.

**Note:** Using the same location for ADF library customizations for all of the projects in your application can help to avoid duplicate customization. For more information, see Section 45.3.7.2, "Specifying a Location for ADF Library Customizations."

For example, say the ADF library you are using contains a page fragment `text.jsff`. In the consuming application, customize this library page in only one project. By doing so, customizations are available for all projects in the application that consume this library at runtime.

You are also restricted from customizing an object from an ADF library when your project already contains an object with the same name. In case of duplication, you must fix the projects by deleting one of the duplicate documents or deleting one and manually merging the differences into the other.

Similarly, if the ADF library contains seeded customizations for an artifact within a given customization context (customization layer and layer value), you cannot implement customizations for that artifact within the same customization context. In this situation, the ADF library artifact is read-only. You can, however, implement customizations for the artifact within other customization contexts.

For example, say the ADF library you are using contains seeded customizations for the Headquarters layer value in the Site layer. When you select this as your tip layer in the Customization Context window, the customized objects in that ADF library are read-only. However, if you select Site/Remote Site 1 as your tip layer, then the objects are customizable.

**Note:** When the consuming application implements customizations on content from an ADF library, the customizations are written to the local project directories, but they are not automatically injected with the `web-app-root` during packaging. For more information, see Section 48.3.2.2, "Creating a MAR Deployment Profile."

### 45.3.10 What Happens at Runtime: How Customizations are Applied

At runtime, the application applies the customization metadata files over the base application in the order of precedence defined in the `cust-config` section of the `adf-config.xml` file.

The layer value is retrieved from the customization class at runtime and evaluated in the context the application is running, and the appropriate customizations for that layer value are applied.
45.3.11 What You May Need to Know About Customized Applications

When you are customizing an application, you might be using integrated source control or customizing resource strings. When you use these features, there is additional information you need to know.

45.3.11.1 Customization and Integrated Source Control

When working in the Customization Developer role, your source control integration complements the process of customization. If JDeveloper is configured to automatically check out and add new files to source control and you attempt to customize a base document that is available from a source control system, JDeveloper behaves in the following way:

- If the corresponding customization file is not already available, then a new customization file is created in source control and the customizations are written to it.
- If the corresponding customization file exists, it is checked out and customizations are written to it.
- If the corresponding customization file exists and it is already checked out or not yet in version control, customizations are written to it without any further version control operation.

Since the base document is not modified in the Customization Developer role, the base document is not checked out.

If JDeveloper is not configured to automatically check out or add new files to source control, you must manually make the customization files editable and check in newly created customization files to source control. For more information about using source control in JDeveloper, see section Section 1.4.2, "Using a Source Control System."

45.3.11.2 Editing Resource Bundles in Customized Applications

During the course of customizing your application, you might want to customize the content to use different resource bundle keys or define and use new resource keys.

You can open a customizable application in the Customization Developer role and use the Properties window to customize the usages of resource bundle strings. You can change a document to use another already existing resource key in a resource bundle, or create a new resource. For more information about resource bundles, see Section 4.7, "Working with Resource Bundles."

New resource keys (created in the Customization Developer role) are saved to an application-level override bundle (in XLIFF format), and JDeveloper adds an entry to the adf-config.xml file like the one shown in Example 45–8 to configure the application-level override bundle.

You must also configure the adf-config.xml file to support the overriding of the base resource bundle. As shown in Example 45–8, you must tag the bundleId element with override="true" to make it overrideable. After it is marked as overridden, customizations of that bundle are stored in the application’s override bundle.

Example 45–8  adf-resourcebundle-config Section in adf-config.xml

```xml
<adf-resourcebundle-config
xmlns="http://xmlns.oracle.com/adf/resourcebundle/config">
  <applicationBundleName>
    path-to-resource-bundle/bundle-name
  </applicationBundleName>
</adf-resourcebundle-config>
```
45.4 How to Package and Deploy Customized Applications

After you customize the application, you will want to deploy it. Before you deploy the customized application, you must follow the configuration procedures for setting up your MDS repository, as described in Administering Oracle Fusion Middleware.

An enterprise application can contain model and user interface projects, and both types of projects can contain customized metadata. The customized metadata is packaged into a MAR for deployment. By default, the customizations from both types of projects are added to a single MAR. For information about how to create a MAR profile, see Section 48.3.2.2, "Creating a MAR Deployment Profile."

45.4.1 Implicitly Creating a MAR Profile

When you use JDeveloper to package a Fusion web application, JDeveloper creates an auto-generated MAR profile that includes default metadata (such as customizations), when either of the following conditions are met.

- The Enable User Customizations > Across Sessions using MDS checkbox is selected on the ADF View settings page of the Project Properties dialog for the user interface project.
- The MDS configuration section of the adf-config.xml file contains a <metadata-store-usage> element that is marked as deploy-target="true", as shown in Example 45–9.

Example 45–9  metadata-store-usage Element in adf-config.xml

```xml
< . . . >

<persistence-config>
<metadata-namespaces>
namespace path="/oracle/apps" metadata-store-usage="repos1"/>
</metadata-namespaces>
<metadata-store-usages>
<metadata-store-usage id="repos1" deploy-target="true"/>
. . .
</metadata-store-usage>
</metadata-store-usages>
</persistence-config>
< . . . >
```
45.4.2 Explicitly Creating a MAR Profile

For customizations created in JDeveloper to take effect in the application when it is deployed, these customizations need to be made available to the application at runtime. There are two techniques you can use to accomplish this:

- Package the customizations along with the application using a MAR profile.
  
  Create a MAR profile that includes the customization metadata. The MAR profile should be included in the deployed EAR file to ensure that the customizations are available at runtime. Your customization classes must be packaged in the EAR file such that they are in the application-level class loader.

  **Note:** If you have only seeded customizations, you do not need to create a MAR profile to import them into the MDS repository unless you also want to support runtime customizations. If you have seeded customizations and do not have cross-session persistence enabled, the seeded customizations will be packaged in the EAR file by default and loaded from the class path.

- Import the customizations to the runtime repository used by the application.
  
  You typically use this approach if customizations to library metadata need to be applied to an application that is deployed separately. Using this approach, you package the customizations into a JAR file and then use the command `importMetadata` with Oracle WebLogic Scripting Tool (WLST) to import them to the MDS runtime repository. For more information about this and other WLST commands, see the *WLST Command Reference for Infrastructure Components*.

If your application has customizations on objects from an ADF library, the customization metadata is implicitly included when you create the MAR profile. If you change the location of ADF library customizations in the Project Properties dialog, you must re-create the MAR profile before packaging.

If you plan to use design time at runtime capabilities to add or edit resource keys in the override bundle at runtime, the override bundle must be packaged as part of the MAR profile. By default, the override bundle is packaged as part of the auto-generated MAR profile if the application contains seeded customizations. However, if the application doesn’t contain seeded customizations, you must explicitly create the MAR deployment profile to package the override bundle. When the MAR profile is created explicitly, the override bundle is added and included by default as part of the user metadata.

When you package and deploy the completed customized application, you should do so from the **Studio Developer** role, rather than from the **Customization Developer** role. For information about how to create a MAR profile, see Section 48.3.2, “How to Create Deployment Profiles.”

45.5 Extended Metadata Properties

Extended metadata is data that describes the metadata content. The extended metadata file contains additional information about the metadata file. One use of this extended information is to identify which parts of the metadata can be customized at runtime (design time at runtime customizations) and who can customize them. For more information about this use of extended metadata properties, see Section 45.5.2, "How to Enable Customization for Design Time at Runtime."
You can open a metadata file (such as a .jspx file) in JDeveloper and use the Properties window to view and edit its extended metadata properties. When you open a metadata file, its extended metadata properties are displayed in the Properties window. These properties can be edited to add metadata information at either of the following levels:

- File-level: These properties are displayed in the Properties window when the root element is selected in the Structure window.
- Element-level: These properties are displayed in the Properties window when an element is selected in the Structure window. The selected element should have a non-null identifier.

Extended metadata properties are supported for file types that support customizations and can be packaged in a MAR, such as .jsff and .jspx files.

Extended metadata for a metadata document is stored in an associated resource description framework (RDF) file. RDF is a W3C standard used to define an XML framework for defining metadata. The RDF file associated with the metadata document is created when the first property value is specified using the Properties window. Extended metadata properties are editable only when JDeveloper is in the Studio Developer role. RDF files are read-only in the Customization Developer role.

The RDF file is stored in the mdssys directory. For example, if the metadata being described is stored in the file system as /myapp/data/page1.jspx, the corresponding extended metadata document would be stored as /myapp/data/mdssys/mdx/page1.jspx.rdf. The extended metadata document must then be packaged with the corresponding metadata base file and added to the same deployment profile. For more information about creating a MAR deployment profile, see Section 48.3.2, "How to Create Deployment Profiles."

---

**Note:** Don’t edit the extended metadata documents directly. Use the Properties window.

---

### 45.5.1 How to Edit Extended Metadata Properties

You can use extended metadata properties to provide additional metadata information that is not covered in the metadata file (such as a .jspx file). When you open the metadata file in JDeveloper, extended metadata properties are displayed in the Properties window, which you can use to edit these properties when you are using JDeveloper in the Studio Developer role.

For example, suppose you want to deliver a metadata file in some form to external customers. Along with metadata file, you need to provide additional information about the file, such as the creator, subject, description, format, and rights. You can accomplish this by creating an extended metadata property file for your metadata file.

**Before you begin:**

It may be helpful to have an understanding of how extended metadata is used. For more information, see Section 45.5, "Extended Metadata Properties."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete this task:

- Launch JDeveloper using the Studio Developer role, and open the application.
To edit extended metadata properties:
1. In the Applications window, select the object for which you want to edit extended metadata properties.
2. In the Structure window, select the appropriate element (typically the root element).
3. In the Properties window, expand the appropriate node to edit the properties.
   To display the Properties window with the values for the selected component, choose Window > Properties from the main menu.
4. Edit the value for the desired property and press Enter.
5. From the main menu, choose File > Save to save your changes.

If you have edited extended metadata properties for a metadata file, you must package your extended metadata (or RDF) files with the metadata files when you deploy the application.

45.5.2 How to Enable Customization for Design Time at Runtime

You can also use extended metadata properties to provide information about which parts of the metadata can be customized at runtime and who can customize the metadata content.

By default, all components that you can add to a .jspx page are preconfigured to allow runtime customization to support implicit user personalization (such as changing the order of columns in a table).

Components that are preconfigured to allow customization need no further modification to enable design time at runtime customizations. If you use them in a .jspx page, then they are customizable by default.

Depending on the requirements of your application, you will need to modify customization properties in the following situations:

- For components that are configured to allow customization, you can override the default settings to disallow customization.
- For components that are not configured to allow customization and metadata objects (such as .jspx pages), you can override the settings to allow customization.
- For components that are configured to allow customization, you can optionally restrict who is allowed to perform customizations at runtime.

If you edit customization properties, you must package your extended metadata (RDF) files with the metadata files when you deploy the application.

Additionally, you can restrict customizations on an entire subtree of components by marking the root of the subtree to disallow customizations. You can then mark individual components of that subtree as customizable to allow customizations for those specific components.

45.5.2.1 Editing Customization Properties in the Properties window

In the Customization group in the Properties window, there are two properties that allow you to specify whether customizations for an object are permitted at runtime and who is permitted to do them. The CustomizationAllowed property can be set on any element to specify whether or not it can be customized. The CustomizationAllowedBy property controls which users can customize the element. These settings are not enforced when you are implementing seeded customizations.
using JDeveloper, but are instead enforced when the application is customized at runtime (design time at runtime customizations).

For example, say you have a .jspx page with a form that contains two panels, and you need to allow runtime customization for content in Panel1, but not Panel2. You would set **CustomizationAllowed** to `true` for Panel1, and set it to `false` for Panel2. If you need to allow runtime customization on an entire page, you would set **CustomizationAllowed** to `true` for the .jspx page root.

**Before you begin:**
It may be helpful to have an understanding of how extended metadata is used. For more information, see Section 45.5, "Extended Metadata Properties."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 45.1.3, "Additional Functionality for Customization."

You will also need to complete these tasks:

- Create your customizable application, as described in Section 45.2, "Developing a Customizable Application."
- Launch JDeveloper using the Studio Developer role, and open the application.

**To edit customization properties:**

1. In the Applications window, select the object for which you want to edit customization properties.
2. In the Structure window, select the appropriate element.
3. In the Properties window, expand the **Customization** node to edit the customization properties.
   
   To display the Properties window with the values for the selected component, choose **Window > Properties** from the main menu.
4. Edit the property value and press Enter.
   
   For example, to allow runtime customizations on a .jspx file, select the file and set the **CustomizationAllowed** property to `true`.
5. From the main menu, choose **File > Save** to save your changes.

### 45.5.2.2 Using a Standalone Annotations File to Specify Type-Level Customization Properties

You can optionally use a standalone annotations file to specify whether or not customizations are allowed for a given type of component. This file allows you to set customization properties on element types, rather than on instances. You can override the setting for a given type by explicitly setting `true` or `false` on a specific instance. **Example 45–10** shows the contents of a sample standalone annotations file.

**Example 45–10 Contents of a Standalone Annotations file**

```xml
<grammarMetadata xmlns="http://xmlns.oracle.com/bali/xml/metadata"
                 xmlns:md="http://xmlns.oracle.com/bali/xml/metadata"
                 xmlns:mmd="http://xmlns.oracle.com/bali/xml/metadata/model"
                 xmlns:mds="http://xmlns.oracle.com/mds"
                 namespace="http://www.oracle.com/mds/restrictCustomizations">
  <elementMetadata elementName="orderDetail">
</grammarMetadata>
```
If you use a standalone annotations file, you must register it with MDS in the adf-config.xml file. Create a mds:standalone-definitions section in the mds:type-config section of the adf-config.xml file, as shown in Example 45–11.

Example 45–11 standalone-definitions Section in adf-config.xml

```xml
<?xml version="1.0"?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
    xmlns:mdsc="http://xmlns.oracle.com/mds/config">
    <mdsdata>
        <mdsc:mds-config version="11.1.1.000">
            <mdsc:type-config>
                <mdsc:type-definitions>
                    <mdsc:url>jar:file:/c:/jdev/lib/oafwk.jar!/oracle/apps/schemas/oa.xsd</mdsc:url>
                    <mdsc:mds>/oracle/mds/TypeSeven.xml</mdsc:mds>
                    <mdsc:mds>/oracle/mds/TypeEight.xml</mdsc:mds>
                    <mdsc:file>typefile7.xsd</mdsc:file>
                    <mdsc:file>typefile8.xsd</mdsc:file>
                </mdsc:type-definitions>
                <mdsc:standalone-definitions>
                    <mdsc:url>jar:file:/c:/jdev/lib/oafwk.jar!/oracle/apps/schemas/oa.xsd</mdsc:url>
                    <mdsc:mds>/oracle/mds/standAloneSeven.xml</mdsc:mds>
                    <mdsc:mds>/oracle/mds/standAloneEight.xml</mdsc:mds>
                    <mdsc:file>standAloneFile7.xsd</mdsc:file>
                    <mdsc:file>standAloneFile8.xsd</mdsc:file>
                </mdsc:standalone-definitions>
            </mdsc:type-config>
        </mdsdata>
    </mdsc:mds-config>
```
45.6 Enabling Runtime Modification of Customization Configuration

You can prepare your customized application to accept overrides to the customization configuration (the `cust-config` section of the `adf-config.xml` file) at runtime on a per-session basis, thus allowing the user to change the way customizations are applied for a given session (or web request).

Consider a scenario where an application is configured with a site layer and a user layer and you want to make design time at runtime customizations to the site layer. If you use the application’s customization configuration (defined in the `adf-config.xml` file), any customizations that you implement are applied to the user layer. So, you need to be able to adjust the customization configuration for a given session to allow your customizations to be applied to the site layer.

Or perhaps you have a requirement that an administrator wants to see the base metadata document with the site layer customizations alone. For cases like this, you need to specify a modified customization configuration, other than what was originally specified in application’s `adf-config.xml` file.

For each web request, Oracle ADF creates an MDS session. For any MDS customization configuration modifications that apply to a session (web request), the user could programatically provide modified MDS session options with a new customization configuration to Oracle ADF that would be applied on top of the original MDS configuration while creating a MDS session.

To implement this functionality, use the following ADF interfaces for `sessionOptionsFactory`:

- `oracle.adf.share.mds.SessionOptionsFactory` is the interface you use to specify modified MDS session options for a web request in a Fusion web application.

  ```
  SessionOptionsFactory :: oracle.mds.core.SessionOptions
  createSessionOptions(oracle.mds.core.SessionOptions defaultOptions)
  ```

  You implement this method to return the modified MDS `sessionOptions` to ADF.

- `oracle.adf.share.config.ConfigUtils` is the public class you can use to register your session options factory with ADF.

  ```
  ConfigUtils :: public static void setSessionOptionsFactory(ADFContext context,
  SessionOptionsFactory factory)
  ```

  See your ADF API documentation for further detail on these interfaces.

You register your `sessionOptionsFactory` with Oracle ADF so that ADF can get modified session options from your implementation before the MDS session is created in request lifecycle.

Example 45–12 shows how you can implement `sessionOptionsFactory`. This example sets a modified customization configuration for the session to use the site customization layer alone regardless of the customization configuration specified in the `adf-config.xml` file. See the Javadoc for `oracle.mds` for more information.
Example 45–12 Sample sessionOptionsFactory Class

```java
package mycompany;

import oracle.adf.share.mds.SessionOptionsFactory;
import oracle.mds.config.CustClassListMapping;
import oracle.mds.config.CustConfig;
import oracle.mds.config.MDSConfigurationException;
import oracle.mds.core.SessionOptions;
import oracle.mds.cust.CustClassList;
import oracle.mds.cust.CustomizationClass;

public class MySessionOptionsFactory implements SessionOptionsFactory {

    public MySessionOptionsFactory() {
        super();
    }

    /**
     * Called to allow the application code to create a new SessionOptions object.
     * The application code should make sure to read the values from the
     * defaultOptions object as part of construction of their new object and make
     * sure they only override the intended values.
     * @param defaultOptions
     * @return modified MDS session options
     */
    public SessionOptions createSessionOptions(SessionOptions defaultOptions) {
        // create new mds Customization configuration
        CustConfig custconfig = null;

        // create customization class array. Just put SiteCC implementation as we
        // wish to apply site customizations alone.
        CustomizationClass[] custclassarray = new CustomizationClass[] {new SiteCC>();

        CustClassList custclasslist = new CustClassList(custclassarray);

        // specify the base metadata package namespace mapping on which site
        // customizations would apply
        CustClassListMapping[] mappings =
            new CustClassListMapping[] {new CustClassListMapping("mycompany/package",
                                        null, null, custclasslist)};

        // create new customization configuration
        try{
            custconfig = new CustConfig(mappings);
        } catch (Exception ex){
            // do nothing
        }

        // now return modified sessionOptions to ADF with new mds customization
        // configuration. Only use newly created customization configuration in here.
        // For rest of option, use whatever available in defaultOptions.
        return new SessionOptions(defaultOptions.getIsolationLevel(),
                                  defaultOptions.getLocale(),
                                  custconfig,
                                  defaultOptions.getVersionContext(),
                                  defaultOptions.getVersionCreatorName(),
                                  defaultOptions.getCustomizationPolicy(),
                                  defaultOptions.getServletContextAsObject());
    }
}
```
Allowing User Customizations at Runtime

This chapter describes how to use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime.

This chapter includes the following sections:

- Section 46.1, "About User Customizations"
- Section 46.2, "Enabling Runtime User Customizations for a Fusion Web Application"
- Section 46.3, "Configuring User Customizations"
- Section 46.4, "Controlling User Customizations in Individual JSF Pages"
- Section 46.5, "Implementing Custom User Customizations"
- Section 46.6, "Creating Implicit Change Persistence in Custom Components"

46.1 About User Customizations

Certain ADF Faces components have attributes that can be saved for a specific user. For example, the value of the disclosed attribute on a panelBox component can be saved for a specific user during the current session. Say the myOrders page in an application contains four panelBox components that display order information. By default, they are expanded, as shown in Figure 46–1.
However, suppose a user decides to collapse one of the boxes, as shown in Figure 46–2.

**Figure 46–2 panelBox Component Remains Collapsed**
Because this application is configured to allow user customizations, then during the user’s session, anytime that user returns to the page, the Payment Information box remains collapsed. You need only to enable user customizations for the project in order for these changes to be persisted to the user’s session.

**Note:** The user session begins when the user logs in to the application, and ends when the user leaves the application. It is possible that while using an application, the user could navigate across application boundaries (for example, to a peer application) and thereby leave the application, at which point the user session would end.

Table 46–1 shows the attribute value changes persisted by an ADF Faces application, after you configure the application to allow user customizations.

<table>
<thead>
<tr>
<th>Component</th>
<th>Attribute</th>
<th>Affect at Runtime</th>
</tr>
</thead>
<tbody>
<tr>
<td>panelBox</td>
<td>disclosed</td>
<td>Users can display or hide content using an icon in the header. Detail content will either display or be hidden, based on the last action of the user.</td>
</tr>
<tr>
<td>showDetail</td>
<td></td>
<td></td>
</tr>
<tr>
<td>showDetailHeader</td>
<td></td>
<td></td>
</tr>
<tr>
<td>showDetailItem</td>
<td></td>
<td>Users can change these proportions, and the new values will be persisted.</td>
</tr>
<tr>
<td>showDetailItem (used in a panelAccordion component)</td>
<td>flex</td>
<td>The heights of multiple showDetailItem components are determined by their relative value of the flex attribute. The showDetailItem components with larger flex values will be taller than those with smaller values. Users can change these proportions, and the new values will be persisted.</td>
</tr>
<tr>
<td>showDetailItem (used in a panelAccordion component)</td>
<td>inflexibleHeight</td>
<td>Users can change the size of a panel, and that size will remain.</td>
</tr>
<tr>
<td>panelSplitter</td>
<td>collapsed</td>
<td>Users can collapse either side of the splitter. The collapsed state will remain as last configured by the user.</td>
</tr>
<tr>
<td>panelSplitter</td>
<td>splitterPosition</td>
<td>The position of the splitter in the panel will remain where last moved by user.</td>
</tr>
<tr>
<td>richTextEditor</td>
<td>editMode</td>
<td>The editor will display using the mode (either WYSIWYG or source) last selected by the user.</td>
</tr>
<tr>
<td>calendar</td>
<td>activeDay</td>
<td>The day considered active in the current display will remain the active day.</td>
</tr>
<tr>
<td>calendar</td>
<td>view</td>
<td>The view (day, week, month, or list) that currently displays activities will be retained.</td>
</tr>
</tbody>
</table>
Users can change the height of a panelWindow or dialog component, and that height will remain.

Users can change the width of a panelWindow or dialog component, and that width will remain.

When users change the contentHeight attribute value of a panelWindow or dialog component, any associated windowHeight value on a command component is also changed and will remain.

When users change the contentWidth attribute value of a panelWindow or dialog component, any associated windowWidth value on a command component is also changed and will remain.

ADF Faces columns can be reordered by the user at runtime. The displayIndex attribute determines the order of the columns. (By default, the value is set to -1 for each column, which means the columns will display in the same order as the data source). When a user moves a column, the value on each column is changed to reflect the new order. These new values will be persisted.

ADF Faces columns can be frozen so that they will not scroll. When a column’s frozen attribute is set to true, all columns before that column (based on the displayIndex value) will not scroll. When you use the table with a panelCollection component, you can configure the table so that a button appears that allows the user to freeze a column.

The content of the column will either wrap or not. You need to create code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from true to false.

The selected column is based on the column last selected by the user.

<table>
<thead>
<tr>
<th>Component</th>
<th>Attribute</th>
<th>Affect at Runtime</th>
</tr>
</thead>
<tbody>
<tr>
<td>panelWindow</td>
<td>contentHeight</td>
<td>Users can change the height of a panelWindow or dialog popup component, and that height will remain.</td>

Table 46–1 (Cont.) Implicitly Persisted Attribute Values
### About User Customizations

Allowing User Customizations at Runtime

The column will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from true to false.

The width of the column will remain the same size as the user last set it.

ADF Faces tables can contain a component that allows users to filter the table rows by an attribute value. For a table that is configured to use a filter, the filter will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a button that allows a user to toggle the value from true to false.

The time range for the data displayed on a graph time axis can be specified for all data visualization graph components. By default, all data is displayed. The time range can also be set for a relative time range from the last or first data point, or an explicit time range. You will need to write code that allows the user to change this attribute value. For example, you might create a dropdown list to choose the time range for a graph.

The legend for data visualization project, resource utilization, and scheduling Gantt chart components will either be visible or not inside the information panel. You will need to write code that allows the user to change this attribute value, for example, a hide and show button to display the legend.

The data visualization hierarchy viewer component supports nine hierarchy layout options including a top-to-bottom vertical, tree, circle, radial, and so on. Users can change the layout in the map control panel and the last selected layout will be retained.

</tr>
</tbody>
</table>
46.1.1 Runtime User Customization Use Cases and Examples

You can configure an application so that the value of the attributes listed in Table 46–1 can be persisted across sessions using the MDS repository. For example, if an application allowed persistence to the MDS repository, then a user could collapse the Payment Information box, as shown in Figure 46–2, and it would be collapsed the next time that user entered the application.

Note: Before you can enable persistence to the repository, you must first follow all MDS configuration procedures as documented in Administering Oracle Fusion Middleware.

Along with the automatic persistence available through ADF Faces, you can create your own custom user customization capabilities for the following types of changes:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

If you want to create these types of custom user customizations, you need to add code (for example, in an event handler) that will call the APIs to handle the persistence.

Enabling an application to use the change persistence framework requires that you first enable your application to allow user customizations. Part of this process is determining where those changes should be persisted, either to the session or the MDS repository.

If you choose to persist changes to the session, by default all values as shown in Table 46–1 will be saved for the user’s session. However if you choose to persist changes to a repository, you must explicitly configure which of these attribute values will be persisted to the repository. Instead of persisting all these attribute values, you can restrict changes so that only certain attribute value changes for a component are persisted, or so that only specific instances of the components persist changes.

Note: You cannot persist changes to a component that is contained inside (anywhere in the subtree) of af:forEach or af:iterator tags using the addComponentChange() method. While such structure results in multiple copies of a component in the view tree, each component has only a single representation in the JSP document. However, the addDocumentChange() method does allow persistence for such components. For more information, see the discussion of the DocumentChange and ComponentChange classes in Section 46.5.1, "What You May Need to Know About the Change Persistence Framework API."

For any applications that persist changes to an MDS repository, when you deploy your application, you must create a metadata archive (MAR) profile in the application’s EAR assembly. For more information, see Section 48.3.2, "How to Create Deployment Profiles."
46.1.2 Additional Functionality for Runtime User Customization

You may find it helpful to understand other features before you start working with user customizations. Following are links to other functionality that may be of interest.

- For information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see to the section about managing the MDS repository in Administering Oracle Fusion Middleware.

- The MDS framework allows you to create customizable applications that can be customized and subsequently deployed by a customer. For information, see Chapter 45, "Customizing Applications with MDS."

46.2 Enabling Runtime User Customizations for a Fusion Web Application

Enabling an application to allow user customizations (whether for the default changes that some ADF Faces components provide, or for custom capabilities that you create) requires that you configure your application to use the change persistence framework and that you also determine where those changes should be persisted (either the session or the MDS repository).

**Note:** If you are planning on persisting changes to the MDS repository, before configuring an ADF Faces application to use change persistence, you must first follow all MDS configuration procedures as documented in Administering Oracle Fusion Middleware.

46.2.1 How to Enable User Customizations

You enable your application to use the change persistence framework by editing the web.xml and adf-config.xml files.

**Before you begin:**

It may be helpful to have an understanding of the features of runtime user customization. For more information, see Section 46.2, "Enabling Runtime User Customizations for a Fusion Web Application."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 46.1.2, "Additional Functionality for Runtime User Customization."

You will need to launch JDeveloper using the Studio Developer role, and open (or create) the application in which you want to enable runtime user customization.

**To enable user customizations:**

1. In the Applications window, double-click the web project in your application.
2. In the Project Properties dialog, select the ADF View node.
3. On the ADF View page, select the Enable User Customizations checkbox. If you want the changes to be persisted to only the session, select the For Duration of Session radio button. If you want the changes to persist to the MDS repository, select Across Sessions Using MDS.
4. If you choose to persist to the repository, you now need to declare each component tag and associated attribute values that you want persisted to the repository (if you choose to persist only to the session, all values will be persisted).
For procedures to accomplish this task, see Section 46.3, "Configuring User Customizations." Once that configuration is complete, you can override those settings on a per component instance basis. For procedures, see Section 46.4, "Controlling User Customizations in Individual JSF Pages."

---

**Note:** If you have created custom user customization capabilities as documented in Section 46.5, "Implementing Custom User Customizations," then you also need to declare those attribute values or operations.

---

### 46.2.2 What Happens When You Enable User Customizations

When you elect to save changes only to the session, JDeveloper adds the `CHANGE_PERSISTENCE` context parameter to the `web.xml` file, and sets the value to `session`. This context parameter registers the `ChangeManager` class that will be used to handle persistence. If you instead elect to save the changes to the MDS repository, the value is set to `oracle.adf.view.rich.change.FilteredPersistenceChangeManager`, as shown in Example 46–1.

#### Example 46–1  Context Parameter in web.xml Used For Change Persistence

```xml
<context-param>
  <param-name>org.apache.myfaces.trinidad.CHANGE_PERSISTENCE</param-name>
  <param-value>
    oracle.adf.view.rich.change.FilteredPersistenceChangeManager
  </param-value>
</context-param>
```

**Tip:** If needed, you can manually set this value to `oracle.adf.view.rich.change.MDSDocumentChangeManager` if you do not want any customizations to be restricted based on configurations in the `adf-config.xml` file or on the individual JSF pages, and you always want the changes to be persisted to the MDS repository and not the session.

When you elect to persist to the repository, JDeveloper also does the following:

- Adds the following JARs to the class path if they don’t exist:
  - `javatools-nodep.jar`
  - `facesconfigmodel.jar`
  - `taglib.jar`

- Adds another context parameter to `web.xml` to register the `MDSJSPProviderHelper` class to handle merging MDS customization documents with the base JSP document, as shown in Example 46–2

#### Example 46–2  Context Parameter in web.xml Used For Merging Changes

```xml
<context-param>
  <param-name>oracle.adf.jsp.provider.0</param-name>
  <param-value>oracle.mds.jsp.MDSJSPProviderHelper</param-value>
</context-param>
```

- Adds the ADF Faces Change Manager Runtime 11 library to the project.
In the adf-config.xml descriptor file, sets the persistent-change-manager element to the MDSDocumentChangeManager, which is the class that will be used to persist the changes. Example 46–3 shows the configuration for persisting to the MDS repository.

Example 46–3 Registered ChangeManager Class for Restricted Change Persistence

```
<persistent-change-manager>
  <persistent-change-manager-class>
    oracle.adf.view.rich.change.MDSDocumentChangeManager
  </persistent-change-manager-class>
</persistent-change-manager>
```

Creates JSF JSP pages as XML documents. For more information, see Section 46.4, "Controlling User Customizations in Individual JSF Pages."

Additionally, when you elect to save the changes to the MDS repository, and you include facelets in your application, JDeveloper adds the faceletCache context parameter to the web.xml file. The value of this parameter is set to oracle.adfinternal.view.faces.facelets.rich.MDSFaceletCache, as shown in Example 46–4.

Example 46–4 Context Parameter in web.xml Used For Facelet Caching

```
<context-param>
  <param-name>com.sun.faces.faceletCache</param-name>
  <param-value>oracle.adfinternal.view.faces.facelets.rich.MDSFaceletCache</param-value>
</context-param>
```

The facelets cache enhances the performance of your application and the cache capacity can be configured in MDS on the server. For more information, see Administering Oracle Fusion Middleware.

46.3 Configuring User Customizations

If you choose to persist changes to an MDS repository, you must decide which of the attribute values that are by default persisted to the session (as shown in Table 46–1) should also be persisted to the repository. Alternatively, you can configure which changes you do not want persisted.

**Tip:** Often, a system administrator is the one to set the configurations in the adf-config.xml. The persist and dontPersist attributes on a component allow page authors to override that setting as needed.

For example, suppose you decide that you don’t want the value for the width attribute on columns to be persisted to the repository, but you do want all other default attribute changes for columns to be persisted. You must explicitly set the other default column values that you want to be persisted, and you also must explicitly configure the application to NOT persist the width attribute.

**Note:** If you have created custom user customization capabilities as documented in Section 46.5,"Implementing Custom User Customizations," then you must explicitly declare those attribute values or operations as well.
You set (and unset) these values using the overview editor for the adf-config.xml file. Figure 46–3 shows the overview editor where only certain attribute values for the column component will be persisted.

**Figure 46–3 Overview Editor for the adf-config.xml File**

Once set, you can override persistence for a specific component on a page. For example, suppose you want to disallow change on the width attribute on only one table’s columns. You want the rest of the tables in the application to persist changes to that attribute. You would configure the columns to globally persist changes to the width attribute, but then for that one table, you would override the global configuration directly on the JSF page. For more information, see Section 46.4, “Controlling User Customizations in Individual JSF Pages.”

**Note:** If you’ve enabled just session persistence, then all attribute values shown in Table 46–1 will be persisted to the session. There is no way to override this either globally or on an instance.

### 46.3.1 How to Configure Change Persistence

By default, when you configure your application to use any type of change persistence (that is, to either the session or a repository), the values of all attributes shown in Table 46–1 will always be persisted to the user’s session. If you configured your changes to be persisted to a repository, then you must declare the attributes whose values should be persisted to that repository. If there are any values that you don’t want persisted, then you need to configure those values as well.

**Before you begin:**

It may be helpful to have an understanding of how runtime user customization are persisted. For more information, see Section 46.3, "Configuring User Customizations."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 46.1.2, "Additional Functionality for Runtime User Customization."

You will need to launch JDeveloper using the Studio Developer role, and open (or create) the application in which you want to enable runtime user customization.
To declare attribute value persistence to a repository:

1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click adf-config.xml.

2. In the overview editor, click the View navigation tab.

3. In the View page, in the Tag Persistence section, in the Components table, select the component whose changes you want to persist (or not persist) to the repository.

If the component does not appear in the table, click the Add icon to select and add it.

**Note:** The filter rules specified in the adf-config.xml file are applicable only when you have chosen to persist to the MDS repository (see Section 46.2.1, "How to Enable User Customizations"). These rules do not apply for persistence within session scope.

If persistence fails for any reason (for example if one of the filter rules fails or there are MDS repository errors), then the values will be stored only within the session scope.

The Attributes table displays all the attributes for the selected component whose values can be persisted.

4. In the Attributes table, select Persist Changes for each of the attributes whose values you want persisted. Deselect any if you do not want the values persisted.

**Note:** If you are implementing custom user customizations (see Section 46.5, "Implementing Custom User Customizations"), then you will need to edit the adf-config.xml manually to add the configuration. See Example 46–5 for an example on how to configure user customizations.

### 46.3.2 What Happens When You Configure Change Persistence

When you select the component tags and attribute values to be persisted in the adf-config.xml file, JDeveloper enters tag library information for the components and attributes that are to be persisted. Example 46–5 shows the entry for persisting the value of the disclosed attribute on the panelBox component.

**Example 46–5  Registration of Attribute Changes in adf-config.xml**

```xml
<taglib-config>
  <taglib uri="http://xmlns.oracle.com/adf/faces/rich">
    <tag name="panelBox">
      <attribute name="disclosed">
        <persist-changes>
          true
        </persist-changes>
      </attribute>
      ...
    </tag>
  </taglib>
</taglib-config>
```
46.4 Controlling User Customizations in Individual JSF Pages

Once you have enabled your application to allow user customizations, you can control user customizations for specific components on the page.

By default, the framework persists changes for all component instances, based on the configuration in the `adf-config.xml` file. You can override this default behavior by explicitly setting what should be persisted and what should not be persisted on each component instance using the `persist` and `dontPersist` attributes.

---

**Note:** The filter rules specified using the `persist` and `dontPersist` attributes are applicable only when you have chosen to persist to the MDS repository (see Section 46.2.1, "How to Enable User Customizations"). These rules do not apply for persistence within session scope.

If persistence fails for any reason (for example if one of the filter rules fails or there are MDS repository errors), then the values will be stored only within the session scope.

---

The following components support the `persist` and `dontPersist` attributes:

- `panelBox`
- `showDetail`
- `showDetailHeader`
- `showDetailItem`
- `column`
- `tree`
- `treeTable`
- `panelSplitter`
- `calendar`
- `dvt:projectGantt`
- `dvt:resourceUtilizationGantt`
- `dvt:schedulingGantt`
- `dvt:ganntLegend`
- `dvt:hierarchyViewer`
- `dvt:timeAxis`

46.4.1 How to Control User Customizations on a JSF Page

You can override any globally set persistence configuration for a component using its `persist` and `dontPersist` attributes.

**Tip:** Often, a system administrator is the one to set the configurations in the `adf-config.xml`. The `persist` and `dontPersist` attributes allow page authors to override that setting as needed.
Before you begin:

It may be helpful to have an understanding of how runtime user customizations can be restricted on an individual page. For more information, see Section 46.4, "Controlling User Customizations in Individual JSF Pages.”

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 46.1.2, "Additional Functionality for Runtime User Customization.”

You will need to launch JDeveloper using the Studio Developer role, open the application, and open the page for which you want to modify user customization behavior.

To implement user customizations on a JSF Page:

1. In the Applications window, double-click the page that contains components that will be persisting changes.

2. If you want to persist all persistable attributes for a component:
   a. In the Properties window, expand the Advanced section.
   b. From the dropdown list for the Persist field, select All Available.

3. If you do not want to persist any attributes, repeat Step 2 for the Don’t Persist field.

4. If more than one attribute can be persisted for the component, and you do not want to persist all of them:
   a. In the Properties window, from the dropdown menu to the right of the Persist field, choose Edit.
   b. In the Edit Property dialog, shuttle any attributes to be persisted from Available to Selected.

5. If you do not want to persist an attribute value, repeat Step 4 for the Don’t Persist field.

Note: The filter rules specified using the persist and dontPersist attributes take precedence over any adf-config.xml configuration set for global component-level restrictions.

Values specified for the dontPersist attribute take precedence over values specified for the persist attribute. For example, if for a panelBox component you set disclosed as the value for both the persist and dontPersist attributes, the value of the disclosed attribute will not be persisted.

If you set the value of the persist or dontPersist attribute to All Available, then any values entered as choices using the Edit dialog and the shuttle will be ignored and all available attribute values will be persisted or not persisted.

46.4.2 What Happens at Runtime: How Changes are Persisted

When an application is configured to persist changes to the session, any changes made during the session are recorded in a session variable in a data structure that is indexed according to the view ID and the component’s ID attribute value. Every time the page is requested, in the subsequent create View or Restore View phase, all changes are applied in the same order as they were added. This means that the changes registered
through the session will be applied only during subsequent requests in the same session.

When an application is configured to persist changes to the MDS repository, any changes made during the session are recorded by mutating the Document Object Model that MDS maintains for the JSP document behind the view. A JSF phase listener registered by ADF controller triggers a commit on the MDS session during the appropriate lifecycle phase, resulting in the change document being persisted in the MDS store. Every time the page is requested, Oracle's JSP engine seeks the JSP document from an MDS JSP provider, which provides a flattened document after merging the stored changes to the base document. MDS records the change against the unique value of the component's ID attribute.

**Tip:** If changes are applied in response to a partial submit of the page (for example, a button with the `partialSubmit` attribute set to `true`), the component for which changes are applied must be set as the value for the `partialTarget` attribute.

Additionally, be aware that when you run the application from JDeveloper in the Integrated WebLogic Server, MDS creates a local file-based repository to persist metadata customizations. In contrast, when the application is deployed to a test or production environment, customizations are persisted to the configured MDS repository. For more information about MDS repository configuration, see the *Administering Oracle Fusion Middleware*. For more information about deploying an application, see Section 48.4, "Deploying the Application."

### 46.4.3 What You May Need to Know About Using Change Persistence on Templates and Regions

How changes are persisted for components on templates or regions is handled differently, depending on whether the changes are persisted to the session or to the MDS repository. With session persistence, changes are recorded and restored on components against the `viewId` for the given session. As a result, when the change is applied on a component that belongs to a region or page template, that change is applicable only in scope of the page that uses the region or template. It does not span all pages that consume the region or template.

For example, suppose you have `pageOne.jsp` and `pageTwo.jsp`, and they both contain the region defined in `region.jsf`, which in turn contains a `showDetail` component. When `pageOne.jsp` is rendered and the `disclosed` attribute on the `showDetail` component changes, the implicit attribute change is recorded and will be applied only for `pageOne.jsp`. If the user navigates to `pageTwo.jsp`, no attribute change is applied.

When you persist changes to the MDS repository, MDS records and restores customizations for a document identified by a combination of the JSP page path and customization name/value configuration setting as set on the customization class (for more information, see Section 45.2.1.1, "Customization Classes"). As a result, for a given page that is rendered, when MDS applies a change on a component within a region or template, it is applicable for all pages that consume the region or template and that have the same customization name and value as the source page.

In the previous example, assume that the `showDetail` component uses the ID of `myShowDetail`. When `pageOne.jsp` is rendered and the `disclosed` attribute on the `showDetail` component changes, the attribute change is recorded for `region.jsf` (and not the page that consumes it). This change is applied when any page that contains the region is rendered, as long as the ID remains the same.
46.5 Implementing Custom User Customizations

In addition to the user customization capabilities built into certain ADF Faces components, you can create your own custom user customization capabilities. The change persistence framework supports the following types of user customizations:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

To create custom user customizations, you must create a customization class for each type of user customization and then configure your application to use that class. You also need to set up the layers of customization for your application. For more information about both of these procedures, see Section 45.2, "Developing a Customizable Application."

Once those prerequisites are satisfied, you add logic that calls methods on the ADF Faces classes that handle persisting change either to the session or the MDS repository. To handle the change, you create code that uses the APIs from one of the ADF Faces specialized component change classes. For most cases, you add this code to the event handler method on a managed bean associated with the page the persisting component is on. If you want all instances of a component to persist the same change, you need to add this code for each page on which that component appears.

If you are creating a custom component, you can implement user customizations for the component by adding code directly to the custom component class. In that case, you will need to add the code only to the component class, and not once for each instance of the component. For more information, see Section 46.6, "Creating Implicit Change Persistence in Custom Components."

46.5.1 What You May Need to Know About the Change Persistence Framework API

To better understand what you need to do to create custom user customizations, it may help to have a deeper understanding of the change persistence and MDS frameworks. When you elect to persist changes to the MDS repository, the change persistence framework works in conjunction with the MDS framework. Where and how the customizations are saved are determined by how you set up your MDS repository, your customization layers, and your customization classes. Details about the MDS framework and the repository and how to use it are covered in Chapter 45, "Customizing Applications with MDS."

The change persistence framework uses the underlying change manager classes from Apache MyFaces Trinidad (in the org.apache.myfaces.trinidad.change package) along with a few ADF Faces-specific classes (in the oracle.adf.view.rich.change package). The instance of the registered ChangeManager class is accessible through the RequestContext object. It is responsible for gathering changes as they are created and added during a request, and then persisting them. The SessionChangeManager class is an implementation of ChangeManager which handles persistence within a session only, while the MDSDocumentChangeManager class is an implementation that persists to the MDS repository only. The FilteredPersistenceChangeManager class is an implementation of ChangeManager that stores the changes that pass the filter rules into the repository using the registered persistence change manager. Any change that
does not get persisted to the repository will be persisted to the session when `FilteredPersistenceChangeManager` is used.

Additional classes are used to describe the changes to a component. You use these APIs to handle persisting any changes to components other than the implicit value changes the ADF Faces framework provides (as shown in Table 46–1). `ComponentChange` is the base class for all classes used to implement specific changes that act on the JSF component hierarchy, such as adding or removing a facet or a child component. These changes are automatically applied during subsequent creation of the view, in the same order in which they were added. Classes that extend the `ComponentChange` class and that also implement the `DocumentChange` interface can directly persist changes to the MDS repository. Classes that do not implement the `DocumentChange` interface can persist changes only to the session.

Table 46–2 describes the specialized classes that handle specific customizations. If "yes" appears in the Repository column, then the class implements the `DocumentChange` interface and it can persist changes to the MDS repository.

<table>
<thead>
<tr>
<th>Class Name</th>
<th>Repository</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>AddChildDocumentChange</td>
<td>Yes</td>
<td>Adds a child or complex child (dvt:) component using document mark up. While applying this change, the child or complex child component is created and added to the document.</td>

</tbody>
</table>
Aside from a ChangeManager class, you may also need to implement and register the DocumentChangeFactory interface with the ChangeManager class. If the DocumentChangeFactory implementation can provide an equivalent DocumentChange for a ComponentChange, the ChangeManager will use it to persist the DocumentChange to the repository.

### 46.5.2 How to Create Code for Custom User Customizations

You need to add code to handle any explicit changes you want to create, and to configure the components on the JSF page to handle customization. As with the default user customizations, you also must register the custom changes in the adf-config.xml file.

---

**Note:** When the changes are expressible in more than one form, the change must be recorded in the form with highest precedence. For example:

- Attribute change for a component: The attribute can be specified on the component tag or it can be expressed using the `<f:attribute>` tag. In a JSF JSP document, `<f:attribute>` takes lesser precedence over the attribute specified on the component tag. Therefore, the attribute change on the component tag will be recorded for customization.

- Column header text in a column component: The header text for the column can be specified using either the `headerText` attribute or using header facet. In this case, the facet component will have precedence.

---

**Before you begin:**

It may be helpful to have an understanding of the features of custom runtime user customization. For more information, see Section 46.5, "Implementing Custom User Customizations."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 46.1.2, "Additional Functionality for Runtime User Customization."

You will need to launch JDeveloper using the **Studio Developer** role, open the application, and open the page for which you want to modify user customization behavior.

**To create custom user customizations:**

1. Create a managed bean for the page that contains the component, as described in Section 26.4, "Using a Managed Bean in a Fusion Web Application."

   For more information regarding managed beans and how they are used as backing beans for JSF pages, see the "Creating and Using Managed Beans" section in *Developing Web User Interfaces with Oracle ADF Faces*.

2. Add code to the event handler method for the component that will be used to make the change. This code should obtain the component that contains the change. It should then use the component and the appropriate APIs to create, record, and persist the change.

   Example 46–6 shows the code on the action event handler for a command button for a change that will be persisted to the MDS repository. When a user clicks the
button, that source graphic file changes. The event handler method accesses the component and changes the source attribute for the graphic. It then calls the private `addAttributeChange` method, which first uses the component API to record the change, and then uses the `AttributeComponentChange` class to set the new source attribute value.

**Example 46–6  Persisting Change to the Repository from an Event Handler on a Managed Bean**

```java
public void modifyObjectImage(ActionEvent event) {
    UIComponent uic = event.getComponent().findComponent("oi1");
    String source = "/images/mediumAd.gif";
    uic.getAttributes().put("source", source);
    _addAttributeChange(uic, "source", source);
}
```

```java
private static void _addAttributeChange(UIComponent uic, String attribName, Object attribValue) {
    FacesContext fc = FacesContext.getCurrentInstance();
    ChangeManager cm =
        RequestContext.getCurrentInstance().getChangeManager();
    ComponentChange cc =
        new AttributeComponentChange(attribName, attribValue);
    cm.addComponentChange(fc, uic, cc);
}
```

**Note:** When you persist changes, in addition to explicitly recording a change on the component (which is done in Example 46–6 using `uic.getAttributes().put("source", source)` method), you must also directly apply the change using the component API, as was done using the private `addAttributeChange(uic, "source", source)` method. Applying the change in this way allows the user to see the change in response to the same request. If the change is recorded on the component, then the change will not be seen until a subsequent request.

Additionally, if you know that the component will always persist to the repository regardless of any restricted change persistence settings, you can instead call the `AdfFacesContext.getCurrentInstance().getPersistentChangeManager()` method.

3. The ChangeManager class provides support for automatically converting an `AttributeComponentChange` into an `AttributeDocumentChange`, thereby allowing persistence to a repository. However, if you need to convert another type of change and you use a specialized change manager class that does not implement the `DocumentChange` class, you need to create a custom `DocumentFactory` implementation that converts the component change to a document change.
4. If you create a custom `DocumentFactory` implementation, you need to register it with the appropriate change manager class using the following method in your bean:

```java
public static void registerDocumentFactory(String targetClassName,
                                          String converterClassName)
```

Where `targetClassName` is the name of the `ComponentChange` class and `converterClassName` is the name of your `DocumentChangeFactory` extension that is capable of converting the target `ComponentChange` into a `DocumentChange`. The semantics of name for these classes is same as that of `getName()` in the `java.lang.Class` class.

5. If the class you use to create the component change adds a child that has a subtree of components, and you want to persist the changes to the repository, you must create a `DocumentFragment` to represent the change.

Example 46-7 shows how to use the `AddComponentDocumentChange` specialized class to create a `DocumentChange` object and use a `DocumentFragment` to represent the change.

```java
Example 46–7 Converting a `ComponentChange` Object to a `DocumentChange` Object

public void appendChildToDocument(ActionEvent event)
{
    UIComponent eventSource = event.getComponent();
    UIComponent uic = eventSource.findComponent("pg1");
    // only allow the image to be added once
    if (_findChildById(uic,"oi3") != null)
        return;
    FacesContext fc = FacesContext.getCurrentInstance();
    DocumentFragment imageFragment = _createDocumentFragment(_IMAGE_MARK_UP);
    DocumentChange change = new AddChildDocumentChange(imageFragment);
    ChangeManager apm = RequestContext.getCurrentInstance().getChangeManager();
    apm.addDocumentChange(fc, uic, change);
}
```

```java
private static final String _IMAGE_MARK_UP =
"<af:objectImage id='oi3' height='100' width='120' " +
  "source='http://www.somewhere.com/someimage.jpg' " +
  "xmlns:af='http://xmlns.oracle.com/adf/faces'/>
";
```

```java
private static DocumentFragment _createDocumentFragment(String markUp)
{
    // prepend XML declaration
    markUp = "<?xml version = '1.0' encoding = 'ISO-8859-1'?>" + markUp;
}
```

---

**Note:** Automatic conversion of `AttributeComponentChange` into an `AttributeDocumentChange` assumes that the component attribute is represented as an attribute of the same name on the associated element in the JSPX document.

Only those attribute values that are expressible in the JSPX document can be persisted using `AttributeDocumentChange`. In other words, `CharSequence`, `Number`, `Boolean` and `ValueExpression` are the only supported data types.

Only values that implement `java.io.Serializable` can be persisted using `AttributeComponentChange`. 
DocumentBuilderFactory factory = DocumentBuilderFactory.newInstance();
factory.setNamespaceAware(true);
factory.setValidating(false);
DocumentBuilder builder;
try {
    builder = factory.newDocumentBuilder();
} catch (ParserConfigurationException pce) {
    _LOG.log(Level.WARNING, "Unable to get XML Parser:", pce);
    return null;
}
try {
    // use a version explicitly with ISO-8859-1 instead
    byte[] markupBytes = markUp.getBytes();
    Document newDoc = builder.parse(new ByteArrayInputStream(markupBytes));
    DocumentFragment fragment = newDoc.createDocumentFragment();
    // add the document's root element to the fragment
    fragment.appendChild(newDoc.getDocumentElement());
    return fragment;
} catch (SAXException se) {
    _LOG.log(Level.WARNING, "Unable to parse markup:" + markUp, se);
    return null;
} catch (IOException ioe) {
    _LOG.log(Level.WARNING, "IO Problem with markup:" + markUp, ioe);
    return null;
}
}

6. Register the user customizations in the adf-config.xml file, as documented in Section 46.3, "Configuring User Customizations." If the custom changes are of any type other than AttributeDocumentChange, you will need to manually edit the adf-config.xml file and indicate that all changes are allowed for the component, as shown in Example 46–8.

Example 46–8 Custom Registration in adf-config.xml

<tag name='inputText'>
    <attribute name='label'>
        <persist-changes>true</persist-changes>
    </attribute>
    <persist-operations>ALL</persist-operations>
</tag>

46.6 Creating Implicit Change Persistence in Custom Components

When you create a custom component, you may decide that you want certain attribute values on that component to be persisted whenever change persistence is enabled in an application. Setting implicit change on a custom component is similar to setting explicit change persistence on existing components. You add code that executes the actual persistence, but instead of you placing that code on a managed bean, that code can be handled directly by the component class. If your component’s attribute values
are synchronized with the server using events, then you can use the broadcast method to persist the changes. If the attribute value that you want to persist does not use events, then you need to add code in the renderer and component class.

46.6.1 How to Set Implicit Change Persistence For Attribute Values that Use Events

When an attribute value uses events, you need to add code to the component class.

Before you begin:
It may be helpful to have an understanding of how persistence is implemented in custom components. For more information, see Section 46.6, "Creating Implicit Change Persistence in Custom Components."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 46.1.2, "Additional Functionality for Runtime User Customization."

You will need to launch JDeveloper using the Studio Developer role, and open the application.

To set implicit change persistence for attribute values that use events:
1. In the Applications window, double-click the custom component class Java file.
2. Add code to the broadcast method that will use the specialized class to create a new ComponentChange object and then call the ChangeManager to add the change.

Example 46–9 shows the code added to the UIXShowDetail class that persists a change to the disclosed attribute. In this case, the AttributeComponentChange class is used.

Example 46–9 Persisting Change from a Component Class

```java
public class UIXShowDetail extends UIXComponentBase {
    ...
    public void broadcast(FacesEvent event) throws AbortProcessingException {
        super.broadcast(event);
        ...
        if (event instanceof DisclosureEvent) {
            boolean isDisclosed = ((DisclosureEvent) event).isExpanded();
            setDisclosed(isDisclosed);
            //Record a Change for 'disclosed' attribute
            AttributeComponentChange aa = new AttributeComponentChange('disclosed', isDisclosed ? Boolean.TRUE : Boolean.FALSE);
            AdfFacesContext adfContext = AdfFacesContext.getCurrentInstance();
            adfContext.getChangeManager().addComponentChange(getFacesContext(), this, aa);
        }
    }
    ...
}```
46.6.2 How to Set Implicit Change Persistence For Other Attribute Values

When an attribute does not use events, you need to place code in the component’s renderer class.

Before you begin:
It may be helpful to have an understanding of how persistence is implemented in custom components. For more information, see Section 46.6, "Creating Implicit Change Persistence in Custom Components."

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Section 46.1.2, "Additional Functionality for Runtime User Customization."

You will need to launch JDeveloper using the Studio Developer role, and open the application.

To set implicit change persistence for other attribute values:

1. In the Applications window, double-click the custom component’s render class Java file.

2. Use the findTypeConstants method, which takes a ClientMetadata instance and use the addPersistedProperty method to mark certain properties as persisted. Example 46–10 shows code from the renderer class used for the ADF Faces PanelSplitter component, which implicitly persists the splitterPosition attribute value.

Example 46–10  Method in Component Renderer Class to Implicitly Persist Changes

```java
// Code from PanelSplitterRenderer.java
protected void findTypeConstants(
    FacesBean.Type type,
    ClientMetadata metadata)
{
    super.findTypeConstants(type, metadata);
    metadata.addRequiredProperty(
        _orientationKey = type.findKey("orientation"));
    metadata.addRequiredProperty(
        _positionedFromEndKey = type.findKey("positionedFromEnd"));
    metadata.addRequiredProperty(
        _disabledKey = type.findKey("disabled"));
    metadata.addRequiredProperty(
        _splitterPositionKey = type.findKey("splitterPosition"));
    metadata.addPersistedProperty(_splitterPositionKey);
}
```

3. In the JavaScript component peer class, define the attribute value to be persisted, using the setProperty function. This function needs to be invoked with the attribute name (as defined in the renderer in the previous step), the value, and "true", meaning the value of the attribute will be set. Example 46–11 shows code from the panelSplitter class that sets the splitter position.

Example 46–11  Method in Component Class to Implicitly Persist Changes

```javascript
// Code from AdfDhtmlPanelSplitterPeer.js file where we set the splitter position
var component = this.getComponent();
component.setProperty("splitterPosition",position, true);
```
// position is the value to be set
This chapter describes how to work with the ADF Model layer and Active Data Service (ADS) to provide real-time updates to ADF Faces components.

This chapter includes the following sections:

- Section 47.1, "About the Active Data Service"
- Section 47.2, "Configuring the Active Data Service"
- Section 47.3, "Configuring Components to Use the Active Data Service"
- Section 47.4, "Using the Active Data Proxy"
- Section 47.5, "What You May Need to Know About Maintaining Read Consistency"
- Section 47.6, "Using the Active Data with a Scalar Model"

47.1 About the Active Data Service

The Fusion technology stack includes Active Data Service (ADS), which is a server-side push framework that allows you to provide real-time data updates for ADF Faces components. You bind ADF Faces components to a data source and ADS pushes the data updates to the browser client without requiring the browser client to explicitly request it. For example, you may have a table bound to attributes of an ADF data control whose values change on the server periodically, and you want the updated values to display in the table. You can configure your application and the component so that whenever the data changes on the server, the ADF Model layer notifies the component and the component rerenders the changed data with the new value highlighted, as shown in Figure 47–1.

**Figure 47–1 Table Displays Updated Data as Highlighted**
47.1.1 Active Data Service Use Cases and Examples

Using ADS is an alternative to using automatic partial page rendering (PPR) to rerender data that changes on the backend as a result of business logic associated with the ADF data control bound to the ADF Faces component. Whereas automatic PPR requires sending a request to the server (typically initiated by the user), ADS enables changed data to be pushed from the data store as the data arrives on the server. Also, in contrast to PPR, ADS makes it possible for the component to rerender only the changed data instead of the entire component. This makes ADS ideal for situations where the application needs to react to data that changes periodically.

To use this functionality, you must configure the application to use ADS. If your application services do not support ADS, then you also need to create a proxy of the service so that the components can display the data as it updates in the source.

Any ADF Faces page can use ADS. However, you can configure only the following ADF Faces components to work with active data:

- activeImage
- activeOutputText
- table
  
  Note that filtering on a table that will be using active data is not supported. Once a table is filtered at runtime, active data cannot be displayed. Currently, ADS supports table components with the outputText component contained within a column; other components are not supported inside the table column

- tree
- treeTable
- graph, gauge, mapPointTheme, pivotTable, pivotFilterBar, sunburst, and treemap ADF Data Visualization components, as identified in the "Active Data Support" section of Developing Web User Interfaces with Oracle ADF Faces

Note that ADS does not support active data for all graph component types. For a list of supported graph types, see the "How to Configure Databound Graph Components to Display Active Data" section in Developing Web User Interfaces with Oracle ADF Faces.

47.1.2 Limitations of the Active Data Service Framework

The framework for ADS has the following limitations.

- ADS does not support active data for ADF Faces components added dynamically, using PPR.
- ADS does not support active data for ADF Faces components that appear in a web page or region that gets invoked from a task flow call activity. Do not use task flow call activities with bounded task flows when active data is required.
- ADS does not support active data for every type of ADF Faces graph component. For a list of supported graph types, see the "How to Configure Databound Graph Components to Display Active Data" section in Developing Web User Interfaces with Oracle ADF Faces
- ADS does not support active data on ADF Faces table components with filtering enabled. Once a table is filtered at runtime, active data cannot be displayed.
- ADS does not time out from user inactivity by default. To ensure that an active session is not maintained indefinitely, you can configure the web.xml
context-parameter `oracle.adf.view.rich.poll.TIMEOUT` to specify how long ADS should run before it times out from user inactivity. For more information, see Section 47.2.3, "How to Configure Session Timeout for Active Data Service."

### 47.1.3 Active Data Service Framework

The framework for ADS contains a number of components that work together to send the active data from the source to the UI component. When a data event occurs, if the associated ADF Model layer binding is configured for active data, the Active Data model delivers the data to the Event Manager. The Event Manager then retrieves the data and invokes the Push Service, which delivers the data to the correct component, based on how the service is configured (for more information, see Section 47.1.4, "Data Transport Modes"). The component then applies the new data pushed from the server. Figure 47–2 shows the ADS framework.

![Active Data Service Framework](image)

In order to use the Active Data Service, you need to have a data store that publishes events when data is changed, and you need to create business services that react to those events. By default, ADF Business Components does not react to data events. The Active Data Proxy framework allows all types of data sources, including ADF Business Components, to work with ADS. It combines the `ActiveDataModel` with the JSF model, so that you need to override functionality only on this proxy rather than on both the `ActiveDataModel` and the JSF model.

The following comprise the ADS framework:

- `ActiveDataModel` interface: Abstraction of the active data model. Its responsibilities include:
  - Starting and stopping active data
- Keeping track of the current active data event ID
- Letting the renderer know whether the model needs active data or not.

■ Event Manager: A server-side component that works with the ADF Model layer. It is responsible for the following:
  - Listening to binding events
  - Retrieving active data
  - Managing active data encoding
  - Invoking the Push service to send the encoded active data

■ Push service: A delivery channel that interacts with the Event Manager on the server side and with the Active Data Manager on the client side. It provides the following:
  - Establishing and maintaining the connection between the server and the client
  - Transmitting the active data over this connection from the server to the client
  - Ensuring that active data gets delivered within desired parameters and forcing component update if not

■ Active Data Manager: A client-side component that distributes the active data to the correct component. Specifically, it is responsible for the following:
  - Delivering events from the server side that are coming through the channel, using an event delivery service
  - Handling multiple browser windows through a shared channel
  - Dispatching active data events to rich client components, so that the components can render the change accordingly

■ Active Data Proxy: A proxy that allows all types of data sources to enable push functionality. Specifically, the proxy is responsible for the following:
  ■ Implementing and delegating *ActiveDataModel* functionality
  ■ Delegating to JSF models
  ■ Listening to data change events from the data source
  ■ Generating active data events based on the data change events

### 47.1.4 Data Transport Modes

Active data is sent to the client using data streaming (push) or one of two types of data polling. With *data streaming*, there is only one request, which stays open. When a data change event occurs, a partial response is sent (the response is not closed), the client is notified, and the associated component is updated to show the new data, as shown in Figure 47–3.
With data polling, the application is configured to poll the data source at specified intervals, as shown in Figure 47–4. With each request, a response is sent and closed, whether or not a data change event has occurred. If the data has changed, then the client is notified and the component is updated.

Long polling is similar to streaming. When the page is rendered, a request is sent to the active channel. However, a response is not returned until there is a data change event. At that point, the connection is closed. As soon as the connection is closed, a new connection is initiated, which results in the connection being active most of the time: there are no specific intervals. Long polling results in the majority of data change events being received when they occur, because the connection is already established and ready to send a response to the client, as shown in Figure 47–5.

For more information, see Section 47.2.2, "What You May Need to Know About Configuring an ADS Transport Mode."
To use ADS, you need to configure your application to determine the method of data transport, as well as other performance options. You also need to configure the bindings for your components so that they can use ADS. If you are using ADF Business Components, you need to modify your model to implement the `ActiveModel` interface to register itself as the listener for active data events using the Active Data Proxy.

### 47.2 Configuring the Active Data Service

You need to configure ADS to determine the data transport mode, as well as to set other configurations, such as a latency threshold and reconnect information.

**Note:** If you enable ADS but do not configure it, the ADS framework will use the default values shown in Table 47–1.

#### 47.2.1 How to Configure the Active Data Service

Configuration for running the Fusion web application with ADS in JDeveloper and Integrated WebLogic Server is done in the `adf-config.xml` file. For more information about the `adf-config.xml` file, including how to create one if you need to, see the “Configuration in adf-config.xml” section of Developing Web User Interfaces with Oracle ADF Faces.

**Note:** To support automatic replication and failover for web applications within a clustered environment, Oracle WebLogic Server supports mechanisms for replicating HTTP session state across clusters. You can configure Oracle Application Development Framework (Oracle ADF) to ensure the Fusion web application's state can be restored from any server in the cluster. To support failover for pages configured to display active data, it is necessary to enable failover for the ADF Business Components application module and to enable ADF Controller to track changes to the ADF memory scopes. With these ADF settings configured, when failover occurs, the ADF server will detect the failover and request all pages configured to display active data to refresh themselves, after that ADS restarts and data is pushed to the client. For details about how to enable failover for the Fusion web application in a high availability environment, see the High Availability Guide.

---

### Before you begin:

It may be helpful to have an understanding of the ADS configuration choices. For more information, see Section 47.2, “Configuring the Active Data Service.”

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 47.1, “About the Active Data Service.”

### To configure the Active Data Service:

1. In the Application Resources panel, expand the Descriptors and ADF Meta-INF nodes, and then double-click `adf-config.xml`.

2. Click the Source tab to open the file in the source editor, and create an entry for each of the elements shown in Table 47–1.
Example 47–1 shows a sample configuration that has content pushed to the client.

Example 47–1  Sample Configuration for ADS in adf-config.xml

```xml
<?xml version='1.0' encoding='utf-8' ?>
<adf-config xmlns='http://xmlns.oracle.com/adf/config'
            xmlns:ads='http://xmlns.oracle.com/adf/activedata/config'>
```

---

### Table 47–1  ADS Configuration Elements in adf-config.xml

<table>
<thead>
<tr>
<th>Element</th>
<th>Description</th>
<th>Default Value (in milliseconds)</th>
<th>Minimum Value (in milliseconds)</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>&lt;transport&gt;</code></td>
<td>The method by which data will be delivered to the client. Value values are:</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>■ streaming (default)</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>■ polling</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>■ long-polling</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>For more information, see Section 47.2.2, &quot;What You May Need to Know About Configuring an ADS Transport Mode.&quot;</td>
<td></td>
<td></td>
</tr>
<tr>
<td><code>&lt;latency threshold&gt;</code></td>
<td>Latency threshold in milliseconds. Active data messages with network delays greater than this threshold will be treated as late.</td>
<td>10000</td>
<td>1000</td>
</tr>
<tr>
<td><code>&lt;keep-alive-interval&gt;</code></td>
<td>Frequency in milliseconds for sending keep-alive messages when no events are generated.</td>
<td>10000</td>
<td>5000</td>
</tr>
<tr>
<td><code>&lt;polling-interval&gt;</code></td>
<td>When <code>&lt;transport&gt;</code> set to polling, frequency in milliseconds of the poll request.</td>
<td>5000</td>
<td>1000</td>
</tr>
<tr>
<td><code>&lt;max-reconnect-attempt-time&gt;</code></td>
<td>Maximum period of time in milliseconds a client will attempt to reconnect the push channel to the server upon getting disconnected.</td>
<td>1800000 (30 minutes)</td>
<td>0</td>
</tr>
<tr>
<td><code>&lt;reconnect-wait-time&gt;</code></td>
<td>Time interval in milliseconds to wait between reconnect attempts.</td>
<td>10000</td>
<td>1000</td>
</tr>
</tbody>
</table>

**Performance Tip:** Keep the following in mind when configuring the ADS.

- Set the latency threshold to more than 1000 to avoid frequent component refreshing.
- Set the keep-alive interval and reconnect wait time to be less than the browser's keep-alive timeout.
- Set the max reconnect time to be less than your web server’s session timeout.

Performance Tip: Keep the following in mind when configuring the ADS.

- Set the latency threshold to more than 1000 to avoid frequent component refreshing.
- Set the keep-alive interval and reconnect wait time to be less than the browser's keep-alive timeout.
- Set the max reconnect time to be less than your web server’s session timeout.

Example 47–1 shows a sample configuration that has content pushed to the client.
Configuring the Active Data Service

<ads:adf-activedata-config xmlns="http://xmlns.oracle.com/adf/activedata/config">
  <transport>streaming</transport>
  <latency-threshold>5000</latency-threshold>
  <keep-alive-interval>10000</keep-alive-interval>
  <max-reconnect-attempt-time>90000</max-reconnect-attempt-time>
  <reconnect-wait-time>8000</reconnect-wait-time>
</ads:adf-activedata-config>
</adf-config>

3. Synchronize the clocks on the data server and on the application server. If these are not synchronized, then events may appear to ADS to have occurred in the future.

47.2.2 What You May Need to Know About Configuring an ADS Transport Mode

ADS can use one of three transport modes to deliver active data to the component: streaming, polling, or long polling.

When you configure ADS to use the streaming mode, data is pushed to the client whenever a change event is raised by the data. On the client side, after the push channel is established, if there is no activity within the time of the value for the latency-threshold element plus the keep-alive-interval, an establish-channel-request will be sent out repeatedly based on the value of the reconnect-wait-time element, until the amount of time passed reaches the value of the max-reconnect-attempt-time element. After that, the connection will be considered disconnected. For example, given the values in Example 47–1, if there is no activity in 15,000 milliseconds, an establish channel request will be sent out every 8,000 milliseconds for up to 90,000 milliseconds. After that, the connection will be considered disconnected.

On the server side, the server disconnects the push channel and starts a timer to clean up with a cleanup-delay-time when there is an empty active data message or when it fails to send out an active data message. The cleanup-delay-time is calculated as max-reconnect-attempt-time + 30 * 1000 ms. Its default value is 30 minutes.

When you configure ADS to use the polling mode, on the client side the polling request is scheduled to be sent out repeatedly after the value of the polling-interval element has been reached. If no response is received after the value of the max-reconnect-attempt-time has elapsed, the connection is treated as disconnected and no more requests will be sent. After receiving a polling response, if the time the response has taken is greater than the polling-interval element, the service sends the next request out right away. If it is less, the next request will be sent as scheduled.

For the server side, the session ends after the polling response is returned. At that point, a timer with a cleanup-delay-time is set up to trigger cleanup. If a new request comes in before the timer fires, the old timer is canceled, and new timer is created.

When you configure ADS to use the long polling mode, requests are made as they are in streaming mode; however, as soon as the connection is treated as disconnected, a new connection is initiated. The result is a significant reduction in latency.

Table 47–2 compares the three different modes.
### Table 47–2 Comparison of Streaming, Polling, and Long-Polling Modes

<table>
<thead>
<tr>
<th></th>
<th>Streaming</th>
<th>Polling</th>
<th>Long-Polling</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Latency</strong></td>
<td>Very good.</td>
<td>Poor, depending on the polling interval.</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Directly after an event occurs on the server side, a partial response is sent to the client. If there is another event, immediately, it is also sent as a partial response. There is almost no latency with this approach.</td>
<td>If the polling interval is short (for example, 0.5 seconds), it will slow down the network because the connections are repeatedly opened. It is also expensive on the client- and server-side resources.</td>
<td>Good. However, when there is a new event immediately after a response has been closed, there is some latency until the new data appears on the client side. On average, this is not a problem.</td>
</tr>
<tr>
<td><strong>HTTP Proxy</strong></td>
<td>Poor. For some older servers, because the response is never released, when a proxy is sitting between client and server, it is possible that the proxy will buffer responses. This is an unfortunate optimization that prevents real-time data from flowing into the browser. Long polling should be used if a proxy is used.</td>
<td>Good. Good.</td>
<td>Good. Good.</td>
</tr>
<tr>
<td><strong>Number of live connections</strong></td>
<td>Poor. Many concurrent connections, as the stream is always live.</td>
<td>Good. Connections are live only during the actual poll. Note however that if there is a high polling rate then the number of concurrent connections will also be high.</td>
<td>Poor. Many concurrent connections, as the stream is almost always live.</td>
</tr>
<tr>
<td><strong>Communication channel</strong></td>
<td>HTTP GET This can result in the display of a &quot;busy&quot; cursor or the animation of a browser’s &quot;throbber&quot; icon.</td>
<td>XMLHttpRequest (XHR)</td>
<td>XMLHttpRequest (XHR)</td>
</tr>
</tbody>
</table>

**47.2.3 How to Configure Session Timeout for Active Data Service**

By default, applications that you configure to use ADS will not time out. In polling mode, the client periodically sends polling request to server. In long polling mode, the client sends a new polling request immediately after a polling request is returned from the server. In streaming mode, the server holds the GET request response and will indefinitely write active data to it. Due to the behavior of each data transport mode, ADS will maintain the application session active whether or not the user interacts with the application.
To prevent this situation of maintaining an active session indefinitely due to ADS, the web.xml configuration file contains the oracle.adf.view.rich.poll.TIMEOUT context-parameter, which specifies how long ADS should run before it times out from user inactivity. The ADS client is considered eligible to time out if there is no keyboard or mouse activity. The default timeout period is set at ten minutes. So if the user remains inactive for ten minutes, that is, does not use the keyboard or mouse, then ADS will stop polling or will abort its connection with server, and from that point on, the application participates in the standard server-side session timeout. For example, if the server-side session timeout is 65 minutes, and the polling timeout parameter is set to 15 minutes, then it is expected that the session should expire when the user is inactive for more than 80 minutes.

You can override this timeout setting for a specific web page using the ADF Faces poll component timeout attribute. The poll component allows you to deliver a heartbeat to the server to prevent users from being timed out of their session for specific pages. For more information about the oracle.adf.view.rich.poll.TIMEOUT context-parameter and individual web pages, see the "Using Polling Events to Update Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

**Before you begin:**

It may be helpful to have an understanding of the ADS configuration choices. For more information, see Section 47.2, "Configuring the Active Data Service."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 47.1, "About the Active Data Service."

To configure the Active Data Service to timeout after session becomes inactive:

1. In the Applications window, in the user interface project, expand the Web Content and WEB-INF nodes, and then double-click web.xml.

2. In the overview editor for the web.xml file, click the Application navigation tab and in the Context Initialization Parameters section, click the Create icon to add the polling timeout parameter as follows:

   - **Name**: Enter the context parameter oracle.adf.view.rich.poll.TIMEOUT.
   - **Value**: Enter the amount of time in milliseconds after which all pages configured to use active data will time out and ADS will stop. To disable ADF time out due to user inactivity, enter -1. The default value for ADS to timeout is 600000 milliseconds (ten minutes).

### 47.3 Configuring Components to Use the Active Data Service

How you configure components to use ADS depends on whether or not you must use the Active Data proxy. If your application uses a data store that publishes events when data is changed, and your business services react to those events (for example, if your application uses BAM), then you do not need to use the Active Data proxy.

If your business services do not react to those events (for example, if your application uses ADF Business Components), then you must use the Active Data proxy and follow different procedures for configuring your components.
47.3.1 How to Configure Components to Use the Active Data Service Without the Active Data Proxy

To use ADS without the proxy, you need to set a value on the binding element in the corresponding page definition file.

Before you begin:
It may be helpful to have an understanding of the ADS configuration choices. For more information, see Section 47.3, "Configuring Components to Use the Active Data Service."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 47.1, "About the Active Data Service."

To configure a component to display active data without the Active Data proxy:

1. From the Data Controls panel, drag and drop a collection onto a JSF page, and from the context menu, choose the desired component.

2. If you are dropping the collection as an ADF bound tree or tree table, you need to ensure the following:
   - That the binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
   - That the binding rule contains a single attribute.
   - That the table does not use filtering.
   - That the tree component’s nodeStamp facet contains a single outputText tag and contains no other tags, as described in Section 47.3.3, "What You May Need to Know About Displaying Active Data in ADF Trees."

3. From the Application window, right-click the page and choose Go to Page Definition.
   The editor for the page definition file opens for the selected page.

4. In the Structure window, select the node that represents the attribute binding for the component.

5. In the Properties window, expand the Advanced section, and select Push from the ChangeEventPolicy dropdown menu.

Note: If your business service requires the use of the Active Data proxy, then you can only use the following components with active data:

- table
- tree
- treeTable
- ADF Data Visualization gauge, graph, mapPointTheme, pivotTable, pivotFilterBar, sunburst, and treemap components
47.3.2 How to Configure Components to Use the Active Data Service with the Active Data Proxy

To use ADS with the proxy, you need bind the value of your component to decorator class that will use the proxy. For more information about this class, see Section 47.4, "Using the Active Data Proxy" to set a value on the binding element in the corresponding page definition file.

Before you begin:
It may be helpful to have an understanding of the ADS configuration choices. For more information, see Section 47.3, “Configuring Components to Use the Active Data Service.”

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 47.1, "About the Active Data Service.”

To configure a component to display active data with the Active Data proxy:
1. From the Data Controls panel, drag and drop a collection onto a JSF page, and from the context menu, choose the desired component.

2. If you are using an ADF bound tree or tree table, you need to ensure the following:
   - That the binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
   - That the binding rule contains a single attribute.
   - That the table does not use filtering.
   - That the tree component’s nodeStamp facet contains a single outputText tag and contains no other tags, as described in Section 47.3.3, "What You May Need to Know About Displaying Active Data in ADF Trees.”

3. From the Application window, right-click the page and choose Go to Page Definition.

   The editor for the page definition file opens for the selected page.

4. In the Structure window, select the node that represents the attribute binding for the component.

5. In the Properties window, change the value attribute to be bound to a decorator class that you will create for use with the proxy.

   For more information, see Section 47.4, "Using the Active Data Proxy."

47.3.3 What You May Need to Know About Displaying Active Data in ADF Trees

When you create an ADF Faces tree (or tree table) component, you configure a nodeStamp facet, which is a holder for the component used to display the data for each node of the tree. Each node is rendered (stamped) once, repeatedly for all nodes.

Because of this stamping behavior, only certain types of components are supported as children inside an ADF Faces tree component. When the tree component is not bound
to an active data source, all components that have no behavior are supported. However, when you configure the tree to use ADS, only the outputText component is supported inside of the nodeStamp facet, as shown in Example 47–2. The nodeStamp facet must not contain any other tags. So, for example, active data will not work if you add panelGroupLayout tags to the nodeStamp facets of a tree configured to use ADS.

Example 47–2 Tree Configured to Use ADS Must Contain outputText Component

```xml
<f:facet name="nodeStamp">
  <af:outputText value="#{row.str2}"/>
</f:facet>
```

47.3.4 What Happens at Runtime: How Components Render When Bound to Active Data

After you configure your application and the component for ADS, whenever the data changes on the server, the component is notified and rerenders with only the changed data. In contrast, a component not configured for either active data or automatic PPR will need to be explicitly refreshed after a data change occurs. The explicit refresh will refetch all data that is visible on the client, including data that has not changed. Consequently, this will force the entire component to rerender. Additionally, when the component is bound to an active data source (with active data policy "Push"), the component rerenders with the new value highlighted.

47.3.5 What You May Need to Know About Running ADS in a Google Chrome Browser

When the Fusion web application runs in the Google Chrome web browser and a user presses Ctrl+N (or Ctrl+T) to open a new window (or tab) and then copies the URL from the original window into the new window, active data in the original window will stop streaming. According to the Google Chrome process model, the new browser window will be created in a separate process and both windows will share the same HTTP session. However, because browser windows that are created in two separate processes cannot communicate with each other, ADS will become out of sync between the client and server and will stop streaming. As a workaround, to allow active data in multiple Google Chrome windows, before copying the URL from the original window into the new window users must press Ctrl-Shift-N to open the browser window in incognito mode (private browsing). Because Ctrl-Shift-N opens the window in a separate process and a separate HTTP session, ADS will not attempt to synchronize between the windows and streaming will be unaffected.

47.4 Using the Active Data Proxy

You use the active data proxy when your business services do not react to data events. If you want your components to update based on events passed into ADF Business Components, then you need to use the Active Data Proxy.

Tip: If your application uses BAM for the business service, then you do not need to use the Active Data Proxy.
Using the Active Data Proxy

47.4.1 How to Use the Active Data Proxy

You will create a Java class that subclasses one of the following decorator classes:

- ActiveCollectionModelDecorator class
- ActiveDataModelDecorator class (for use with graphs)
- ActiveGeoMapDataModelDecorator class
- ActiveGaugeDataModelDecorator class

These classes are wrapper classes that delegate the active data functionality to a default implementation of ActiveDataModel. The ActiveDataModel class listens for data change events and interacts with the Event Manager. Specifically, it does the following:

- Starts and stops the active data and the ActiveDataModel object, and registers and unregisters listeners to the data source.
- Wraps the JSF model interface. For example, the ActiveCollectionModelDecorator class wraps the CollectionModel class.
- Generates active data events based on data change events from the data source.
- Manages listeners from the Event Manager and pushes active data events to the Event Manager.

You need to implement methods on this Java class that registers itself as the listener of the active data source and gets the model to which the data is being sent.

---

**Note:** If your business service requires the use of the Active Data Proxy, then you can only use the following components with active data:

- table
- tree
- treeTable
- ADF Data Visualization gauge, graph, mapPointTheme, pivotTable, pivotFilterBar, sunburst, and treemap components

---

**Note:** The Active Data framework does not support complicated business logic or transformations that require the ADF runtime context, such as a user profile or security. For example, the framework cannot convert an ADF context locale-dependent value and return a locale-specific value.

As an example of complicated business logic, say you have logic that allows a user to move an order from open status to pending. This change results in an update event, which should cause the order to be removed from a data object called “Open Orders.” The framework cannot handle this event type transformation based on business logic. Instead, you need to have your data source handle this before publishing the data change event.
Before you begin:

It may be helpful to have an understanding of the active data proxy. For more information, see Section 47.4, "Using the Active Data Proxy."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see Section 47.1, "About the Active Data Service."

You will need to complete this task:

Implement the logic to fire the active data events asynchronously from the data source. For example, this logic might be a business process that updates the database, or a JMS client that gets notified from JMS.

To use the active data service:

1. Create a Java class that extends the decorator class appropriate for your component. Example 47–3 shows a class created for a table.

   **Example 47–3 Extend the Decorator Class**

   ```java
   package view;

   import oracle.adf.view.rich.model.ActiveCollectionModelDecorator;
   import oracle.adf.view.rich.activedata.ActiveDataEventUtil;
   import oracle.adf.view.rich.activedata.JboActiveDataEventUtil;

   /**
   * This code wraps the existing collection model in the page and implements the
   * ActiveDataModel interface to enable ADS for the existing page.
   */
   public class DeptModel
     extends ActiveCollectionModelDecorator
     {
     
   }

   2. Implement the method that returns the model. Example 47–4 shows an implementation of the `getCollectionModel()` method that relies on expression language (EL) to avoid needing to typecast to an internal class. The method returns the `DepartmentsView1` collection from the binding container.

   **Example 47–4 Return the Model**

   ```java
   public CollectionModel getCollectionModel()
   {
      if (_model == null)
      {
         FacesContext fc = FacesContext.getCurrentInstance();
         Application app = fc.getApplication();
         ExpressionFactory elFactory = app.getExpressionFactory();
         ELContext el = fc.getELContext();

         // This is EL to avoid typecasting to an Internal class.
         ValueExpression ve = elFactory.createValueExpression(el,
                     "#{bindings.DepartmentsView1.collectionModel}", Object.class);

         // Now GET the collectionModel
         _model = (CollectionModel)ve.getValue(el);
      }
      return _model;
   }
   ```
3. Create an inner class that is your own implementation of an ActiveDataModel class, which the decorator can use to start and stop the active data and connect and disconnect from the data source. This class should also use the changeCount API to maintain data read consistency, as shown in Example 47–5. For more information, see Section 47.5, "What You May Need to Know About Maintaining Read Consistency."

Example 47–5 Connect to the Data Source

```java
public class MyActiveDataModel extends BaseActiveDataModel {
    protected void startActiveData(Collection<Object> rowKeys,
                                    int startChangeCount)
    {
        _listenerCount.incrementAndGet();
        if (_listenerCount.get() == 1)
        {
            System.out.println("start up");
            Runnable dataChanger = new Runnable()
            {
                public void run()
                {
                    System.out.println("MyThread starting.");
                    try
                    {
                        Thread.sleep(2000);
                        System.out.println("thread running");
                        triggerDataChange(MyActiveDataModel.this);
                    }
                    catch (Exception exc)
                    {
                        System.out.println("MyThread exceptioned out.");
                    }
                    System.out.println("MyThread terminating.");
                }
            };
            Thread newThrd = new Thread(dataChanger);
            newThrd.start();
        }
    }

    protected void stopActiveData(Collection<Object> rowKeys)
    {
        _listenerCount.decrementAndGet();
        if (_listenerCount.get() == 0)
        {
            System.out.println("tear down");
        }
    }

    public int getCurrentChangeCount()
    {
        return _currEventId.get();
    }

    public void bumpChangeCount()
    {
        _currEventId.incrementAndGet();
    }
```
4. Implement the method that will return the `ActiveDataModel` class, as shown in Example 47–6.

Example 47–6  Return the `ActiveDataModel`

```java
public ActiveDataModel getActiveDataModel()
{
    return _activeDataModel;
}
```

5. Create a method that creates application-specific events that can be used to insert or update data on the active model.

   Example 47–7 shows the `triggerDataChange()` method, which uses the active model (an instance of `MyActiveDataModel`) to create `ActiveDataUpdateEvent` objects to insert and update data. You will need to import `oracle.adf.view.rich.activedata.ActiveDataEventUtil` and `oracle.adf.view.rich.activedata.JboActiveDataEventUtil` to implement this method.

Example 47–7  Create Event Objects to Update Model

```java
public void triggerDataChange(MyActiveDataModel l)
throws Exception
{

    // do an update on dept 1
    l.bumpChangeCount();
    ActiveDataUpdateEvent event =
    ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.UPDATE,
    l.getCurrentChangeCount(),
    JboActiveDataEventUtil.convertKeyPath(new Key
    { new Object[]{ new Long(1), new Integer(0) } }),
    null,
    new String[] { "name" },
    new Object[] { "Name Pushed" });

    l.dataChanged(event);

    try
    {
        Thread.sleep(2000);
    }
    catch (InterruptedException ie)
    {
        ie.printStackTrace();
    }
```
// insert dept 99

1.bumpChangeCount();
  event =
      ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.INSERT_AFTER,
          1.getCurrentChangeCount(),
          JboActiveDataEventUtil.convertKeyPath(new Key
              { new Long(99), new Integer(0) })),
          JboActiveDataEventUtil.convertKeyPath(null),
          new String[] { "addr1", "name" },
          new Object[] { "Addr Inserted", "Name Inserted" });

  l.dataChanged(event);

try
{
    Thread.sleep(2000);
}
catch (InterruptedException ie)
{
    ie.printStackTrace();
}

// delete dept 10

1.bumpChangeCount();
  event =
      ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REMOVE,
          1.getCurrentChangeCount(),
          JboActiveDataEventUtil.convertKeyPath(new Key
              { new Long(9), new Integer(0) })),
          null, null, null);

  l.dataChanged(event);

try
{
    Thread.sleep(2000);
}
catch (InterruptedException ie)
{
    ie.printStackTrace();
}

// refresh the entire table

1.bumpChangeCount();
  event =
      ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REFRESH,
          1.getCurrentChangeCount(),
          null, null, null, null);

  l.dataChanged(event);
}

private MyActiveDataModel _activeDataModel = new MyActiveDataModel();
private CollectionModel _model = null;
}

47.5 What You May Need to Know About Maintaining Read Consistency

Using active data means that your component has two sources of data: the active data feed and the standard data fetch. Because of this, you must make sure your application maintains read consistency.

For example, say your page contains a table and that table has active data enabled. The table has two methods of delivery from which it updates its data: normal table data fetch and active data push. Say the back end data changes from foo to bar to fred. For each of these changes, an active data event is fired. If the table is refreshed before those events hit the browser, the table will display fred because standard data fetch will always get the latest data. But then, because the active data event might take longer, some time after the refresh the data change event would cause foo to arrive at the browser, and so the table would update to display foo instead of fred for a period of time. Therefore, you must implement a way to maintain the read consistency.

To achieve read consistency, the ActiveDataModel has the concept of a change count, which effectively timestamps the data. Both data fetch and active data push need to maintain this changeCount object by monotonically increasing the count, so that if any data returned has a lower changeCount, the active data event can throw it away. Example 47–7 shows how you can use your implementation of the ActiveDataModel class to maintain read consistency.

47.6 Using the Active Data with a Scalar Model

ADF components that display collection-based data can be configured to work with ADS and require no extra setup in the view layer. However, imagine that your JSPX page uses an activeOutputText component to display new counts based on a Java timer. In this case, you will replace the model layer with scalar or "flat" data that you display from a Java Bean.

47.6.1 How to Use the Active Data with a Scalar Model

To implement the scalar model, follow these basic steps (as illustrated in the Example 47–8):

1. Use the ActiveModelContext API to register the bean with ADS so the bean (a scalar model) imitates an actual model.

2. Implement a custom mechanism to push the data to the view layer.

Example 47–8 Implement the Scalar Model in the Java Bean

```java
package oracle.adfdemo.view.feature.rich;

import java.util.Collection;
import java.util.Timer;
import java.util.TimerTask;
import java.util.concurrent.atomic.AtomicInteger;
import oracle.adf.view.rich.activedata.ActiveModelContext;
import oracle.adf.view.rich.activedata.BaseActiveDataModel;
```
import oracle.adf.view.rich.activedata.ActiveDataEventUtil;
import oracle.adf.view.rich.event.ActiveDataEntry;
import oracle.adf.view.rich.event.ActiveDataUpdateEvent;

public class CounterBean extends BaseActiveDataModel
// Example using a Java timer to create new counts
{
    public CounterBean()
        // 1. Use the ActiveModelContext API to register the scalar model key path for
        //    the "state" attribute.
        {
            ActiveModelContext context = ActiveModelContext.getActiveModelContext();
            Object[] keyPath = new String[0];
            context.addActiveModelInfo(this, keyPath, "state");

            timer.schedule(new UpdateTask(), 2000, 2000);
        }

    public String getState()
    {
        return String.valueOf(counter);
    }

    // Not needed. We do not need to connect to a (real) active data source.
    protected void startActiveData(Collection<Object> rowKeys, int startChangeCount) {}

    // Not needed. We do not need to connect to a (real) active data source.
    protected void stopActiveData(Collection<Object> rowKeys) {}

    public int getCurrentChangeCount()
    {
        return counter.get();
    }

    protected class UpdateTask extends TimerTask
    {
        public void run()
        {
            counter.incrementAndGet();

            // 2. Use ActiveDataEventUtil to create an event object to update the model.
            ActiveDataUpdateEvent event =
                ActiveDataEventUtil.buildActiveDataUpdateEvent(
                    ActiveDataEntry.ChangeType.UPDATE,
                    counter.get(),
                    new String[0],
                    null,
                    new String[] { "state" },
                    new Object[] { counter.get() });
            fireActiveDataUpdate(event);
        }
    }

    private static final Timer timer = new Timer();
    private final AtomicInteger counter = new AtomicInteger(0);
}
After you create the bean, register the bean as a managed bean in the faces-config.xml file (as illustrated for counterBean in Example 47–9):

**Example 47–9  Register the Managed Bean**

```xml
...<managed-bean>
  <managed-bean-name>counterBean</managed-bean-name>
  <managed-bean-class>
    oracle.adfdemo.view.feature.rich.CounterBean
  </managed-bean-class>
  <managed-bean-scope>session</managed-bean-scope>
</managed-bean>
```

Once the bean is registered, you can use ADS to stream the data to the view layer. Your ADF Faces component use expression language to receive the pushed data (as illustrated by the activeOutputText component value attribute in Example 47–10):

**Example 47–10  Display the Active Data**

```xml
...<f:view>
  <f:attribute name="tagName" value="Active Data Visual Design"/>
  <f:attribute name="demoKind" value="visualDesign"/>

```
Deploying Fusion Web Applications

This chapter describes how to deploy Oracle ADF applications to a target application server. It describes how to create deployment profiles, how to create deployment descriptors, and how to load ADF runtime libraries. It includes instructions for running an application in the Integrated WebLogic Server as well as deploying to a standalone Oracle WebLogic Server.

This chapter includes the following sections:

- Section 48.1, "About Deploying Fusion Web Applications"
- Section 48.2, "Running a Fusion Web Application in Integrated WebLogic Server"
- Section 48.3, "Preparing the Application"
- Section 48.4, "Deploying the Application"
- Section 48.5, "Postdeployment Configuration"
- Section 48.6, "Testing the Application and Verifying Deployment"

48.1 About Deploying Fusion Web Applications

Deployment is the process of packaging application files as an archive file and transferring that file to a target application server. You can use JDeveloper to deploy Oracle ADF applications directly to the application server (such as Oracle WebLogic Server), or indirectly to an archive file as the deployment target, and then install this archive file to the target server. For application development, you can also use JDeveloper to run an application in Integrated WebLogic Server. JDeveloper supports deploying to server clusters, but you cannot use JDeveloper to deploy to individual Managed Servers that are members of a cluster.

Figure 48-1 shows the flow diagram that describes the overall deployment process. Note that preparing the target application server for deployment by installing the ADF runtime is described in Administering Oracle ADF Applications.
ADF Java EE applications are based on standardized, modular components and can be deployed to the following application servers:

- **Oracle WebLogic Server**

  Oracle WebLogic Server provides a complete set of services for those modules and handles many details of application behavior automatically, without requiring programming. For information about which versions of Oracle WebLogic Server are compatible with JDeveloper, see the certification information website at http://www.oracle.com/technetwork/developer-tools/jdev/documentation/index.html.

Deploying a Fusion web application is slightly different from deploying a standard Java EE application. JSF applications that contain ADF Faces components have a few additional deployment requirements:

---

**Note:** Normally, you use JDeveloper to deploy applications for development and testing purposes. If you are deploying Oracle ADF applications for production purposes, you can use Enterprise Manager or scripts to deploy to production-level application servers.

For more information about deployment to later-stage testing or production environments, see *Administering Oracle ADF Applications*.
ADF Faces requires Sun’s JSF Reference Implementation 1.2 and MyFaces 1.0.8 (or later).

You can use JDeveloper to:

- Run applications in Integrated WebLogic Server
  You can run and debug applications using Integrated WebLogic Server and then deploy to standalone WebLogic Server.

- Deploy directly to the standalone application server
  You can deploy applications directly to the standalone application server by creating a connection to the server and choosing the name of that server as the deployment target.

- Deploy to an archive file
  You can deploy applications indirectly by choosing an EAR file as the deployment target. The archive file can subsequently be installed on a target application server.

The Summit sample application for Oracle ADF demonstrates the use of the Fusion web application technology stack to create transaction-based web applications. You can run the Summit sample application in JDeveloper using Integrated WebLogic Server. For more information about the Summit ADF sample applications, see Chapter 2, "Introduction to the ADF Sample Application."

48.1.1 Developing Applications with Integrated WebLogic Server

If you are developing an application in JDeveloper and you want to run the application in Integrated WebLogic Server, you do not need to perform the tasks required for deploying directly to Oracle WebLogic Server or to an archive file. JDeveloper has a default connection to Integrated WebLogic Server and does not require any deployment profiles or descriptors. Integrated WebLogic Server has a preconfigured domain that includes the ADF libraries, as well as the -Djps.app.credential.overwrite.allowed=true setting, that are required to run Oracle ADF applications. You can run an application by choosing Run from the JDeveloper main menu.

You debug the application using the features described in Chapter 42, "Testing and Debugging ADF Components."

48.1.2 Developing Applications to Deploy to Standalone Application Server

Typically, for deployment to standalone application servers, you test and develop your application by running it in Integrated WebLogic Server. You can then test the application further by deploying it to standalone Oracle WebLogic Server in development mode to more closely simulate the production environment.

In general, you use JDeveloper to prepare the application or project for deployment by:

- Creating a connection to the target application server
- Creating deployment profiles (if necessary)
- Creating deployment descriptors (if necessary, and that are specific to the target application server)
- Updating application.xml and web.xml to be compatible with the application server (if required)
Enabling the application for Real User Experience Insight (RUEI) in `web.xml` (if desired)

Migrating application level security policy data to a domain-level security policy store

Configuring the Oracle Single Sign-On (Oracle SSO) service and properties in the domain `jps-config.xml` file when you intend the web application to run using Oracle SSO

You must already have an installed application server. For Oracle WebLogic Server, you can use the Oracle 11g Installer or the Oracle Fusion Middleware 11g Application Developer Installer to install one. For other application servers, follow the instructions in the applications server documentation to obtain and install the server.

You must also prepare the application server for Fusion web application deployment. For more information, see the "Preparing the Standalone Application Server for Deployment" section of *Administering Oracle ADF Applications*.

Installing the ADF runtime into the application server installation:

- For WebLogic Server
  - If you installed Oracle WebLogic Server together with JDeveloper using the Oracle 11g Installer for JDeveloper, the ADF runtime should already be installed.
  - If the ADF runtime is not installed and you want to use Oracle Enterprise Manager to manage standalone ADF applications (which are applications without Oracle SOA Suite or Oracle WebCenter Portal components), use the Oracle Fusion Middleware 11g Application Developer Installer. This installer will install the necessary Oracle Enterprise Manager components into the Oracle WebLogic installation.
  - If the ADF runtime is not installed and you do not need to install Enterprise Manager, use the Oracle 11g Installer for JDeveloper.

Extending Oracle WebLogic Server domains to be ADF-compatible using the ADF runtime

For WebLogic, setting the Oracle WebLogic Server credential store overwrite setting as required (`-Djps.app.credential.overwrite.allowed=true` setting).

Creating a global JDBC data source for applications that require a connection to a data source

After the application and application server have been prepared, you can:

Use JDeveloper to:

- Directly deploy to the application server using the deployment profile and the application server connection.
- Deploy to an EAR file using the deployment profile. For Oracle ADF applications, WAR and MAR files can be deployed only as part of an EAR file.

Use Enterprise Manager, scripts, or the application server’s administration tools to deploy the EAR file created in JDeveloper. For more information, see *Administering Oracle ADF Applications*. 
48.2 Running a Fusion Web Application in Integrated WebLogic Server

JDeveloper is installed with Integrated WebLogic Server which you can use to test and develop your application. For most development purposes, Integrated WebLogic Server will suffice. When your application is ready to be tested, you can select the run target and then choose the Run command from the main menu.

---

**Note:** The first time you run an application in Integrated WebLogic Server, the Configure Default Domain dialog appears for you to define an administrative password for the new domain.

---

When you run the application target, JDeveloper detects the type of Java EE module to deploy based on artifacts in the projects and workspace. JDeveloper then creates an in-memory deployment profile for deploying the application to Integrated WebLogic Server. JDeveloper copies project and application workspace files to an "exploded EAR" directory structure. This file structure closely resembles the EAR file structure that you would have if you were to deploy the application to an EAR file. JDeveloper then follows the standard deployment procedures to register and deploy the "exploded EAR" files into Integrated WebLogic Server. The "exploded EAR" strategy reduces the performance overhead of packaging and unpackaging an actual EAR file.

In summary, when you select the run target and run the application in Integrated WebLogic Server, JDeveloper:

- Detects the type of Java EE module to deploy based on the artifacts in the project and application
- Creates a deployment profile in memory
- Copies project and application files into a working directory with a file structure that would simulate the "exploded EAR" file of the application.
- Performs the deployment tasks to register and deploy the simulated EAR into Integrated WebLogic Server
- Automatically migrates identities, credentials, and policies

Later on, if you plan to deploy the application to a standalone WebLogic Server instance, you will need to migrate this security information. For more information, see Section 48.3.4, "How to Deploy Applications with ADF Security Enabled."

---

**Note:** JDeveloper ignores the deployment profiles that were created for the application when you run the application in Integrated WebLogic Server.

---

The application will run in the base domain in Integrated WebLogic Server. This base domain has the same configuration as a base domain in a standalone WebLogic Server instance. In other words, this base domain will be the same as if you had used the Oracle Fusion Middleware Configuration Wizard to create a base domain with the default options in a standalone WebLogic Server instance.

JDeveloper will extend this base domain with the necessary domain extension templates, based on the JDeveloper technology extensions. For example, if you have installed JDeveloper Studio, JDeveloper will automatically configure the Integrated WebLogic Server environment with the ADF runtime template (JRF Fusion Middleware runtime domain extension template).
You can explicitly create a default domain for Integrated WebLogic Server. You can use the default domains to run and test your applications. Open the Application Servers window, right-click **IntegratedWebLogicServer** and choose **Create Default Domain**.

### 48.2.1 How to Run an Application in Integrated WebLogic Server

You can test an application by running it in Integrated WebLogic Server. You can also set breakpoints and then run the application within the ADF Declarative Debugger.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you run an application in the Integrated WebLogic Server. For more information, see Section 48.2, "Running a Fusion Web Application in Integrated WebLogic Server."

To run an application in Integrated WebLogic Server:

1. In the Applications window, select the project, unbounded task flow, JSF page, or file as the run target.
2. Right-click the run target and choose Run or Debug.

   The Configure Default Domain dialog appears for the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

### 48.2.2 How to Run an Application with Metadata in Integrated WebLogic Server

When an application is running in Integrated WebLogic Server, the MAR (Metadata Archive) profile itself will not be deployed to a repository, but a simulated MDS repository will be configured for the application that reflects the metadata information contained in the MAR. This metadata information is simulated, and the application runs based on this location in source control.

Any customizations or documents created by the application that are not configured to be stored in other MDS repositories are written to this simulated MDS repository directory. For example, if you customize an object, the customization is written to the simulated MDS repository. If you execute code that creates a new metadata object, then this new metadata object is also written to the same location in the simulated MDS repository. You can keep the default location for this directory (`ORACLE_HOME\jdeveloper\systemXX.XX\o.mds.dt\adrs\Application\AutoGeneratedMar\mds_adrs_writedir`), or you can set it to a different directory. You also have the option to preserve this directory across different application runs, or to delete this directory before each application run.

If your workspace has different working sets, only the metadata from the projects defined in the working set and their dependent projects will be included in the MAR.

You can view and change a project’s dependencies by right-clicking the project in the Applications window, choosing **Project Properties**, and then selecting **Dependencies**. For instance, an application may have several projects but `workingsetA` is defined to be `viewcontroller2` and `viewcontroller5`, and `viewcontroller5` has a dependency on `modelproject1`. When you run or debug `workingsetA`, only the metadata for `viewcontroller2`, `viewcontroller5`, and `modelproject1` will be included in the MAR for deployment.
Before you begin:

It may be helpful to have an understanding of the options that are available to you when you run an application with metadata in the Integrated WebLogic Server. For more information, see Section 48.2, "Running a Fusion Web Application in Integrated WebLogic Server."

You will need to complete this task:

- Created a MAR profile, either manually or automatically by JDeveloper.

To deploy the MAR profile to Integrated WebLogic Server:

1. In the Applications window, right-click the application and choose Application Properties.

2. In the Application Properties dialog, expand Run and choose MDS.

3. On the Run MDS page:
   - Select the MAR profile from the MAR Profile dropdown list
   - Enter a directory path in Override Location if you want to customize the location of the simulated MDS repository.
   - Select the Directory Content option. You can chose to preserve the customizations across application runs or delete customizations before each run.

Select the MAR profile from the MAR Profile dropdown list. Figure 48–2 shows Demometadata1 selected as the MAR profile.

Figure 48–2 Setting the Run MDS Options
48.3 Preparing the Application

Before you deploy a Fusion web application to a standalone application server, you must perform prerequisite tasks within JDeveloper to prepare the application for deployment.

Figure 48–3 show the process flow to prepare the application for deployment. After the application has been prepared and the application server has been prepared as described in *Administering Oracle ADF Applications*, you can proceed to deploy the application as described in Section 48.4, ”Deploying the Application.”

![Preparing the Application for Deployment Flow Diagram](image)

48.3.1 How to Create a Connection to the Target Application Server

You can deploy applications to the application server via JDeveloper application server connections.

If your application involves customization using MDS, you should register your MDS repository with the application server:

- WebLogic: register the MDS into the WebLogic Domain
  
  For more information about registering MDS in WebLogic, see *Administering Oracle Fusion Middleware*.

  For more information about registering MDS, see *Administering Oracle Fusion Middleware*. 

48-8 Developing Fusion Web Applications with Oracle Application Development Framework
Before you begin:

It may be helpful to have an understanding of the options that are available to you when you prepare an application for deployment. For more information, see Section 48.3, "Preparing the Application."

You will need to complete this task:

- Installed an application server.

To create a connection to an application server:

1. Launch the Application Server Connection wizard.
   
   You can:
   
   - In the Applications Servers window, right-click Application Servers and choose New Application Server.
   - In the New Gallery, expand General, select Connections and then Application Server Connection, and click OK.
   - In the Resources window, choose New > IDE Connections > Application Server.

2. In the Create Application Server Connection dialog, on the Usage page, select Standalone Server and click Next.

3. On the Name and Type page, enter a connection name.

4. In the Connection Type dropdown list, choose:
   
   - WebLogic to create a connection to Oracle WebLogic Server

5. Click Next.

6. On the Authentication page, enter a user name and password for the administrative user authorized to access the application server.

7. Click Next.

8. On the Configuration page, enter the information for your server:

   For WebLogic:
   
   - The Oracle WebLogic host name is the name of the WebLogic Server instance containing the TCP/IP DNS where your application (.jar,.war,.ear) will be deployed.
   - In the Port field, enter a port number for the WebLogic Server instance on which your application (.jar,.war,.ear) will be deployed. If you don’t specify a port, the port number defaults to 7001.
   - In the SSL Port field, enter an SSL port number for the WebLogic Server instance on which your application (.jar,.war,.ear) will be deployed. Specifying an SSL port is optional. It is required only if you want to ensure a secure connection for deployment. If you don’t specify an SSL port, the port number defaults to 7002.
   - Select Always Use SSL to connect to the WebLogic Server instance using the SSL port.
   - Optionally enter a WebLogic Domain only if WebLogic Server is configured to distinguish non-administrative server nodes by name.

9. Click Next.
10. Click Next.

11. If the SSL Signer Exchange Prompt dialog appears, click Y.

12. On the Test page, click Test Connection to test the connection.

JDeveloper performs several types of connections tests. The JSR-88 test must pass for the application to be deployable. If the test fails, return to the previous pages of the wizard to fix the configuration.

13. Click Finish.

### 48.3.2 How to Create Deployment Profiles

A deployment profile defines the way the application is packaged into the archive that will be deployed to the target environment. The deployment profile:

- Specifies the format and contents of the archive file that will be created
- Lists the source files, deployment descriptors, and other auxiliary files that will be packaged
- Describes the type and name of the archive file to be created
- Highlights dependency information, platform-specific instructions, and other information

You need a WAR deployment profile for each web user interface project that you want to deploy in your application. If you want to package seeded customizations or place base metadata in the MDS repository, you need an application level metadata archive (MAR) deployment profile as well. For more information about seeded customizations, see Chapter 45, "Customizing Applications with MDS." If the application has customization classes, you need a JAR file for those classes and you need to add that JAR when you create the EAR file. Finally, you need an application level EAR deployment profile and you must select the projects (such as WAR and MAR profiles and customization classes JAR files) to include from a list. When the application is deployed, the EAR file will include all the projects that were selected in the deployment profile.

---

**Note:** If you create your project or application using the ADF Fusion Web Application template, JDeveloper automatically creates default WAR, EAR, MAR, and JAR deployment profiles. Typically, you would not need to edit or create deployment profiles manually.

---

For Oracle ADF applications, you can deploy the application only as an EAR file. The WAR and MAR files that are part of the application should be included in the EAR file when you create the deployment profile.

---

**Note:** If your Fusion web application has business services that you want to deploy, you will need to create a Business Component Service Interface deployment profile and deploy it. For more information about business services, see Section 15.2.21, "How to Deploy Web Services to Oracle WebLogic Server."
48.3.2.1 Creating a WAR Deployment Profile

You will need to create a WAR deployment profile for each web-based project you want to package into the application. Typically, the WAR profile will include the dependent data model projects it requires.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a WAR deployment profile. For more information, see Section 48.3, "Preparing the Application."

You will need to complete this task:

Create web-based projects. If you used the ADF Fusion Web Application template, you should already have a default WAR deployment profile.

To create WAR deployment profiles for an application:

1. In the Applications window, right-click the web project that you want to deploy and choose New > From Gallery. You will create a WAR profile for each web project.

2. In the New Gallery, expand General, select Deployment Profiles and then WAR File, and click OK.

   If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- WAR File dialog, enter a name for the project deployment profile and click OK.

4. In the Edit WAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

   - If you have customization classes in your application, they must be loaded from the EAR-level application class loader and not from the WAR. You will later add these customization classes to the EAR.
     
     By default, customization classes are added to the data model project’s WAR class path. So for each WAR, you must exclude the customization classes.

     If you created your customization classes in an extension project of the application, be sure to deselect any customization class archive on the Library Dependencies page of the WAR deployment profile for each user interface project.

     If you created your customization classes in the data model project of the application, deselect any customization classes in the Edit WAR Deployment Profiles Properties dialog Filters page for each user interface project. If you are using a customization.properties file, it should also be deselected.

   - You might also want to change the Java EE web context root setting. To do so, choose General in the left pane.

     By default, when Use Project’s Java EE Web Context Root is selected, the associated value is set to the project name, for example, Application1-Project1-context-root. You need to change this if you want users to use a different name to access the application.
If you are using custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

5. Click OK to exit the Deployment Profile Properties dialog.

6. Click OK again to exit the Project Properties dialog.

7. Repeat Steps 1 through 7 for all web projects that you want to deploy.

48.3.2.2 Creating a MAR Deployment Profile

If you have seeded customizations or base metadata that you want to place in the MDS repository, you need to create a MAR deployment profile.

The namespace configuration under `<mds-config>` for MAR content in the `adf-config.xml` file is generated based on your selections in the MAR Deployment Profile Properties dialog.

Although uncommon, an enterprise application (packaged in an EAR) can contain multiple web application projects (packaged in multiple WARs), but the metadata for all these web applications will be packaged into a single metadata archive (MAR). The metadata contributed by each of these individual web applications can be global (available for all the web applications) or local to that particular web application.

To avoid name conflicts for metadata with global scope, make sure that all metadata objects and elements have unique names across all the web application projects that forms part of the enterprise application.

JDeveloper creates an auto-generated MAR when the Enable User Customizations and Across Sessions using MDS options are selected in the ADF View page of the Project Properties dialog or when you explicitly specify the deployment target directory in the `adf-config.xml` file.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a MAR deployment profile. For more information, see Section 48.3, "Preparing the Application."

You will need to complete this task:

Create an MDS repository for your customization requirements to deploy metadata using the MAR deployment profile. For more information, see the section about managing the MDS repository in Administering Oracle Fusion Middleware. If you used the ADF Fusion Web Application template, you should already have a default MAR deployment profile.

To create a MAR deployment profile:

1. In the Applications window, right-click the application in which you want to create a MAR profile and choose New > From Gallery.

   You will create a MAR profile if you want to include customizations.

2. In the New Gallery, expand General, select Deployment Profiles and then MAR File, and click OK.

   If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- MAR File dialog, enter a name for the MAR deployment profile and click OK.
4. In the Edit MAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Figure 48–4 shows a sample User Metadata directory tree.

**Figure 48–4  Selecting Items for the MAR Deployment Profiles**

Note the following important points:

- To include all customizations, you need only create a file group with the desired directories.

- ADF Model and ADF view directories are added by default. No further action is required to package the ADF Model and ADF view customizations into the MAR. ADF view content is added to **HTML Root dir**, while ADF Model and Business Components content is added to **User Metadata**.

- To include the base metadata in the MDS repository, you need to explicitly select these directories in the dialog.

  When you select the base document to be included in the MAR, you also select specific packages. When you select one package, all the documents (including subpackages) under that package will be used. When you select a package, you cannot deselect individual items under that package.

- To include files from other than ADF Model and ADF view, users should create a new file group under **User Metadata** with the desired directories and explicitly select the required content in the Directories page.

- If a dependent ADF library JAR for the project contains seeded customizations, they will automatically be added to the MAR during MAR packaging. They will not appear in the MAR profile.

- If ADF Library customizations were created in the context of the consuming project, those customizations would appear in the MAR profile dialog by default.

5. Click **OK** to exit the Deployment Profile Properties dialog.
6. Click **OK** again to exit the Application Properties dialog.

### 48.3.2.3 Creating an Application Level EAR Deployment Profile

The EAR file contains all the necessary application artifacts for the application to run in the application server. If you used the ADF Fusion Web Application template, you should already have a default EAR deployment profile. For more information about the EAR file, see Section 48.4.5, "What You May Need to Know About EAR Files and Packaging."

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you create an EAR deployment profile. For more information, see Section 48.3, "Preparing the Application."

You will need to complete these tasks:

1. Add classes into a JAR file, as described in Section 48.3.2.4, "Adding Customization Classes into a JAR."

2. Create the WAR deployment profiles, as described in Section 48.3.2.1, "Creating a WAR Deployment Profile."

**To create an EAR deployment profile for an application:**

1. In the Applications window, right-click the application and choose **New > From Gallery**.
   
   You will create an EAR profile for the application.

2. In the New Gallery, expand **General**, select **Deployment Profiles** and then **EAR File**, and click **OK**.
   
   If you don’t see **Deployment Profiles** in the Categories tree, click the **All Features** tab.

3. In the Create Deployment Profile -- EAR File dialog, enter a name for the application deployment profile and click **OK**.

4. In the Edit EAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

   Be sure that you:

   - Select **Application Assembly** and then in the **Java EE Modules** list, select all the project profiles that you want to include in the deployment, including any **WAR** or **MAR** profiles.

   - Select **Platform**, select the application server you are deploying to, and then select the target application connection from the **Target Connection** dropdown list.

   **Note:** If you are using a custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

5. If you have customization classes in your application, configure these classes so that they load from the EAR-level application class loader.
Preparing the Application

48.3.2.4 Adding Customization Classes into a JAR

If your application has customization classes, create a JAR that contains only these customization classes. When you create your EAR, you can add the JAR to the EAR assembly. And when you create WAR profiles for your web projects, you must make sure they don’t include the customization classes JAR.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you add customization classes. For more information, see Section 48.3, "Preparing the Application."

You will need to complete this task:

- Make sure that your project has customization classes. You do not need to perform this procedure if the application does not have customization classes. For more information about customization classes, see Section 45.2.1, "How to Create Customization Classes."
To add customization classes into a JAR:

1. In the Applications window, right-click the data model project that contains the customization classes for which you want to create a JAR, and choose New > From Gallery.

2. In the New Gallery, expand General, select Deployment Profiles and then JAR File, and click OK.

Alternatively, if you want to create a shared library, select Shared Library JAR File from the list of profile types, and click OK.

---

**Note:** If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- JAR File dialog, enter a name for the project deployment profile (for example, CCArchive) and click OK.

4. In the Edit JAR Deployment Profile Properties dialog, select JAR Options.

5. Enter the location for the JAR file.

6. Expand Files Groups > Project Output > Filters to list the files that can be selected to be included in the JAR.

7. In Filters page, in the Files tab, select the customization classes you want to add to the JAR file.

   If you are using a customization.properties file, it needs to be in the same class loader as the JAR file. You can select the customization.properties file to package it along with the customization classes in the same JAR.

8. Click OK to exit the Edit JAR Deployment Profile Properties dialog.

9. Click OK again to exit the Project Properties dialog.

10. In the Applications window, right-click the project containing the JAR deployment profile, and choose Deploy > deployment profile > to JAR file.

---

**Note:** If this is the first time you deploy to a JAR from this deployment profile, you choose Deploy > deployment profile and select Deploy to JAR in the wizard.

---

### 48.3.2.5 Delivering Customization Classes as a Shared Library

As an alternative to adding your customization classes to the EAR, as described in Section 48.3.2.3, "Creating an Application Level EAR Deployment Profile," you can also include the customization classes in the consuming application as a shared library.

---

**Note:** This procedure describes how to create and use a shared library if you are deploying to Oracle Weblogic Server.

---

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create and use a shared library for customization classes. For more information, see Section 48.3, "Preparing the Application."

You will need to complete this task:
Add customization classes into a JAR using JDeveloper in Studio Developer role. Follow the procedure described in Section 48.3.2.4, "Adding Customization Classes into a JAR," and make sure that you select Shared Library JAR File as the type of archive to create.

**To create and use a shared library for your customization classes:**

1. In the Applications window, right-click the customization classes project, and choose **Deploy > deployment-profile**.
2. In the Deploy wizard, select **Deploy to Application Server** and click **Next**.
3. Select the appropriate application server, and click **Finish**.
   This makes the shared library available on the application server. You must now add a reference to the shared library from the consuming application.
4. Open the application you want to customize in JDeveloper in the Studio Developer role.
5. In the Application Resources panel of the Applications window, double-click the **weblogic-application.xml** file.
6. In the overview editor, click the Libraries navigation tab.
7. On the Libraries page, in the **Shared Library References** section, click the Add icon.
8. In the Library Name field of the newly created row in the **Shared Library References** table, enter the name of the customization classes shared library you deployed, and save your changes.

**48.3.2.6 Viewing and Changing Deployment Profile Properties**

After you have created a deployment profile, you can view and change its properties.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you view deployment profiles. For more information, see Section 48.3, "Preparing the Application."

**To view, edit, or delete a project’s deployment profile:**

1. In the Applications window, right-click the project which you want to view or edit and choose **Project Properties**.
2. In the Project Properties dialog, click **Deployment**.
   The Deployment Profiles list displays all profiles currently defined for the project.
3. In the Deployment Profiles section, select a deployment profile.
4. To edit or delete a deployment profile, click **Edit** or **Delete**.

**48.3.3 How to Create and Edit Deployment Descriptors**

Deployment descriptors are server configuration files that define the configuration of an application for deployment and that are deployed with the Java EE application as needed. The deployment descriptors that a project requires depend on the technologies the project uses and on the type of the target application server. Deployment descriptors are XML files that can be created and edited as source files, but for most descriptor types, JDeveloper provides dialogs or an overview editor that
you can use to view and set properties. If you cannot edit these files declaratively, the XML file opens in the source editor for you to edit its contents.

In addition to the standard Java EE deployment descriptors (for example, application.xml and web.xml), you can also have deployment descriptors that are specific to your target application server. For example, if you are deploying to Oracle WebLogic Server, you can also have weblogic.xml, weblogic-application.xml, and weblogic-ejb-jar.xml.

For WebLogic Server, make sure that the application EAR file includes a weblogic-application.xml file that contains a reference to adf.oracle.domain, and that it includes an ADFApplicationStateListener to clean up application resources between deployment and undeployment actions. Example 48–1 shows a sample weblogic-application.xml file.

Example 48–1 Sample weblogic-application.xml

```xml
<weblogic-application xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
xsi:schemaLocation="http://www.bea.com/ns/weblogic/weblogic-application.xsd"
xmlns="http://www.bea.com/ns/weblogic/weblogic-application">
  <listener>
    <listener-class>oracle.adf.share.weblogic.listeners.ADFApplicationStateListener</listener-class>
  </listener>
  <listener>
    <listener-class>oracle.mds.lcm.weblogic.WLLifecycleListener</listener-class>
  </listener>
  <library-ref>
    <library-name>adf.oracle.domain</library-name>
  </library-ref>
</weblogic-application>
```

If you are deploying web services, you may need to modify your weblogic-application.xml and web.xml files as described in Section 15.2.21, "How to Deploy Web Services to Oracle WebLogic Server."

If you want to enable the application for Real User Experience Insight (RUEI) monitoring, you must add a parameter to the web.xml file, as described in Section 48.3.3.5, "Enabling the Application for Real User Experience Insight and End User Monitoring."

During deployment, the application’s security properties are written to the weblogic-application.xml file to be deployed with the application in the EAR file. For more information, see Section 41.8.2, "What Happens When You Configure Security Deployment Options."

Because Oracle WebLogic Server runs on Java EE 1.5, you may need to modify the application.xml and web.xml files to be compatible with the application server.

48.3.3.1 Creating Deployment Descriptors
JDeveloper automatically creates many of the required deployment descriptors for you. If they are not present, or if you need to create additional descriptors, you can use JDeveloper to create them.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create deployment descriptors. For more information, see Section 48.3, "Preparing the Application."
You will need to complete this task:

Check to see whether JDeveloper has already generated deployment descriptors.

**To create a deployment descriptor:**
1. In the Applications window, right-click the project for which you want to create a descriptor and choose **New > From Gallery**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then a descriptor type, and click **OK**.

If you can’t find the item you want, make sure that you chose the correct project, and then choose the **All Features** tab or use the **Search** field to find the descriptor. If the item is not enabled, check to make sure that the project does not already have a descriptor of that type. A project is allowed only one instance of a descriptor.

JDeveloper starts the Create Deployment Descriptor wizard and then opens the file in the overview or source editor, depending on the type of deployment descriptor you choose.

---

**Note:** For EAR files, do not create more than one deployment descriptor file of the same type per application or workspace. These files can be assigned to projects, but have application workspace scope. If multiple projects in an application have the same deployment descriptor, the one belonging to the launched project will supersede the others. This restriction applies to **application.xml**, **weblogic-jdbc.xml**, **jazn-data.xml**, and **weblogic.xml**.

The best place to create an application level descriptor is in the **Descriptors** node of the Application Resources panel in the Applications window. This ensures that the application is created with the correct descriptors.

Application level descriptors created in the project will be ignored at runtime. Only the application resources descriptors or descriptors generated at the EAR level will be used by the runtime.

---

**48.3.3.2 Viewing or Modifying Deployment Descriptor Properties**

After you have created a deployment descriptor, you can change its properties by using JDeveloper dialogs or by editing the file in the source editor. The deployment descriptor is an XML file (for example, **application.xml**) typically located under the Application Sources node.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you view deployment descriptors. For more information, see Section 48.3, "Preparing the Application."

**To view or change deployment descriptor properties:**

1. In the Applications window or in the Application Resources panel, double-click the deployment descriptor.

2. In the editor window, select either the **Overview tab** or the **Source tab**, and configure the descriptor by setting property values.

   If the overview editor is not available, the file opens in the source editor.
48.3.3.3 Configuring the application.xml File for Application Server Compatibility
You may need to configure your application.xml file to be compliant with your Java EE version.

Note: Typically, your project has an application.xml file that is compatible and you would not need to perform this procedure.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you configure application.xml. For more information, see Section 48.3, "Preparing the Application."

To configure the application.xml file:
1. In the Applications window, right-click the application and choose New > From Gallery.
2. In the New Gallery, expand General, select Deployment Descriptors and then Java EE Deployment Descriptor Wizard, and click OK.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select application.xml and click Next.
4. On the Select Version page, select 5.0 to be compatible with Java EE 5.0 or higher, and click Next.
5. On the Summary page, click Finish.
6. Edit the application.xml file with the appropriate values.

48.3.3.4 Configuring the web.xml File for Application Server Compatibility
You may need to configure your web.xml file to be compliant with your Java EE version. For more information, see Section A.13, "web.xml."

Note: Typically, your project has a web.xml file that is compatible and you would not need to perform this procedure. JDeveloper creates a starter web.xml file when you create a project.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you configure web.xml. For more information, see Section 48.3, "Preparing the Application."

To configure the web.xml file:
1. In the Applications window, right-click the project in which you want to configure a web.xml file and choose New > From Gallery.
2. In the New Gallery, expand General, select Deployment Descriptors and then Java EE Deployment Descriptor, and click OK.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select web.xml and click Next.
4. On the Select Version page, select the version you want to use and click Next.
Version 3.0 is compatible with Java EE 6.0 or higher, and version 2.5 is compatible with Java EE 5.0.

5. On the Summary page, click Finish.

48.3.3.5 Enabling the Application for Real User Experience Insight and End User Monitoring

Real User Experience Insight (RUEI) is a web-based utility to report on real-user traffic requested by, and generated from, your network. It measures the response times of pages and transactions at the most critical points in the network infrastructure. Session diagnostics allow you to perform root-cause analysis.

RUEI enables you to view server and network times based on the real-user experience, to monitor your Key Performance Indicators (KPIs) and Service Level Agreements (SLAs), and to trigger alert notifications on incidents that violate their defined targets. You can implement checks on page content, site errors, and the functional requirements of transactions. Using this information, you can verify your business and technical operations. You can also set custom alerts on the availability, throughput, and traffic of all items identified in RUEI.

For more information about RUEI, see the Oracle Real User Experience Insight documentation at http://www.oracle.com/technetwork/documentation/realuserei-091455.html.

To enable RUEI:

1. In the Applications window, expand WEB-INF and double-click web.xml.

2. In the overview editor, add the context-param tag to the web.xml file, as shown in Example 48–2.

Example 48–2  Enabling RUEI Monitoring for an Application in web.xml

```xml
<context-param>
    <description>This parameter notifies ADF Faces that the ExecutionContextProvider service provider is enabled. When enabled, this will start monitoring and aggregating user activity information for the client initiated requests. By default this param is not set or is false.
    </description>
    <param-name>oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER</param-name>
    <param-value>true</param-value>
</context-param>
```

If there is an EndUserMonitoringService service provider available, you can use it to log performance metrics and data by registering it in your application. The service provider should have been implemented by extending the EndUserMonitoringService class. For more information about this class, see the Javadoc.

Note that the context-parameter oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER needs to be set when an EndUserMonitoringService provider is used within an ADF application.
To enable End User Monitoring in an application:

1. Verify that an `EndUserMonitoringService` service provider has been implemented.

2. Navigate to the application’s `<application_home>/src/META-INF/services` folder using your operating system tools.
   If the `services` folder does not exist, create one.

3. In the `<application_home>/src/META-INF/services` folder, create a file named
   `oracle.adf.view.rich.monitoring.EndUserMonitoringService`
   where `EndUserMonitoringService` is the name of the service interface.

4. Open the file in an editor and add this entry:
   `<package>.MyEndUserMonitoringService`
   where `package` is the Java package name where the service provider resides and
   `MyEndUserMonitoringService` is the name of the `EndUserMonitoringService` service provider.

48.3.4 How to Deploy Applications with ADF Security Enabled

If you are developing an application in JDeveloper using Integrated WebLogic Server, application security deployment properties are configured by default, which means that the application and security credentials and policies will be overwritten each time you redeploy for development purposes. However, the application security deployment properties are the same for Integrated WebLogic Server and the standalone WebLogic Server.

You can change the default behavior in the Application Properties dialog, as described in Section 41.8.1, "How to Configure, Deploy, and Run a Secure Application in JDeveloper."

48.3.4.1 Applications That Will Run Using Oracle Single Sign-On (SSO)

Before you can deploy and run the web application with ADF Security enabled on the application server, the administrator of the target server must configure the domain-level `jps-config.xml` file for the Oracle Access Manager (OAM) security provider. To complete this configuration task, you can use Oracle WebLogic Scripting Tool (WLST) provided with the JDeveloper install. For details about running WLST (with command `addOAMSSOProvider(loginuri, logouturi, autologinuri)`), see the section "Integrating Access Manager With Web Applications Using Oracle ADF Security and the OPSS SSO Framework" in Appendix A, "Integrating Oracle ADF Applications with Access Manager SSO" of the Administrator’s Guide for Oracle Access Management.

Running the `addOAMSSOProvider()` command ensures that the ADF Security framework defers to the OAM service provider to clear the `ObSSOCookie` token. OAM uses this token to save the identity of authenticated users and, unless it is cleared during logout, the user will be unable to log out.

After the system administrator runs the command on the target server, the domain `jps-config.xml` file will contain the following security provider definition that is specific for ADF Security:

```xml
<propertySet name="props.auth.uri">
    <property name="login.url.FORM" value="/${app.context}/adfAuthentication"/>
    <property name="logout.url" value=""/>
</propertySet>
```
Additionally, the authentication type required by SSO is CLIENT-CERT. The web.xml authentication configuration for the deployed application must specify the <auth-method> element as one of the following CLIENT-CERT types.

WebLogic supports two types of authentication methods:

- For FORM-type authentication method, specify the elements like this:

  `<login-config>
  <auth-method>CLIENT-CERT,FORM</auth-method>
  <realm-name>myrealm</realm-name>
  <form-login-config>
    <form-login-page>/login.html</form-login-page>
    <form-error-page>/error.html</form-error-page>
  </form-login-config>
  </login-config>

- For BASIC-type authentication method, specify the elements like this:

  `<login-config>
  <auth-method>CLIENT-CERT,BASIC</auth-method>
  <realm-name>myrealm</realm-name>
  </login-config>

You can configure the web.xml file either before or after deploying the web application. For further details about setting up the authentication method for Single Sign-On, see Part IV, “Managing Access Manager SSO, Policies, and Testing” of the Administrator’s Guide for Oracle Access Management.

### 48.3.4.2 Configuring Security for Weblogic Server

In a development environment, JDeveloper will automatically migrate application level credentials, identities, and policies to the standalone WebLogic Server instance only if the server is set up to be in development mode. Integrated WebLogic Server is set up in development mode by default. You can set up a standalone WebLogic Server to be in development mode during Oracle WebLogic Server domain creation using the Oracle Fusion Middleware Configuration Wizard. For more information about configuring Oracle WebLogic Server domains, see Creating WebLogic Domains Using the Configuration Wizard.

JDeveloper will not migrate application level security credentials to WebLogic Server set up in production mode. Typically, in a production environment, administrators will use Enterprise Manager or WLST to deploy an application, including its security requirements.

When you deploy an application to WebLogic Server, credentials (in the cwallet.sso file) and security policies (in the jazn-data.xml file) will either overwrite or merge with the WebLogic Server’s domain-level credential store, depending on whether an option in weblogic-application.xml is set to OVERWRITE or MERGE. In production-mode WebLogic Server, to avoid security risks, only MERGE is allowed. For development-mode WebLogic Server, you can set to OVERWRITE to test user names and passwords. You can also set the option by running setDomainEnv.cmd or setDomainEnv.sh with the following option added to the command (usually located in ORACLE_HOME/user_projects/domains/MyDomain/bin).

For setDomainEnv.cmd:

```bash
set EXTRA_JAVA_PROPERTIES=-Djps.app.credential.overwrite.allowed=true
%EXTRA_JAVA_PROPERTIES%
```
For setDomainEnv.sh:

```bash
EXTRA_JAVA_PROPERTIES='*[-Djps.app.credential.overwrite.allowed=true
 ${(EXTRA_JAVA_PROPERTIES)}]*
export EXTRA_JAVA_PROPERTIES
```

If the Administration Server is already running, you must restart it for this setting to take effect.

You can check to see whether WebLogic Server is in production mode by using the Oracle WebLogic Server Administration Console or by verifying the following line in WebLogic Server’s `config.xml` file:

```xml
<production-mode-enabled>true</production-mode-enabled>
```

By default, JDeveloper sets the application’s credential, identities, and policies to OVERWRITE mode. That is, the Application Policies, Credentials, and Users and Groups options are selected by default in the Application Properties dialog Deployment page. However, an application’s credentials will be migrated only if the target WebLogic Server instance is set to development mode with `-Djps.app.credential.overwrite.allowed=true`

Policy migration only works in development-mode. Identity migration only works when using JDeveloper to directly deploy to WebLogic Server regardless of whether it is in development or production-mode.

When your application is ready for deployment to a production environment, you should remove the identities from the `jazn-data.xml` file or disable the migration of identities by deselecting Users and Groups from the Application Properties dialog. Application credentials must be manually migrated outside of JDeveloper.

---

**Note:** Before you migrate the `jazn-data.xml` file to a production environment, check that the policy store does not contain duplicate permissions for a grant. If a duplicate permission (one that has the same name and class) appears in the file, the administrator migrating the policy store will receive an error and the migration of the policies will be halted. You should manually edit the `jazn-data.xml` file to remove any duplicate permissions from a grant definition.

---

For more information about migrating application credentials and other `jazn-data` user credentials, see the "Configuring the OPSS Security Store" chapter in *Securing Applications with Oracle Platform Security Services*.

### 48.3.4.2.1 Applications with JDBC URL for WebLogic

If your application has components that use JDBC URL connections, the connection user names and passwords are also stored in the application level credential and policy stores. For the deployed application to be able to connect to the database using the JDBC URL, these credentials and policies must be migrated. That is, if WebLogic Server is in production mode, system administrators must migrate this security information. If WebLogic Server is in development mode, it must have domain-level credential and policy stores set to OVERWRITE to allow the migration of security information.

### 48.3.4.2.2 Applications with JDBC Data Source for WebLogic
If your application uses application level JDBC data sources with password indirection for database connections, you may need to create credential maps in WebLogic Server to enable the database connection. For more information, see Administering Oracle ADF Applications.

### 48.3.5 How to Replicate Memory Scopes in a Clustered Environment

If you are deploying an application that is intended to run in a clustered environment, you need to ensure that all managed beans with a lifespan longer than one request are serializable, and that Oracle ADF is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

For more information, see Section 26.4.3, "How to Set Managed Bean Memory Scopes in a Server-Cluster Environment."

### 48.3.6 How to Enable the Application for ADF MBeans

A Fusion web application uses many XML files for setting configuration information. Three of these configuration files have ADF MBean counterparts that are deployed with the application. After the application has been deployed, you can change configuration properties by accessing the ADF MBeans using the Enterprise Manager Fusion Middleware Control MBean browser.

To enable ADF MBeans, register them in the `web.xml` file. Example 48–3 shows a `web.xml` file with listener entries for connections, configuration, and business components.

**Example 48–3  Enabling ADF MBeans in the web.xml File**

```
<listener>
    <listener-class>
        oracle.adf.mbean.share.connection.ADFConnectionLifeCycleCallBack
    </listener-class>
</listener>

<listener>
    <listener-class>
        oracle.adf.mbean.share.config.ADFConfigLifeCycleCallBack
    </listener-class>
</listener>

<listener>
    <listener-class>
        oracle.bc4j.mbean.BC4JConfigLifeCycleCallBack
    </listener-class>
</listener>
```

Additionally, you must configure a writable MDS repository to enable post-deployment configuration of `connections.xml` using ADF Connections MBeans and `bc4j.xcfg` using ADF Business Components MBeans.

MDS configuration entries in the `adf-config.xml` file for a database-based MDS are shown in Example 48–4. For more information about configuring MDS, see Administering Oracle Fusion Middleware.

**Example 48–4  MDS Configuration Entries in the adf-config.xml File**

```
<adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
    
    <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
        
        <persistence-config>
            
            <metadata-store-usages>
                
                <metadata-store-usage
default-cust-store="true" deploy-target="true" id="myStore">
```

Deploying Fusion Web Applications  48-25
In a production environment, an MDS repository that uses a database is required. You can use JDeveloper, Enterprise Manager Fusion Middleware Control or scripts to switch from a file-based repository to a database MDS repository.

Additionally, if several applications are sharing the same MDS configuration, each application can achieve distinct customization layers by defining a `adf:adf-properties-child` property in the `adf-config.xml` file. JDeveloper automatically generates this entry when creating applications. If your `adf-config.xml` file does not have this entry, add it to the file with code similar to that of Example 48–5.

**Example 48–5  Adding MDS Partition Code to the adf-config.xml File**

```xml
<adf:adf-properties-child xmlns="http://xmlns.oracle.com/adf/config/properties">
  <adf-property name="adfAppUID" value="Application3-4434"/>
  <adf-property name="partition_customizations_by_application_id" value="true"/>
</adf:adf-properties-child>
```

The `value` attribute is either generated by JDeveloper or you can set it to any unique identifier within the server farm where the application is deployed. This value can be set to the `value` attribute of the `adfAppUID` property.

When `adf-property name` is set to `adfAppUid`, then the corresponding `value` property should be set to the name of the application. By default, JDeveloper generates the `value` property using the application’s package name. If the package name is not specified, JDeveloper generates the `value` property by using the workspace name and a four digit random number.

For more information about configuring ADF applications using ADF MBeans, see *Administering Oracle ADF Applications*.

### 48.3.7 What You May Need to Know About JDBC Data Source for Oracle WebLogic Server

ADF applications can use either a JDBC data source or a JDBC URL for database connections. You use the Oracle WebLogic Server Administration Console to configure a JDBC data source. For more information about database access, see *Section 13.3, "Configuring Your Application Module Database Connection."

---

**Best Practice:** Fusion web applications are not compatible with data sources defined with the JDBC XA driver. When creating a data source on Oracle WebLogic Server, be sure to change the Fusion web application data source’s JDBC driver from “Oracle’s Driver (Thin XA)” to “Oracle’s Driver (Thin)”. Because XA data sources close all cursors upon commit, random JBO-27122 and closed statement errors may result when running the the Fusion web application with an XA data source.

The Fusion web application module in the data model project can be configured to use a JDBC URL connection type, a JDBC data source connection type, or a combination of
both types. By default, Fusion web application modules use a JDBC URL connection. A component that uses a JDBC URL will attempt to connect directly to the database using the JDBC URL, and it will ignore any JDBC data sources (global or application level) that are available in WebLogic Server. For more information about migrating JDBC URL security information (user names and passwords) from the application to WebLogic Server, see Section 48.3.4, "How to Deploy Applications with ADF Security Enabled."

A Fusion web application can use a JDBC data source to connect to the database. A JDBC data source has three types: global, application level, and application level with password indirection. You generally set up a global JDBC data source in WebLogic Server. Any application that requires access to that database can use that JDBC data source. An application can also include application level JDBC data sources. When the application is packaged for deployment, if the Auto Generate and Synchronize weblogic-jdbc.xml Descriptor During Deployment option is selected, JDeveloper creates a connection_name-jdbc.xml file for each connection that was defined. Each connection’s information is written to the corresponding connection_name-jdbc.xml file (entries are also changed in weblogic-application.xml and web.xml). When the application is deployed to WebLogic Server, the server looks for application level data source information before it looks for the global data source.

If the application is deployed with password indirection set to true, WebLogic Server will look for the connection_name-jdbc.xml file for user name information and it will then attempt to locate application level credential maps for these user names to obtain the password. If you are using JDeveloper to directly deploy the application to WebLogic Server, JDeveloper automatically creates the credential map and populates the map to the server using an MBean call.

However, if you are deploying to an EAR file, JDeveloper will not be able to make the MBean call to WebLogic Server. You must set up the credential maps using the Oracle WebLogic Administration Console. Even if you have a global JDBC data source set up, if you do not also have credential mapping set up, WebLogic Server will not be able to map the credentials with passwords and the connection will fail.

Once the data source has been created in Oracle WebLogic Server, it can be used by an application module. For more information, see the "Preparing the Standalone Application Server for Deployment" section of Administering Oracle ADF Applications.

### 48.4 Deploying the Application

You can use JDeveloper to deploy ADF applications directly to the standalone application server or you can create an archive file and use other tools to deploy to the application server.

---

**Note:** Before you begin to deploy applications that use Oracle ADF to the standalone application server, you need to prepare the application server environment by performing tasks such as installing the ADF runtime and creating and extending domains or cells. For more information, see the "Preparing the Standalone Application Server for Deployment" section of Administering Oracle ADF Applications.

---

Figure 48–5 show the process flow for deploying an application and also for deploying customizations to the target standalone application server.
Table 48–1 describes some common deployment techniques that you can use during the application development and deployment cycle. The deployment techniques are listed in order from deploying on development environments to deploying on production environments. It is likely that in the production environment, the system administrators deploy applications by using Enterprise Manager Fusion Middleware Control or scripts.
Any necessary MDS repositories must be registered with the application server. If the MDS repository is a database, the repository maps to a data source with MDS-specific requirements.

If you are deploying the application to Oracle WebLogic Server, make sure to target this data source to the WebLogic Administration Server and to all Managed Servers to which you are deploying the application. For more information about registering MDS, see Administering Oracle Fusion Middleware.

If you are using the application server’s administrative console or scripts to deploy an application packaged as an EAR file that requires MDS repository configuration in adf-config.xml, you must run the getMDSArchiveConfig command to configure MDS before deploying the EAR file. MDS configuration is required if the EAR file contains a MAR file or if the application is enabled for DT@RT (Design Time At RunTime).

For more information about WLST commands, see the WLST Command Reference for Infrastructure Components.

If you plan to configure ADF connection information, ADF Business Components information, or adf-config.xml using ADF MBeans after the application has been deployed, make sure that the application is configured with MDS and have the MBean listeners enabled in the web.xml file. For more information, see Section 48.3.6, "How to Enable the Application for ADF MBeans."

---

**Table 48–1 Deployment Techniques for Development or Production Environments**

<table>
<thead>
<tr>
<th>Deployment Technique</th>
<th>Environment</th>
<th>When to Use</th>
</tr>
</thead>
<tbody>
<tr>
<td>Run directly from JDeveloper</td>
<td>Test or Development</td>
<td>When you are developing your application. You want deployment to be quick because you will be repeating the editing and deploying process many times. JDeveloper contains Integrated WebLogic Server, on which you can run and test your application.</td>
</tr>
<tr>
<td>Use JDeveloper to directly deploy to the target application server</td>
<td>Test or Development</td>
<td>When you are ready to deploy and test your application on an application server in a test environment. On the test server, you can test features (such as LDAP and Oracle Single Sign-On) that are not available on the development server. You can also use the test environment to develop your deployment scripts, for example, using Ant.</td>
</tr>
<tr>
<td>Use JDeveloper to deploy to an EAR file, then use the target application server’s tools for deployment</td>
<td>Test or Development</td>
<td>When you are ready to deploy and test your application on an application server in a test environment. As an alternative to deploying directly from JDeveloper, you can deploy to an EAR file and then use other tools to deploy to the application server. On the test server, you can test features (such as LDAP and Oracle Single Sign-On) that are not available on the development server. You can also use the test environment to develop your deployment scripts, for example, using Ant.</td>
</tr>

</tbody>
</table>
48.4.1 How to Deploy to the Application Server from JDeveloper

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you deploy an application. For more information, see Section 48.4, "Deploying the Application."

You will need to complete this task:

Create an application level deployment profile that deploys to an EAR file as described in Section 48.3.2.3, "Creating an Application Level EAR Deployment Profile."

To deploy to the target application server from JDeveloper:

1. In the Applications window, right-click the application and choose Deploy > deployment profile.
2. In the Deploy wizard, on the Deployment Action page, select Deploy to Application Server and click Next.
3. On the Select Server page, select the application server connection, and click Next.
4. If you are deploying to a WebLogic Server instance, the WebLogic Options page appears. Select a deployment option and click Next.

Note: If you are deploying an ADF application, do not use the Deploy to all instances in the domain option.

5. Click Finish.

During deployment, you can see the process steps displayed in the deployment Log window. You can inspect the contents of the modules (archives or exploded EAR) being created by clicking on the links that are provided in the log window.
The archive or exploded EAR file will open in the appropriate editor or directory window for inspection.

If the `adf-config.xml` file in the EAR file requires MDS repository configuration, the Deployment Configuration dialog appears for you to choose the target metadata repository or shared metadata repositories, as shown in Figure 48–6. The **Repository Name** dropdown list allows you to choose a target metadata repository from a list of metadata repositories registered with the Administration Server. The **Partition Name** dropdown list allows you to choose the metadata repository partition to which the application’s metadata will be imported during deployment. You can use Oracle WebLogic Scripting Tool (WLST) and Oracle WebLogic Server Administration Tool to configure and register MDS. For more information about managing the MDS Repository, see *Administrating Oracle Fusion Middleware*.

![Figure 48–6 MDS Configuration and Customization for Deployment](image)

**Note:** If you are deploying a Java EE application, click the application menu next to the Java EE application in the Applications window.

For more information on creating application server connections, see Section 48.3.1, “How to Create a Connection to the Target Application Server.”
48.4.2 How to Create an EAR File for Deployment

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using Enterprise Manager, Oracle WebLogic Scripting Tool (WLST), or Oracle WebLogic Server Administration Console.

Although a Fusion web application is encapsulated in an EAR file (which usually includes WAR, MAR, and JAR components), it may have parts that are not deployed with the EAR. For instance, ADF Business Services can be deployed as a JAR. For more information about business services, see Section 15.2.21, "How to Deploy Web Services to Oracle WebLogic Server."

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create an EAR file for deployment. For more information, see Section 48.4, "Deploying the Application."

You will need to complete this task:

Create an application level deployment profile that deploys to an EAR file as described in Section 48.3.2.3, "Creating an Application Level EAR Deployment Profile."

To create an EAR archive file:

1. In the Applications window, right-click the application containing the deployment profile, and choose Deploy > deployment profile.

2. In the Deploy wizard, on the Deployment Action page, select Deploy to EAR and click Finish.

   If an EAR file is deployed at the application level, and it has dependencies on a JAR file in the data model project and dependencies on a WAR file in the user interface project, then the files will be located in the following directories by default:

   - ApplicationDirectory/deploy/EARDeploymentProfile.ear
   - ApplicationDirectory/ModelProject/deploy/JARDeploymentProfile.jar
   - ApplicationDirectory/ViewControllerProject/deploy/WARDeploymentProfile.war

   Tip: Choose View > Log to see messages generated during creation of the archive file.

48.4.3 How to Deploy New Customizations Applied to ADF Library

If you have created new customizations for an ADF Library, you can use the MAR profile to deploy these customizations to any deployed application that consumes that ADF Library. For instance, suppose applicationA, which consumes ADFLibraryB, is deployed to a standalone application server. Later on, when new customizations are added to ADFLibraryB, you only need to deploy the updated customizations into applicationA. You do not need to repackage and redeploy the whole application nor do you need to manually patch the MDS repository.
Deploying the Application

48.4.3.1 Exporting Customization to a Deployed Application
You can export the customizations directly from JDeveloper into the MDS repository for the deployed application on the standalone application server.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you export customizations directly into the application server. For more information, see Section 48.4, "Deploying the Application."

You will need to complete this task:

Create new customizations to the ADF Library. For more information on customizations, see Section 45.3.7, "How to Customize ADF Library Artifacts in JDeveloper."

To export the customizations directly into the application server:
1. In the Applications window, right-click the application and choose Deploy > metadata.
2. In the Deploy metadata dialog, on the Deployment Action page, select Export to a Deployed Application and click Next.
   If the MAR profile is included in the EAR profile of any application, Export to a Deployed Application will be dimmed and disabled.
3. On the Application Server page, select the application server connection and click Next.
4. For WebLogic Server, the Server Instance page appears. In this page, select the server instance where the deployed application is located and click Next.
5. On the Deployed Application page, select the application you want to apply the customizations to and click Next.
6. On the Sandbox Instance page, if you want to deploy to a sandbox, select Deploy to an associated sandbox, choose the sandbox instance, and click Next.
7. On the Summary page, verify the information and click Finish.
48.4.3.2 Deploying Customizations to a JAR
When you deploy the ADF Library customizations to a JAR, you are packaging the contents as defined by the MAR profile.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you deploy customizations as a JAR. For more information, see Section 48.4, "Deploying the Application."

You will need to complete this task:
Create new customizations to the ADF Library. For more information on customizations, see Section 45.3.7, "How to Customize ADF Library Artifacts in JDeveloper."

To deploy the customizations as a JAR
1. In the Applications window, right-click the application and choose Deploy > metadata.
2. In the Deploy Metadata dialog, on the Deployment Action page, select Deploy to MAR.
4. Use Enterprise Manager Fusion Middleware Control or the application server’s administration tool to import the JAR into the MDS repository. For more information about Fusion Middleware Control, see Administering Oracle Fusion Middleware.

48.4.4 What You May Need to Know About ADF Libraries
An ADF Library is a JAR file that contains JAR services registered for ADF components such as ADF task flows, pages, or application modules. If you want the ADF components in a project to be reusable, you create an ADF Library deployment profile for the project and then create an ADF Library JAR based on that profile.

An application or project can consume the ADF Library JAR when you add it using the Resources window or manually by adding it to the library classpath. When the ADF Library JAR is added to a project, it will be included in the project’s WAR file if the Deployed by Default option is selected.

For more information, see Chapter 44, "Reusing Application Components."

48.4.5 What You May Need to Know About EAR Files and Packaging
When you package a Fusion web application into an EAR file, it can contain the following:
- WAR files: Each web-based view controller project should be packaged into a WAR file.
- MAR file: If the application has customizations that are deployed with the application, it should be packaged into a MAR.
- ADF Library JAR files: If the application consumes ADF Library JARs, these JAR files may be packaged within the EAR.
- Other JAR files: The application may have other dependent JAR files that are required. They can be packaged within the EAR.
48.4.6 How to Deploy the Application Using Scripts and Ant

You can deploy the application using commands and automate the process by putting those commands in scripts. The `ojdeploy` command can be used to deploy an application without JDeveloper. You can also use Ant scripts to deploy the application. JDeveloper has a feature to help you build Ant scripts. Depending on your requirements, you may be able to integrate regular scripts with Ant scripts.

For more information about commands, scripts, and Ant, see *Administering Oracle ADF Applications*.

48.4.7 How to Deploy ADF Faces Library JARs with the Application

You can develop applications that only use ADF Faces without using ADF Model. In that case, you can deploy the ADF Faces JARs with the application into the application server.

**Before you begin:**
Create an application with a web-based project. If you used the Fusion Web Application (ADF) template, you should already have a default WAR deployment profile.

**To deploy ADF Faces JARs as part of the application:**
1. In the Applications window, right-click the web project that you want to deploy and choose **Project Properties**.
2. In the Project Properties dialog, select **Deployment** and then the deployment profile and click **Edit**.
   
   If your project does not have a WAR deployment profile, follow Steps 1 to 3 in Section 48.3.2.1, "Creating a WAR Deployment Profile," to create a new WAR deployment profile.
3. Navigate to **File Groups > WEB-INF/lib > Contributors** and select **ADF Faces Runtime 11**.
4. Click **OK** to exit the Deployment Profile Properties dialog.
5. Click **OK** again to exit the Project Properties dialog.
6. Deploy your application as described in this chapter either directly using JDeveloper or by creating a EAR and deploying it using the Enterprise Manager Fusion Middleware Control, the Oracle WebLogic Server Administration Console, or other methods.

   Make sure your application-level EAR contains the WAR file as described in Section 48.3.2.3, "Creating an Application Level EAR Deployment Profile."

48.4.8 What You May Need to Know About JDeveloper Runtime Libraries

When an application is deployed, it includes some of its required libraries with the application. The application may also require shared libraries that have already been loaded to WebLogic Server as JDeveloper runtime libraries. It may be useful to know which JDeveloper libraries are packaged within which WebLogic Server shared library. For a listing of the contents of the JDeveloper runtime libraries, see *Administering Oracle ADF Applications*. 
48.5 Postdeployment Configuration

After you have deployed your application to WebLogic Server, you can perform configuration tasks.

48.5.1 How to Migrate an Application

If you want to migrate a Fusion web application from one WebLogic Server to another WebLogic Server, you may need to perform some of the same steps you did for a first time deployment.

In general, to migrate an application, you would:

- Load the ADF runtime (if it is not already installed) to the target application server.
  
  For more information, see the "Preparing the Standalone Application Server for Deployment" section of Administering Oracle ADF Applications.

- Configure the target application server with the correct database or URL connection information.

- Migrate security information from the source to the target.
  
  For instructions, see Section 48.3.4, "How to Deploy Applications with ADF Security Enabled."

- Deploy the application using Enterprise Manager, administration console, or scripts.
  
  For more information, see Administering Oracle ADF Applications.

48.5.2 How to Configure the Application Using ADF MBeans

If ADF MBeans were enabled and packaged with the deployed application, you can configure ADF properties using the Enterprise Manager MBean Browser. For instructions on how to enable an application for MBeans, see Section 48.3.6, "How to Enable the Application for ADF MBeans."

For information on how to configure ADF applications using ADF MBeans, see Administering Oracle ADF Applications.

48.6 Testing the Application and Verifying Deployment

After you deploy the application, you can test it from the application server. To test-run your ADF application, open a browser window and enter a URL:

- For non-Faces pages: http://<host>:<port>/<context_root>/<page>

- For Faces pages: http://<host>:<port>/<context_root>/faces/<view_id>

  where <view_id> is the view ID of the ADF task flow view activity.

  **Tip:** The context root for an application is specified in the user interface project settings by default as ApplicationName/ProjectName/context-root. You can shorten this name by specifying a name that is unique across the target application server. Right-click the user interface project, and choose Project Properties. In the Project Properties dialog, select Java EE Application and enter a unique name for the context root.
Note: /faces has to be in the URL for Faces pages. This is because JDeveloper configures your web.xml file to use the URL pattern of /faces in order to be associated with the Faces Servlet. The Faces Servlet does its per-request processing, strips out /faces part in the URL, then forwards the URL to the JSP. If you do not include the /faces in the URL, then the Faces Servlet is not engaged (since the URL pattern doesn't match). Your JSP is run without the necessary JSF per-request processing.
This chapter describes the Fusion web application state management facilities and how to use them to specify the release level for ADF application modules to support stateful applications on the web.

This chapter includes the following sections:

- Section 49.1, "Understanding Why State Management is Necessary"
- Section 49.2, "Introduction to Fusion Web Application State Management"
- Section 49.3, "Using Save For Later"
- Section 49.4, "Setting the Application Module Release Level at Runtime"
- Section 49.5, "What Model State Is Saved and When It Is Cleaned Up"
- Section 49.6, "Timing Out the HttpSession"
- Section 49.7, "Managing Custom User-Specific Information"
- Section 49.8, "Managing the State of View Objects"
- Section 49.9, "Using State Management for Middle-Tier Savepoints"
- Section 49.10, "Testing to Ensure Your Application Module is Activation-Safe"
- Section 49.11, "Keeping Pending Changes in the Middle Tier"

49.1 Understanding Why State Management is Necessary

Most real-world business applications need to support multi-step user tasks. Modern sites tend to use a step-by-step style user interface to guide the end user through a logical sequence of pages to complete these tasks. When the task is done, the user can save or cancel everything as a unit. However, the HTTP protocol is built on the concept of individual, stateless requests, so the responsibility of grouping a sequence of user actions into a logical, stateful unit of work falls to the application developer.

49.1.1 Examples of Multi-Step Tasks

In a typical search-then-edit scenario, the end user searches to find an appropriate row to update, then may open several different pages of related master-detail information to make edits before deciding to save or cancel work. Consider another scenario where the end user wants to book a vacation online. The process may involve the end user's entering details about:

- One or more flight segments that comprise the journey
One or more passengers taking the trip
- Seat selections and meal preferences
- One or more hotel rooms in different cities
- Car they will rent

Along the way, the user might decide to complete the transaction, save the reservation for finishing later, or abandon the whole thing.

It's clear these scenarios involve a logical unit of work that spans multiple web pages. You've seen in previous chapters how to use JDeveloper's JSF page navigation diagram to design the page flow for these use cases, but that is only part of the puzzle. The pending changes the end user makes to business domain objects along the way — Trip, Flight, Passenger, Seat, HotelRoom, Auto, etc. — represent the in-progress state of the application for each end user. Along with this, other types of "bookkeeping" information about selections made in previous steps comprise the complete picture of the application state.

### 49.1.2 Stateless HTTP Protocol Complicates Stateful Applications

While it may be easy to imagine these multi-step scenarios, implementing them in web applications is complicated by the stateless nature of HTTP, the hypertext transfer protocol. Figure 49–1 illustrates how an end user's visit to a site comprises a series of HTTP request/response pairs. However, HTTP affords a web server no way to distinguish one user's request from another user's, or to differentiate between a single user's first request and any subsequent requests that user makes while interacting with the site. The server gets each request from any user always as if it were the first (and only) one they make.

**Figure 49–1 Web Applications Use the Stateless HTTP Protocol**

### 49.1.3 How Cookies Are Used to Track a User Session

As shown in Figure 49–2, the technique used to recognize an ongoing sequence of requests from the same end user over the stateless HTTP protocol involves a unique identifier called a cookie. A cookie is a name/value pair that is sent in the header information of each HTTP request the user makes to a site. On the initial request made by a user, the cookie is not part of the request. The server uses the absence of the cookie to detect the start of a user's session of interactions with the site, and it returns a unique identifier to the browser that represents this session for this user. In practice, the cookie value is a long string of letters and numbers, but for the simplicity of the illustration, assume that the unique identifier is a letter like "A" or "Z" that corresponds to different users using the site.

Web browsers support a standard way of recognizing the cookie returned by the server that allows the browser to identify the following:
the site that sent the cookie
- how long it should remember the cookie value

On each subsequent request made by that user, until the cookie expires, the browser sends the cookie along in the header of the request. The server uses the value of the cookie to distinguish between requests made by different users.

Cookies can be set to live beyond a single browser session so that they might expire in a week, a month, or a year from when they were first created, while a session cookie expires when you close your browser.

**Figure 49–2 Tracking State Using a Session Cookies and Server-Side Session**

Java EE-compliant web servers provide a standard server-side facility called the HttpSession that allows a web application to store Java objects related to a particular user's session as named attribute/value pairs. An object placed in this session Map on one request can be retrieved by the application while handling a subsequent request during the same session.

The session remains active while the user continues to send new requests within the timeframe specified by the `<session-timeout>` element in the `web.xml` file. The default session length is typically around 30 minutes, depending on the container.

### 49.1.4 Performance and Reliability Impact of Using HttpSession

The HttpSession facility is an ingredient in most application state management strategies, but it can present performance and reliability problems if not used judiciously. First, because the session-scope Java objects you create are held in the memory of the Java EE web server, the objects in the HTTP session are lost if the server should fail.

As shown in Figure 49–3, one way to improve the reliability is to configure multiple Java EE servers in a cluster. By doing this, the Java EE application server replicates the objects in the HTTP session for each user across multiple servers in the cluster so that if one server goes down, the objects exist in the memory of the other servers in the cluster that can continue to handle the users requests. Since the cluster comprises separate servers, replicating the HTTP session contents among them involves broadcasting the changes made to HTTP session objects over the network.
You can begin to see some of the performance implications of overusing the HTTP session:

- **The more active users, the more HTTP sessions will be created on the server.**
- **The more objects stored in each HTTP session, the more memory you will need.** Note that the memory is not reclaimed when the user becomes inactive; this only happens with a session timeout or an explicit session invalidation. Session invalidations don't always happen because users don't always logout.
- **In a cluster, the more objects in each HTTP session that change, the more network traffic will be generated to replicate the changed objects to other servers in the cluster.**

At the outset, it would seem that keeping the number of objects stored in the session to a minimum addresses the problem. However, this implies leveraging an alternative mechanism for temporary storage for each user's pending application state. The most popular alternatives involve saving the application state to the database between requests or to a file of some kind on a shared file system.

Of course, this is easier said than done. A possible approach involves eagerly saving the pending changes to your underlying database tables and committing the transaction at the end of each HTTP request. But this idea has two key drawbacks:

- **Your database constraints might fail.**
  At any given step of the multi-step process, the information may only be partially complete, and this could cause errors at the database level when trying to save the changes.

- **You complicate rolling back the changes.**
  Cancelling the logical of unit of work would involve carefully deleting all of the eagerly committed rows in possible multiple tables.

These limitations have led developers in the past to invent solutions involving a "shadow" set of database tables with no constraints and with all of the column types defined as character-based. Using such a solution becomes very complex very quickly.
Ultimately, you will conclude that you need some kind of generic application state management facility to address these issues in a more generic and workable way. The solution comes in the form of ADF Business Components, which implements this for you out of the box.

49.2 Introduction to Fusion Web Application State Management

State management enables you to easily create web applications that support multi-step use cases without falling prey to the memory, reliability, or implementation complexity problems described in Section 49.1, "Understanding Why State Management is Necessary."

Application state management is provided at two levels, by the Save For Later feature in a task flow, and application module state management in the model layer.

Save For Later is activated at the controller layer and automatically saves a "snapshot" of the current UI and controller states, and delegates to the model layer to passivate (save) its state as well.

If you are not using ADF data controls, you can still use application module state management alone, but since this will save only the model state, this is an outside case for most applications.

49.2.1 Basic Architecture of the Save for Later Facility

Save for Later saves an incomplete transaction without enforcing validation rules or submitting the data. The end user can resume working on the same transaction later with the same data that was originally saved when the application was exited.

49.2.2 Basic Architecture of the Application Module State Management Facility

Your ADF Business Components-based application automatically manages the application state of each user session. This provides the simplicity of a stateful programming model that you are accustomed to in previous 4GL tools, yet implemented in a way that delivers scalability nearing that of a purely stateless application. Understanding what happens behind the scenes is essential to make the most efficient use of this important feature.

You can use application module components to implement completely stateless applications or to support a unit of work that spans multiple browser pages. Figure 49–4 illustrates the basic architecture of the state management facility to support these multi-step scenarios. An application module supports passivating (storing) its pending transaction state to an XML document, which is stored in the database in a single, generic table, keyed by a unique passivation snapshot ID. It also supports the reverse operation of activating pending transaction state from one of these saved XML snapshots. This passivation and activation is performed automatically by the application module pool when needed.
The ADF binding context is the one object that lives in the HttpSession for each end user. It holds references to lightweight application module data control objects that manage acquiring an application module instance from the pool during the request (when the data control is accessed) and releasing it to the pool at the end of each request. The data control holds a reference to the ADF session cookie that identifies the user session. In particular, business domain objects created or modified in the pending transaction are not saved in the HttpSession using this approach. This minimizes both the session memory required per user and eliminates the network traffic related to session replication if the servers are configured in a cluster.

For improved reliability, serialize your session objects. Objects stored in distributed sessions need to implement the java.io.Serializable interface. Implementing this interface ensures the data can be transported over-the-wire to each server instance in the cluster. Use a custom method like the addObjectToSession(String key, Serializable value) method, instead of the default HttpSession.setAttribute(String key, Object value) method when adding session data. The distinction is, if you were to call the addObjectToSession() method with a nonserializable object, you would see a compile-time error. If you were to try to replicate a session object that had nonserializable objects placed into session with the put() method, you would see a runtime error and potentially, a broken user experience.

Additionally, if you have multiple application servers and you enable the optional ADF Business Components failover support (explained in Section 49.2.2.2, “How Passivation Changes When Optional Failover Mode is Enabled”), then subsequent end-user requests can be handled by any server in your server farm or cluster. The session cookie can reactivate the pending application state from the database-backed XML snapshot if required, regardless of which server handles the request.
49.2.2.1 Understanding When Passivation and Activation Occurs

To better understand when the automatic passivation and activation of application module state occurs, consider the following simple case:

1. At the beginning of an HTTP request, the application module data control handles the `beginrequest` event by checking out an application module instance from the pool.

   The application module pool returns an `unreferenced` instance. An unreferenced application module is one that is not currently managing the pending state for any other user session.

2. At the end of the request, the application module data control handles the `endrequest` event by checking the application module instance back into the pool in "managed state" mode.

   That application module instance is now `referenced` by the data control that just used it. And the application module instance is an object that still contains pending transaction state made by the data control (that is, entity object and view object caches; updates made but not committed; and cursor states), stored in memory. As you’ll see below, it’s not dedicated to this data control, just referenced by it.

3. On a subsequent request, the same data control — identified by its `SessionCookie` — checks out an application module instance again.

   Due to the "stateless with user affinity" algorithm the pool uses, you might assume that the pool returns the exact same application module instance, with the state still there in memory. (To understand this algorithm, read Section 50.1, "About Application Module Pooling" and the discussion of Referenced Pool Size in Section 50.2.7.2, "Pool Sizing Parameters").

Sometimes due to a high number of users simultaneously accessing the site, application module instances must be sequentially reused by different user sessions. In this case, the application pool must recycle a currently referenced application module instance for use by another session, as follows:

1. The application module data control for User A’s session checks an application module instance into the application pool at the end of a request. Assume this instance is named `AM1`.

2. The application module data control for User Z’s new session requests an application module instance from the pool for the first time, but there are no unreferenced instances available. The application module pool then:

   - Passivates the state of instance `AM1` to the database.
   - Resets the state of `AM1` in preparation to be used by another session.
   - Returns the `AM1` instance to User Z’s data control.

3. On a subsequent request, the application module data control for User A’s session requests an application module instance from the pool. The application module pool then:

   - Obains an unreferenced instance.
     - This could be instance `AM1`, obtained by following the same tasks as in Step 2, or another `AM2` instance if it had become unreferenced in the meantime.
   - Activates the appropriate pending state for User A from the database.
   - Returns the application module instance to User A’s data control.
The process of passivation, activation, and recycling allows the state referenced by the data control to be preserved across requests without requiring a dedicated application module instance for each data control. Both browser users in the above scenario are carrying on an application transaction that spans multiple HTTP requests, but the end users are unaware whether the passivation and activation is occurring in the background. They just continue to see the pending changes. In the process, the pending changes never need to be saved into the underlying application database tables until the end user is ready to commit the logical unit of work.

Note that this keeps the session memory footprint low because the only business component objects that are directly referenced by the session (and are replicable) are the data control and the session cookie.

The application module pool makes a best effort to keep an application module instance "sticky" to the current data control whose pending state it is managing. This is known as maintaining user session affinity. The best performance is achieved if a data control continues to use exactly the same application module instance on each request, since this avoids any overhead involved in reactivating the pending state from a persisted snapshot.

### 49.2.2.2 How Passivation Changes When Optional Failover Mode is Enabled

The `jbo.dofailover` parameter controls when and how often passivation occurs. You can set this parameter in your application module configuration on the **Pooling and Scalability** tab of the Edit Configuration dialog. When the failover feature is disabled, which it is by default, then application module pending state will only be passivated on demand when it must be. This occurs just before the pool determines it must hand out a currently referenced application module instance to a different data control.

The passivation activity (and the corresponding wait) occurs only if failover is disabled and session replication is disabled. If either failover or session replication is enabled, then the recycling thread will reuse the snapshot that was already acquired to support the failover.

---

**Note:** Passivation can also occur when an application module is timed out. For more information about application pool removal algorithms (such as `jbo.ampool.timetolive`), see Section 50.2.7.3, "Pool Cleanup Parameters."

---

In contrast, with the failover feature turned on, the application module’s pending state is passivated every time it is checked back into application module pool. This provides the most pessimistic protection against application server failure. The application module instances’ state is always saved and may be activated by any application module instance at any time. Of course, this capability comes at expense of the additional overhead of eager passivation on each request.

When failover is turned on, a failure can occur when Oracle WebLogic Server is configured to forcibly release connections back into the pool. A failure of this type produces a `SQLException` (Connection has already been closed.) that is saved to the server log. The exception is not reported through the user interface. To ensure that state passivation occurs and users’ changes are saved, the server administrator should set an appropriate value for the `weblogic-application.xml` deployment descriptor parameter `inactive-connection-timeout-seconds` on the `<connection-check-params>` pool params element. Setting the deployment descriptor parameter to several minutes, in most cases, should avoid forcing the
inactive connection timeout and the resulting passivation failure. Adjust the setting as needed for your environment.

**Best Practice:** By default, the failover feature is disabled (jbo.dofailover=false) as a performance optimization when there is only one web server instance configured, by reducing the need for passivation and activation. This allows for application module affinity to a specific user session.

For high availability, in a clustered server environment, the failover feature will auto-default to enabled (jbo.dofailover=true). This ensures that more application modules are readily available, thereby increasing scalability. In this mode, passivation occurs at the end of every request.

To understand application module pooling and the "stateless with affinity" algorithm, read Section 50.1, "About Application Module Pooling" and the discussion of Referenced Pool Size in Section 50.2.7.2, "Pool Sizing Parameters."

---

**Note:** When running or debugging an application that uses failover support within the JDeveloper environment, you are frequently starting and stopping the application server. The ADF failover mechanism has no way of knowing whether you stopped the server to simulate an application server failure, or whether you stopped it because you want to retest something from scratch in a fresh server instance. If you intend to do the latter, exit out of your browser before restarting the application on the server. This eliminates the chance that you will be confused by the correct functioning of the failover mechanism when you didn't intend to be testing that aspect of your application.

---

### 49.2.2.3 About State Management Release Levels

When a data control handles the endrequest notification indicating the processing for the current HTTP request has completed, it releases the application module instance by checking it back into the application module pool. The application module pool manages instances and performs state management tasks (or not) based on the release level you use when returning the instance to the pool.

There are three release levels used for returning an instance of an application module to a pool:

- **Managed** - This is the default level, where the application module pool prefers to keep the same application module instance for the same data control, but may release an instance if necessary.

- **Unmanaged** - No state needs to be preserved beyond the current request.

- **Reserved** - A one-to-one relationship is preserved between an application module instance and a data control.
49.2.2.3.1 About Managed Release Level This is the default release level and implies that application module's state is relevant and has to be preserved for this data control to span over several HTTP requests. Managed level does not guarantee that for the next request this data control will receive the same physical application module instance, but it does guarantees that an application module with identical state will be provided so it is logically the same application module instance each time. It is important to note that the framework makes the best effort it can to provide the same instance of application module for the same data control if it is available at the moment. This is done for better performance since the same application module does not need to activate the previous state which it still has intact after servicing the same data control during previous request. However, the data control is not guaranteed to receive the same instance for all its requests and if the application module that serviced that data control during previous is busy or unavailable, then a different application module will activate this data control’s state. For this reason, it is not valid to cache references to application module objects, view objects, or view rows across HTTP requests in controller-layer code.

To specify the managed release level for an application module, set the release mode to Stateful.

Note: If the jbo.ampool.doampooling configuration property is false — corresponding to your unchecking the Enable Application Module Pooling option in the Pooling and Scalability tab of the Edit Configuration dialog — then there is effectively no pool. In this case, when the application module instance is released at the end of a request it is immediately removed. On subsequent requests made by the same user session, a new application module instance must be created to handle each user request, and pending state must be reactivated from the passivation store. Setting this property to false is useful to discover problems in your application logic that might occur when reactivation does occur due to unpredictable load on your system. However, the property jbo.ampool.doampooling set to false is not a supported configuration for production applications and must be set to true before you deploy your application. For further details, see Section 49.10, "Testing to Ensure Your Application Module is Activation-Safe."

49.2.2.3.2 About Unmanaged Release Level This mode implies that no state associated with this data control has to be preserved to survive beyond the current HTTP request. This level is the most efficient in performance because there is no overhead related to state management. However, you should limit its use to applications that require no state management, or to cases when state no longer needs to be preserved at this point. Usually, you can programmatically release the application module with the unmanaged level when you want to signal that the user has ended a logical unit of work.
To specify the unmanaged release level for an application module, set the release mode to *Stateless*.

### 49.2.2.3.3 About Reserved Release Level

This level guarantees that each data control will be assigned its own application module during its first request and for all subsequent requests coming from the *HttpSession* associated with this data control. This data control will always receive the same physical instance of application module. This mode exists for legacy compatibility reasons and for very rare special use cases.

An example of using Reserved level occurs when there is a pending database state across a request resulting from the *postChanges()* method or a PL/SQL stored procedure but not issuing a *commit()* or *rollback()* at the end of the request. In this case, if any other release level is used instead of Reserved, when the application module instance is recycled, a rollback is issued on the database connection associated with this application module instance and all uncommitted changes would be lost.

**Performance Tip:** If you must use Reserved level, call *setReleaseLevel()* on the data control to keep its period as short as possible. For details about changing the release level programmatically, see Section 49.4, "Setting the Application Module Release Level at Runtime."

Consequences of Reserved mode can be adverse. Reliability suffers because if for whatever reason the application module is lost, the data control will not be able to receive any other application module in its place from the pool, and so *HttpSession* gets lost as well, which is not the case for managed level.

The failover option is ignored for an application module released with Reserved release level since its use implies your application absolutely requires working with the same application module instance on each request.

### 49.2.2.4 State Management and Subclassed Entity Objects

If your application employs subclassed entity objects, the key attribute of new entities must be prepopulated. If the key is not prepopulated, passivation and activation will fail. You can prepopulate the key attribute by overriding the *create()* method or by using the *DBSequence* type that will assign a temporary negative value to the key before the real value is fetched from the database after commit. For more information, see Section 4.10.10, "How to Get Trigger-Assigned Primary Key Values from a Database Sequence."

### 49.2.3 What You May Need to Know About Data Consistency and Application Module Affinity

When an entity object is updated concurrently by more than one user and one of those users loses affinity with their application module during the update, it is possible to experience data corruption if a change indicator has not been defined for the entity object.
Consider a scenario where two users (User A and User B) access the same entity object at the same time.

- After querying, User B changes the value of an attribute (for example, changing the `Dept` attribute value from `Accounting` to `Research`) and then commits.
- Meanwhile, User A has also queried and sees the same record where the value of the `Dept` attribute is `Accounting`.
- User A loses affinity with the application module that was used to query, resulting in passivation.
- User A then changes the `Dept` attribute value from `Accounting` to `Sales` and commits, resulting in activation.
- When activation occurs, the new value of the `Dept` attribute is activated but the browser is unaware of the data change, and the commit proceeds without issue.

To avoid this type of scenario, define a change indicator attribute for all entity objects. For more information, see Section 4.10.11, "How to Protect Against Losing Simultaneously Updated Data."

49.2.4 What You May Need to Know About Using Application Scoped Managed Beans in a Clustered Environment

JSF Application Scope beans are backed by a servlet context which can only have one instance per cluster node. Therefore, for each design time configured bean, there will be a runtime instance of the bean for each node in a cluster. Because there is no synchronization across nodes, each instance of the application running on different nodes will have separate instances of that bean with separate values. Therefore, application scoped managed beans should not be used to carry application-wide values that can be updated to be shared across all nodes in a cluster. They can, however, be used to carry constants, read-only values, or values to reflect the state of a single node within the cluster (such as the number of users on a node).

49.3 Using Save For Later

To enable Save For Later, you must first add Save Points to the application at points where you would like application state and data to be preserved if the end user leaves the application. You can use it to save data and state information about a region, view port, or portlet. Later, you use the Save Point Restore activity to restore application state and data associated with a Save Point.

For more information on how create and restore Save Points, see Section 24.7, "Using Save Points in Task Flows."

Save For Later can also perform implicit saves. These occur when data is saved automatically without the end user performing an explicit Save action when the user session times out or closes the browser window, for example.

For more information on how to perform an implicit save, see Section 24.7, "Using Save Points in Task Flows."

49.4 Setting the Application Module Release Level at Runtime

If you do not want to use the default "Managed State" release level for application modules, you can set your desired level programmatically.
49.4.1 How to Set Unmanaged Level

To set a data control to release its application module using the unmanaged level, call the `resetState()` method on the `DCDataControl` class (in the `oracle.adf.model.binding` package).

You can call this method any time during the request. This will cause application module not to passivate its state at all when it is released to the pool at the end of the request. Note that this method only affects the current application module instance in the current request. After this, the application module is released in unmanaged level to the pool, it becomes unreferenced and gets reset. The next time the application module is used by a client, it will be used in the managed level again by default.

**Note:** You can programmatically release the application module with the unmanaged level when you want to signal that the user has ended a logical unit of work. This will happen automatically when the HTTPSession times out, as described below.

49.4.2 How to Set Reserved Level

To set a data control to release its application module using the reserved level, call the `setReleaseLevel()` method of the `DCJboDataControl` class (in the `oracle.adf.model.bc4j` package), and pass the integer constant `ApplicationModule.RELEASE_LEVEL_RESERVED`.

When the release level for an application module has been changed to "Reserved" it will stay so for all subsequent requests until explicitly changed.

49.4.3 How to Set Managed Level

If you have set an application module to use reserved level, you can later set it back to use managed level by calling the `setReleaseLevel()` method of the `DCJboDataControl` class, and passing the integer constant `ApplicationModule.RELEASE_LEVEL_MANAGED`.

49.4.4 How to Set Release Level in a JSF Backing Bean

Example 49–1 shows calling the `resetState()` method on a data control named `UserModuleDataControl` from the action method of a JSF backing bean.

**Example 49–1 Calling resetState() on Data Control in a JSF Backing Bean Action Method**

```
package devguide.advanced.releasestateless.controller.backing;
import devguide.advanced.releasestateless.controller.JSFUtils;
import oracle.adf.model.BindingContext;
import oracle.adf.model.binding.DCDataControl;
/**
 * JSF Backing bean for the 'Example.jspx' page
 */
public class Example {
  /**
   * In an action method, call resetState() on the data control to cause
   * it to release to the pool with the "unmanaged" release level.
   * In other words, as a stateless application module.
   */
  public String button_action() {
    getDataControl("UserModuleDataControl").resetState();
  }
}  
```
return null;
}
private DCDataControl getDataControl(String name) {
    BindingContext bc =
        (BindingContext)JSFUtils.resolveExpression("#{data}");
    return bc.findDataControl(name);
}

49.4.5 How to Set Release Level in an ADF PagePhaseListener

Example 49–2 shows calling the resetState() method on a data control named UserModuleDataControl from the after-prepareRender phase of the ADF lifecycle using a custom ADF page phase-listener class. You would associate this custom class to a particular page by setting the ControllerClass attribute on the page’s page definition to the fully qualified name of this class.

Example 49–2 Calling resetState() on Data Control in a Custom PagePhaseListener
package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.v2.lifecycle.Lifecycle;
import oracle.adf.controller.v2.lifecycle.PagePhaseEvent;
import oracle.adf.controller.v2.lifecycle.PagePhaseListener;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPagePhaseListener
    implements PagePhaseListener {
    /**
     * In the "after" phase of the final 'prepareRender' ADF Lifecycle
     * phase, call resetState() on the data control to cause it to release
     * to the pool with the "unmanaged" release level. In other words,
     * as a stateless application module.
     *
     * @param event ADF page phase event
     *
     */
    public void afterPhase(PagePhaseEvent event) {
        getDataControl("UserModuleDataControl", event).resetState();
    }

    // Required to implement the PagePhaseListener interface
    public void beforePhase(PagePhaseEvent event) {}
    private DCDataControl getDataControl(String name,
        PagePhaseEvent event) {
        return event.getLifecycleContext().
            getBindingContext().
            findDataControl(name);
    }
}

49.4.6 How to Set Release Level in an ADF PageController

Example 49–3 shows calling the resetState() method on a data control named UserModuleDataControl from an overridden prepareRender() method of a custom ADF page controller class. You would associate this custom class to a particular page by setting the ControllerClass attribute on the page’s page definition to the fully qualified name of this class.

Example 49–3 Calling resetState() on Data Control in a Custom PageController
Setting the Application Module Release Level at Runtime

Using State Management in a Fusion Web Application

### Example 49–3 Calling resetState() on Data Control in a Custom ADF PageController

```java
package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.v2.context.LifecycleContext;
import oracle.adf.controller.v2.lifecycle.PageController;
import oracle.adf.controller.v2.lifecycle.PagePhaseEvent;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPageController extends PageController {
    /**
     * After calling the super in the final prepareRender() phase
     * of the ADF Lifecycle, call resetState() on the data control
     * to cause it to release to the pool with the "unmanaged"
     * release level. In other words, as a stateless application module.
     *
     * @param lcCtx ADF lifecycle context
     */
    public void prepareRender(LifecycleContext lcCtx) {
        super.prepareRender(lcCtx);
        getDataControl("UserModuleDataControl", lcCtx).resetState();
    }
}
```

### Example 49–4 Calling resetState() on Data Control in a Custom ADF PageLifecycle

```java
package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.faces.lifecycle.FacesPageLifecycle;
import oracle.adf.controller.v2.context.LifecycleContext;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPageLifecycle extends FacesPageLifecycle {
    /**
     * After calling the super in the final prepareRender() phase
     * of the ADF Lifecycle, call resetState() on the data control
     * to cause it to release to the pool with the "unmanaged"
     * release level. In other words, as a stateless application module.
     *
     * @param lcCtx ADF lifecycle context
     */
    public void prepareRender(LifecycleContext lcCtx) {
        super.prepareRender(lcCtx);
        getDataControl("UserModuleDataControl", lcCtx).resetState();
    }
}
```

#### 49.4.7 How to Set Release Level in a Custom ADF PageLifecycle

If you wanted to build a Fusion web application where every request was handled in a completely stateless way, use a global custom `PageLifecycle` class as shown in Example 49–4. For details on how to configure your application to use your custom lifecycle see Section 27.2, "About the JSF and ADF Page Lifecycles."

### Example 49–4 Calling resetState() on Data Control in a Custom ADF PageLifecycle

```java
package devguide.advanced.releasestateless.controller;
import oracle.adf.controller.faces.lifecycle.FacesPageLifecycle;
import oracle.adf.controller.v2.context.LifecycleContext;
import oracle.adf.model.binding.DCDataControl;
public class ReleaseStatelessPageLifecycle extends FacesPageLifecycle {
    /**
     * After calling the super in the final prepareRender() phase
     * of the ADF Lifecycle, call resetState() on the data control
     * to cause it to release to the pool with the "unmanaged"
     * release level. In other words, as a stateless application module.
     *
     * @param lcCtx ADF lifecycle context
     */
    public void prepareRender(LifecycleContext lcCtx) {
        super.prepareRender(lcCtx);
        getDataControl("UserModuleDataControl", lcCtx).resetState();
    }
}
```
private DCDataControl getDataControl(String name, LifecycleContext lcCtx) {
    return lcCtx.getBindingContext().findDataControl(name);
}

49.5 What Model State Is Saved and When It Is Cleaned Up

The information saved by application model passivation is divided in two parts: transactional and nontransactional state. Transactional state is the set of updates made to entity object data – performed either directly on entity objects or on entities through view object rows – that are intended to be saved into the database. Nontransactional state comprises view object runtime settings, such as the current row index, WHERE clause, and ORDER BY clause.

49.5.1 State Information Saved During Passivation

The information saved as part of the application module passivation snapshot includes the following.

Transactional State
- New, modified, and deleted entities in the entity caches of the root application module for this user session’s (including old/new values for modified ones).

Nontransactional State
- For each active view object (both statically and dynamically created):
  - Current row indicator for each row set (typically one)
  - New rows and their positions. (New rows are treated differently then updated ones. Their index in the view object is traced as well.)
  - ViewCriteria and all related parameters such as view criteria row, etc.
  - Flag indicating whether or not a row set has been executed
  - Range start and Range size
  - Access mode
  - Fetch mode and fetch size
  - Any view object-level custom data

Note: Transient view object attributes can be saved if they are selected for passivation at design time. However, use this feature judiciously because this results in a snapshot that will grow in size with the number of rows that have been retrieved.

Note: SELECT, FROM, WHERE, and ORDER BY clause if created dynamically or changed from the View definition

Note: If you enable ADF Business Components runtime diagnostics, the contents of each XML state snapshot are also saved. See Section 8.3.10, “How to Enable ADF Business Components Debug Diagnostics” for information on how to enable diagnostics.
49.5.2 Where the Model State Is Saved

By default, passivation snapshots are saved in the database, but you can configure it to use the file system as an alternative.

49.5.2.1 How Database-Backed Passivation Works

The passivated XML snapshot is written to a BLOB column in a table named PS_TXN, using a connection specified by the jbo.server.internal_connection property. Each time a passivation record is saved, it is assigned a unique passivation snapshot ID based on the sequence number taken from the PS_TXN_SEQ sequence. The ADF session cookie held by the application module data control in the ADF binding context remembers the latest passivation snapshot ID that was created on its behalf and remembers the previous ID that was used.

49.5.2.2 Controlling the Schema Where the State Management Table Resides

The ADF runtime recognizes a configuration property named jbo.server.internal_connection that controls which database connection and schema should be used for the creation of the PS_TXN table and the PS_TXN_SEQ sequence. If you don’t set the value of this configuration parameter explicitly, then the state management facility creates the temporary tables using the credentials of the current application database connection.

To keep the temporary information separate, the state management facility uses a different connection instance from the database connection pool, but the database credentials are the same as the current user. Since the framework creates temporary tables, and possibly a sequence if they don’t already exist, the implication of not setting a value for the jbo.server.internal_connection is that the current database user must have CREATE TABLE, CREATE INDEX and CREATE SEQUENCE privileges. Since this is often not desirable, Oracle recommends always supplying an appropriate value for the jbo.server.internal_connection property, providing the credentials for a state management schema where table and schema be created. Valid values for the jbo.server.internal_connection property in your configuration are:

- A fully qualified JDBC connection URL like:
  
  `jdbc:oracle:thin:username/password@host:port:SID`

- A JDBC datasource name like:
  
  `java:/comp/env/jdbc/YourJavaEEDataSourceName`

**Performance Tip:** When creating the PS_TXN table, use securefiles to store LOB data (the content column), and create a primary column index on the PS_TXN table as global, partitioned reverse key index. The securefile configuration delivers superior performance over the basicfile configuration when working with LOB data. The reverse key index helps by reducing contention that can happen when the rate of inserts is high.

49.5.2.3 Configuring the Type of Passivation Store

Passivated information can be stored in several places. You can control it programmatically or by configuring an option in the application module configuration. The choices are database or a file stored on local file system:

- File
This choice may be the fastest available, because access to the file is faster than access to the database. This choice is good if the entire middle tier is either installed on the same machine or has access to a commonly shared file system, so passivated information is accessible to all. Usually, this choice may be good for a small middle tier where one Oracle WebLogic Server domain is used. In other words this is a very suitable choice for small middle tier such as one Oracle WebLogic Server instance with all its components installed on one physical machine. The location and name of the persistent snapshot files are determined by \texttt{jbo.tmpdir} property if specified. It follows usual rules of ADF property precedence for a configuration property. If nothing else is specified, then the location is determined by \texttt{user.dir} if specified. This is a default property and the property is OS specific.

- Database

This is the \textit{default} choice. While it may be a little slower than passivating to file, it is by far the most reliable choice. With passivation to file, the common problem might be that it is not accessible to Oracle WebLogic Server instances that are remotely installed. In this case, in a cluster environment, if one node goes down the other may not be able to access passivated information and then failover will not work. Another possible problem is that even if file is accessible to the remote node, the access time for the local and remote node may be very different and performance will be inconsistent. With database access, time should be about the same for all nodes.

To set the value of your choice in design time, set the property \texttt{jbo.passivationstore} to \texttt{database} or \texttt{file}. The value \texttt{null} will indicate that a connection-type-specific default should be used. This will use database passivation for Oracle or DB2, and file serialization for any others.

To set the storage programmatically use the method \texttt{setStoreForPassiveState()} of interface \texttt{oracle.jbo.ApplicationModule}. The parameter values that you can pass are:

- \texttt{PASSIVATE_TO_DATABASE}
- \texttt{PASSIVATE_TO_FILE}

### 49.5.3 Cleaning Up the Model State

Under normal circumstances, the ADF state management facility provides automatic cleanup of the passivation snapshot records.

#### 49.5.3.1 Previous Snapshot Removed When Next One Taken

When a passivation record is saved to the database on behalf of a session cookie, as described above, this passivation record gets a new, unique snapshot ID. The passivation record with the previous snapshot ID used by that same session cookie is deleted as part of the same transaction. In this way, assuming no server failures, there will only ever be a single passivation snapshot record per active end-user session.

#### 49.5.3.2 Passivation Snapshot Removed on Unmanaged Release

The passivation snapshot record related to a session cookie is removed when the application module is checked into the pool with the unmanaged state level. This can occur when:

- Your code specifically calls \texttt{resetState()} on the application module data control.
What Model State Is Saved and When It Is Cleaned Up

- Your code explicitly invalidates the HttpSession, for example, as part of implementing an explicit "Logout" functionality.
- The HttpSession times out due to exceeding the session timeout threshold for idle time and failover mode is disabled (which is the default).

In each of these cases, the application module pool also resets the application module referenced by the session cookie to be "unreferenced" again. Since no changes were ever saved into the underlying database tables, once the pending session state snapshots are removed, there remains no trace of the unfinished work the user session had completed up to that point.

49.5.3.3 Passivation Snapshot Retained in Failover Mode

When the failover mode is enabled, if the HttpSession times out due to session inactivity, then the passivation snapshot is retained so that the end user can resume work upon returning to the browser.

After a break in the action, when the end user returns to the browser and continues to use the application, it continues working as if nothing had changed. The session cookie is used to reactivate any available application module instance with the user’s last pending state snapshot before handling the request. So, even though the users next request will be processed in the context of a new HttpSession (perhaps even in a different application server instance), the user is unaware that this has occurred.

---

**Note:** If an application module was released with reserved level then the HttpSession times out, the user will have to go through authentication process, and all unsaved changes are lost.

---

49.5.4 Cleaning Up Temporary Storage Tables

JDeveloper supplies the adfbc_purge_statesnapshots.sql script to help with periodically cleaning up the application module state management table. You can find this file in the oracle_common subdirectory of your Oracle Middleware installation directory (for example, $ORACLE_HOME/oracle_common/common/sql).

Persistent snapshot records can accumulate over time if the server has been shutdown in an abnormal way, such as might occur during development or due to a server failure. Running the script in SQL*Plus will create the BC4J_CLEANUP PL/SQL package. The two relevant procedures in this package are:

- **PROCEDURE Session_State(olderThan DATE)**
  
  This procedure cleans up application module session state storage for sessions older than a given date.

- **PROCEDURE Session_State(olderThan_minutes INTEGER)**
  
  This procedure cleans up application module session state storage for sessions older than a given number of minutes.

You can schedule periodic cleanup of your ADF temporary persistence storage by submitting an invocation of the appropriate procedure in this package as a database job.

You can use an anonymous PL/SQL block like the one shown in Example 49–5 to schedule the execution of bc4j_cleanup.session_state() to run starting tomorrow at 2:00 am and each day thereafter to cleanup sessions whose state is over 1 day (1440 minutes) old.
Example 49–5  Scheduling Periodic Cleanup of the State Management Table

```
SET SERVEROUTPUT ON
DECLARE
  jobId  BINARY_INTEGER;
  firstRun DATE;
BEGIN
  -- Start the job tomorrow at 2am
  firstRun := TO_DATE(TO_CHAR(SYSDATE+1,'DD-MON-YYYY') || ' 02:00',
                      'DD-MON-YYYY HH24:MI');
  -- Submit the job, indicating it should repeat once a day
  dbms_job.submit(job => jobId,
                  what => 'bc4j_cleanup.session_state(1440);',
                  next_date => firstRun,
                  interval => 'SYSDATE + 1');
  dbms_output.put_line('Successfully submitted job. Job Id is ' || jobId);
END;
```

49.6 Timing Out the HttpSession

Since HTTP is a stateless protocol, the server receives no implicit notice that a client has closed the browser or gone away for the weekend. Therefore any Java EE-compliant server provides a standard, configurable session timeout mechanism to allow resources tied to the HTTP session to be freed when the user has stopped performing requests. You can also programmatically force a timeout.

49.6.1 How to Configure the Implicit Timeout Due to User Inactivity

You configure the session timeout threshold using the `<session-timeout>` tag in the `web.xml` file. The default value is typically around 30 minutes, depending on the container. When the `HttpSession` times out the `BindingContext` goes out of scope, and along with it, any data controls that might have referenced application modules released to the pool in the managed state level. The application module pool resets any of these referenced application modules and marks the instances unreferenced again.

49.6.2 How to Code an Explicit HttpSession Timeout

To end a user’s session before the session timeout expires, you can call the `invalidate()` method on the `HttpSession` object from a backing bean in response to the user’s click on a Logout button or link. This cleans up the `HttpSession` in the same way as if the session time had expired. Using JSF and ADF, after invalidating the session, you must perform a redirect to the next page you want to display, rather than just doing a forward. Example 49–6 shows sample code to perform this task from a Logout button.

Example 49–6  Programatically Terminating a Session

```
public String logoutButton_action() throws IOException{
  ExternalContext ectx = FacesContext.getCurrentInstance().getExternalContext();
  HttpServletResponse response = (HttpServletResponse)ectx.getResponse();
```
Managing Custom User-Specific Information

It is fairly common practice to add custom user-defined information in the application module in the form of member variables or some custom information stored in oracle.jbo.Session user data hashtable. The ADF state management facility provides a mechanism to save this custom information to the passivation snapshot as well, by overriding the passivateState() method and the activateState() methods in the ApplicationModuleImpl class.

**Note:** Similar methods are available on the ViewObjectImpl class and the EntityObjectImpl class to save custom state for those objects to the passivation snapshot as well.

49.7.1 How to Passivate Custom User-Specific Information

You can override passivateState() and activateState() to ensure that custom application module state information is included in the passivation/activation cycle. Example 49–7 shows how this is done.

In the example, jbo.counter contains custom values you want to preserve across passivation and activation of the application module state. Each application module has an oracle.jbo.Session object associated with it that stores application module-specific session-level state. The session contains a user data hashtable where you can store transient information. For the user-specific data to "survive" across application module passivation and reactivation, you need to write code to save and restore this custom value into the application module state passivation snapshot.

**Example 49–7  Passivating and Activating Custom Information in the State Snapshot XML Document**

```java
/**
 * Overridden framework method to passivate custom XML elements
 * into the pending state snapshot document
 */
public void passivateState(Document doc, Element parent) {
    // 1. Retrieve the value of the value to save
    int counterValue = getCounterValue();
    // 2. Create an XML element to contain the value
    Node node = doc.createElement(COUNTER);
    // 3. Create an XML text node to represent the value
    Node cNode = doc.createTextNode(Integer.toString(counterValue));
    // 4. Append the text node as a child of the element
    node.appendChild(cNode);
    // 5. Append the element to the parent element passed in
    parent.appendChild(node);
}
/**
 * Overridden framework method to activate custom XML elements
 */
```
* into the pending state snapshot document
*/
public void activateState(Element elem) {
    super.activateState(elem);
    if (elem != null) {
        // 1. Search the element for any <jbo.counter> elements
        NodeList nl = elem.getElementsByTagName(COUNTER);
        if (nl != null) {
            // 2. If any found, loop over the nodes found
            for (int i=0, length = nl.getLength(); i < length; i++) {
                // 3. Get first child node of the <jbo.counter> element
                Node child = nl.item(i).getFirstChild();
                if (child != null) {
                    // 4. Set the counter value to the activated value
                    setCounterValue(new Integer(child.getNodeValue()).intValue()+1);
                    break;
                }
            }
        }
    }
}

/*
* Helper Methods
*/
private int getCounterValue() {
    String counterValue = (String)getSession().getUserData().get(COUNTER);
    return counterValue == null ? 0 : Integer.parseInt(counterValue);
}
private void setCounterValue(int i) {
    getSession().getUserData().put(COUNTER,Integer.toString(i));
}
private static final String COUNTER = "jbo.counter";

49.7.2 What Happens When You Passivate Custom Information

In Example 49–7, when activateState() is overridden, the following steps are performed:

1. Search the element for any jbo.counter elements.
2. If any are found, loop over the nodes found in the node list.
   It should be a DOM Text node whose value is the string you saved when your
   passivateState() method above got called, representing the value of the
   jbo.counter attribute.
4. Set the counter value to the activated value from the snapshot.

When passivateState() is overridden, it performs the reverse job by doing the following:

1. Retrieve the value of the value to save.
2. Create an XML element to contain the value.
3. Create an XML text node to represent the value.
4. Append the text node as a child of the element.
5. Append the element to the parent element passed in.
49.7.3 What You May Need to Know About Activating Custom Information

The `activateState()` method is called at the end of the activation process after the view objects have been activated. Most of the time this is where you want to place the application module state activation logic. However, if your application module activation logic needs to set up custom state information before the ADF state management facility activates the view objects (for example, you might need to write custom code to allow the view objects to internally reference custom values at execution time), then the `prepareForActivation()` method in the `ApplicationModuleImpl` class would be the right place because it fires at the beginning of the activation process.

49.8 Managing the State of View Objects

By default, all view objects are marked as passivation-enabled, so their state will be saved. However, view objects that have transient attributes do not have those attributes passivated by default. You can change how a view object is passivated, and even which attributes are passivated, using the Tuning page of the view object overview editor.

49.8.1 How to Manage the State of View Objects

Each view object can be declaratively configured to be passivation-enabled or not. If a view object is not passivation enabled, then no information about it gets written in the application module passivation snapshot.

**Performance Tip:** There is no need to passivate read-only view objects since they are not intended to be updated and are easily re-created from the XML definition. This eliminates the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

**Before you begin:**

It may be helpful to have an understanding of passivation in view objects. For more information, see Section 49.8, "Managing the State of View Objects."

You will also need to perform the following task:

- Open the application in JDeveloper.

**To set the passivation state of a view object:**

1. In the Applications window, double-click the view object for which you want to set the passivation state.

2. In the overview editor, click the General navigation tab.

3. On the General page, expand the Tuning section and select Passivate State to make sure the view object data is saved.

---

**Note:** The APIs used to manipulate nodes in an XML document are provided by the Document Object Model (DOM) interfaces in the `org.w3c.dom` package. These are part of the Java API for XML Processing (JAXP). See the Javadoc for the `Node`, `Element`, `Text`, `Document`, and `NodeList` interfaces in this package for more details.
49.8.2 What You May Need to Know About Passivating View Objects

The activation mechanism is designed to return your view object to the state it was in when the last passivation occurred. To ensure that, Oracle ADF stores in the state snapshot the values of any bind variables that were used for the last query execution. These bind variables are in addition to those that are set on the row set at the time of passivation. The passivated state also stores the user-supplied WHERE clause on the view object related to the row set at the time of passivation.

49.8.3 How to Manage the State of Transient View Objects and Attributes

Because view objects are marked as passivated by default, a transient view object — one that contains only transient attributes — is marked to be passivation enabled, but only passivates its information related to the current row and other nontransactional state.

**Performance Tip:** Transient view object attributes are not passivated by default. Due to their nature, they are usually intended to be read-only and are easily re-created. So, it often doesn’t make sense to passivate their values as part of the XML snapshot. This also avoids the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

**Before you begin:**
It may be helpful to have an understanding of passivation in view objects. For more information, see Section 49.8, “Managing the State of View Objects.”

You will also need to perform the following task:

- Open the application in JDeveloper.

**To individually set the passivation state for transient view object attributes:**
1. In the Applications window, double-click the view object that contains the transient attributes for which you want to specify the passivation state.
2. In the overview editor, click the **Attributes** navigation tab.
3. On the Attributes page, select the transient attribute you want to passivate and click the **Details** tab.
4. In the Details page, select the **Passivate** checkbox.

49.8.4 What You May Need to Know About Passivating Transient View Objects

Passivating transient view object attributes is more costly resource-wise and performance-wise, because transactional functionality is usually managed on the entity object level. Since transient view objects are not based on an entity object, this means that all updates are managed in the view object row cache and not in the entity cache. Therefore, passivating transient view objects or transient view object attributes requires special runtime handling.
Managing the State of View Objects

Usually passivation only saves the values that have been changed, but with transient
view objects passivation has to save entire row. The row will include only the view
object attributes marked for passivation.

49.8.5 How to Use Transient View Objects to Store Session-level Global Variables

Using passivation, you can use a view object to store one or more global variables,
each on a different transient attribute. When you mark a transient attribute as
passivated, the ADF Business Components framework will remember the transient
values across passivation and activation in high-throughput and failover scenarios.
Therefore, it is an easy way to implement a session-level global value that is backed up
by the state management mechanism, instead of the less-efficient HTTP Session
replication. This also makes it easy to bind to controls in the UI if necessary.

There are two basic approaches to store values between invocations of different
screens, one is controller-centric, and the other is model-centric.

To implement this task in the ADF controller layer using the controller-centric
approach involves storing and referencing values using attributes in the pageFlow
scope. This approach might be appropriate if the global values do not need to be
referenced internally by any implementations of ADF Business Components. For more
information about pageFlow scope, see Section 20.2.4, "What You May Need to Know
About Memory Scope for Task Flows."

The model-centric approach involves creating a transient view object, which is
conceptually equivalent to a nondatabase block in Oracle Forms.

Before you begin:
It may be helpful to have an understanding of passivation in view objects. For more
information, see Section 49.8, "Managing the State of View Objects."

You will also need to perform the following tasks:

1. Open the application in JDeveloper.
2. Create a new view object using the View Object wizard, as described in
   Section 5.2.1, "How to Create an Entity-Based View Object."
   a. On Page 1 of the wizard, select the option for Data Source: Programmatic.
   b. On Page 2, click New to define the transient attribute names and types the
      view object should contain.
   c. On Page 3, set the Updatable option to Always for each attribute.
   d. Click Finish and the newly created view object appears in the overview editor.

To store session-level global variables using the model-centric approach:
1. Disable any entries from being performed in the view object:
   a. In the overview editor, on the General page, expand the Tuning section.
   b. In the Retrieve from the Database group, select the No Rows option.

2. Make sure data in the view object is not cleared out during a rollback operation. To
   implement this, you enable a custom Java class for the view object and override
two rollback methods.
   a. In the overview editor, click the Java navigation tab, and click the Edit icon for
      the Java Classes section.
b. In the Select Java Options dialog, select **Generate View Object Class** and click OK.

c. In the overview editor, click the link next to View Object Class in the **Java Classes** section.

d. From the main menu, choose **Source > Override Methods**.

e. In the Override Methods dialog, select the **beforeRollback()** and **afterRollback()** methods to override, and click then OK.

f. In both the **beforeRollback()** and **afterRollback()** methods, comment out the call to **super** in the Java code.

3. Add an instance of the transient view object to your application module's data model, as described in Section 13.2.3.2, "Adding Master-Detail View Object Instances to an Application Module."

4. Create an empty row in the view object when a new user begins using the application module:

   a. In the Applications window, double-click the application module.

   b. Generate an application module Java class if you don't have one yet, as described in Section 13.7.1, "How to Generate a Custom Class for an Application Module."

   c. Override the **prepareSession()** method of the application module, as described in Section 13.11.1, "How to Override a Built-in Framework Method."

   d. After the call to **super.prepareSession()**, add code to create a new row in the transient view object and insert it into the view object.

Now you can bind read-only and updatable UI elements to the "global" view object attributes just as with any other view object using the Data Controls panel.

### 49.9 Using State Management for Middle-Tier Savepoints

In the database server you are likely familiar with the savepoint feature that allows a developer to rollback to a certain point within a transaction instead of rolling back the entire transaction. An application module offers the same feature but implemented in the middle tier.

---

**Best Practice:** Oracle ADF provides a declarative approach to working with savepoints, described in Section 24.7, "Using Save Points in Task Flows." Use the programmatic approach described in Section 49.9.1, "How to Use State Management for Savepoints" only if the declarative approach doesn’t meet your needs.

---

### 49.9.1 How to Use State Management for Savepoints

To use state management for implementing middle-tier savepoints, you override three methods in the `oracle.jbo.ApplicationModule` interface:

```java
public String passivateStateForUndo(String id, byte[] clientData, int flags)
public byte[] activateStateForUndo(String id, int flags)
public boolean isValidIdForUndo(String id)
```

You can use these methods to create a stack of named snapshots and restore the pending transaction state from them by name. Keep in mind that those snapshots do
not survive past duration of transaction (for example, events of commit or rollback). This feature could be used to develop complex capabilities of the application, such as the ability to undo and redo changes. Another ambitious goal that could exploit this functionality would be functionality to make the browser back and forward buttons behave in an application-specific way. Otherwise, simple uses of these methods can come in quite handy.

49.10 Testing to Ensure Your Application Module is Activation-Safe

If you have not explicitly tested that your application module functions when its pending state gets activated from a passivation snapshot, then you may encounter an unpleasant surprise in your production environment when heavy system load tests this aspect of your system for the first time.

49.10.1 Understanding the jbo.ampool.doampooling Configuration Parameter

The jbo.ampool.doampooling configuration property corresponds to the Enable Application Module Pooling option in the Pooling and Scalability tab of the Edit Configuration dialog. By default, this checkbox is checked so that application module pooling is enabled. Whenever you deploy your application in a production environment the default setting of jbo.ampool.doampooling to true is the way you will run your application. But, as long as you run your application in a test environment, setting the property to false can play an important role in your testing. When this property is false, there is effectively no application pool. When the application module instance is released at the end of a request it is immediately removed. On subsequent requests made by the same user session, a new application module instance must be created to handle it and the pending state of the application module must be reactivated from the passivation store.

49.10.2 How To Disable Application Module Pooling to Test Activation

As part of your overall testing plan, you should adopt the practice of testing your application modules with the jbo.ampool.doampooling configuration parameter set to false. This setting completely disables application module pooling and forces the system to activate your application module’s pending state from a passivation snapshot on each page request. It is an excellent way to detect problems that might occur in your production environment due to assumptions made in your custom application code.

---

**Caution:** It is important to reenable application module pooling after you conclude testing and are ready to deploy the application to a production environment. The configuration property jbo.ampool.doampooling set to false is not a supported configuration for production applications and must be set to true before deploying the application.

---

For example, if you have transient view object attributes you believe should be getting passivated, this technique allows you to test that they are working as you expect. In addition, consider situations where you might have introduced:

- Private member fields in application modules, view objects, or entity objects
- Custom user session state in the Session user data hashtable
Keeping Pending Changes in the Middle Tier

Your custom code likely assumes that this custom state will be maintained across HTTP requests. As long as you test with a single user on the JDeveloper Integrated WebLogic Server, or test with a small number of users, things will appear to work fine. This is due to the "stateless with affinity" optimization of the ADF application module pool. If system load allows, the pool will continue to return the same application module instance to a user on subsequent requests. However, under heavier load, during real-world use, it may not be able to achieve this optimization and will need to resort to grabbing any available application module instance and reacting its pending state from a passivation snapshot. If you have not correctly overridden passivateState() and activateState() (as described in Section 49.7, "Managing Custom User-Specific Information") to save and reload your custom component state to the passivation snapshot, then your custom state will be missing (i.e. null or back to your default values) after this reactivation step. Testing with jbo.ampool.doampooling set to false allows you to quickly isolate these kinds of situations in your code.

49.11 Keeping Pending Changes in the Middle Tier

The ADF state management mechanism relies on passivation and activation to manage the state of an application module instance. Implementing this feature in a robust way is only possible if all pending changes are managed by the application module transaction in the middle tier. The most scalable strategy is to keep pending changes in middle-tier objects and not perform operations that cause pending database state to exist across HTTP requests. This allows the highest leverage of the performance optimizations offered by the application module pool and the most robust runtime behavior for your application.

Caution: When the jbo.doconnectionpooling configuration parameter is set to true — typically in order to share a common pool of database connections across multiple application module pools — upon releasing your application module to the application module pool, its JDBC connection is released back to the database connection pool and a ROLLBACK will be issued on that connection. This implies that all changes which were posted but not committed will be lost. On the next request, when the application module is used, it will receive a JDBC connection from the pool, which may be a different JDBC connection instance from the one it used previously. Those changes that were posted to the database but not committed during the previous request are lost.

The jbo.doconnectionpooling configuration parameter is set by checking the Disconnect Application Module Upon Release property on the Pooling and Scalability tab of the Edit Configuration dialog.

49.11.1 How to Confirm That Applications Use Optimistic Locking

Oracle recommends using optimistic locking, the default mode for web applications. Pessimistic locking should not be used for web applications as it creates pending transactional state in the database in the form of row-level locks. If pessimistic locking is set, state management will work, but the locking mode will not perform as expected. Behind the scenes, every time an application module is recycled, a rollback is issued in the JDBC connection. This releases all the locks that pessimistic locking had created.
To ensure your configuration uses optimistic locking, open the **Properties** tab of the Edit Configuration dialog and confirm that the value of the `jbo.locking.mode` property is set to `optimistic` or `optupdate`.

**Note:** To open the Edit Configuration dialog, double-click the application module in the Applications window, and select the **Configurations** navigation tab from the overview editor. Then, in the Configurations page of the overview editor, select the configuration and click **Edit**.

Optimistic locking (optimistic) issues a `SELECT FOR UPDATE` statement to lock the row, then detects whether the row has been changed by another user by comparing the change indicator attribute — or, if no change indicator is specified, the values of all the persistent attributes of the current entity as they existed when the entity object was fetched into the cache.

Optimistic update locking (optupdate) does not perform any locking. The `UPDATE` statement determines whether the row was updated by another user by including a `WHERE` clause that will match the existing row to update only if the attribute values are unchanged since the current entity object was fetched.

### 49.11.2 How to Avoid Clashes Using the `postChanges()` Method

The transaction-level `postChanges()` method exists to force the transaction to post unvalidated changes without committing them. This method is not recommended for use in web applications unless you can guarantee that the transaction will definitely be committed or rolled-back during the same HTTP request. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

### 49.11.3 How to Use the Reserved Level For Pending Database States

If for some reason you need to create a transactional state in the database in a particular request by invoking the `postChanges()` method or by calling a PL/SQL stored procedure, but you cannot issue a commit or rollback by the end of that same request, then you **must** release the application module instance with the reserved level from that request until a subsequent request when you either commit or rollback.

**Performance Tip:** Use as short a period of time as possible between creation of transactional state in the database and performing the concluding commit or rollback. This ensures that reserved level doesn’t have to be used for a long time, as it has adverse effects on application’s scalability and reliability.

Once an application module has been released with reserved level, it remains at that release level for all subsequent requests until release level is explicitly changed back to
managed or unmanaged level. So, it is your responsibility to set release level back to managed level once commit or rollback has been issued.

For more information, see Section 49.4, "Setting the Application Module Release Level at Runtime."
This chapter describes how ADF Business Components application module pools work and how you can tune both application module pools and database connection pools to optimize application performance.

This chapter includes the following sections:

- Section 50.1, "About Application Module Pooling"
- Section 50.2, "Setting Pool Configuration Parameters"
- Section 50.3, "Initializing Database State and Pooling Considerations"
- Section 50.4, "Deployment Environment Scenarios and Pooling"

## 50.1 About Application Module Pooling

An application module pool is a collection of application module runtime instances of the same type. To provision a number of users visiting it, an application can be configured to provide one or more application module instances from the pool to service users at runtime.

Each application module instance in a pool is shared by multiple browser clients whose typical "think time" between submitting web pages allows optimizing the number of application module components to be effectively smaller than the total number of active users working on the system. For example, twenty users visiting the website from their browser might be able to be serviced by 5 or 10 application module instances instead of having as many application module instances as you have browser users. Therefore, not only can the pool service more users than the number of application modules available, but in addition the middle tier requires less memory to service this smaller set of application modules allowing ADF applications to scale further on limited hardware resources.

Through your design-time configuration, application modules can be used to support Fusion web application scenarios that are completely stateless, or they can be used to support a unit of work that spans multiple browser pages. As a performance optimization, when an instance of an application module is returned to the pool in "managed state" mode, the pool tracks session references to the application module. The application module instance is still in the pool and available for use, but it would prefer to be used by the same session that was using it the last time because maintaining this "session affinity" improves performance.

So, at any one moment in time, the instances of application modules in the pool are logically partitioned into three groups, reflecting their state:
Unconditionally available for use
- Available for use, but referenced for session affinity reuse by an active user session
- Unavailable, inasmuch as it’s currently in use (at that very moment) by some thread in the web container.

Section 50.2.5, “What You May Need to Know About Configuration Property Scopes” describes the application module pool configuration parameters and how they affect the behavior of the pool.

50.1.1 Types of Pools Created When Running the Fusion Web Application

There are two kinds of pools in use when running a typical Fusion web application, application module pools and database connection pools. Applications typically use application module pools, but rarely use connection pools. Connection pools are only used when your application defines the JDBC URL connection type, instead of the default JNDI data source connection type. You primarily need to understand how many of each kind of pool your application will create.

50.1.1.1 Application Module Pools

Application Module components can be used at runtime in two ways:
- As an application module the client accesses directly
- As a reusable component aggregated (or “nested”) inside of another application module instance

When a client accesses it directly, an application module is called a root application module. Clients access nested application modules indirectly as a part of their containing application module instance. It’s possible, but not common, to use the same application module at runtime in both ways. The important point is that ADF Business Components only creates an application module pool for a root application module.

The basic rule is that one application module pool is created for each root application module used by a Fusion web application in each Java VM where a root application module of that type is used by the ADF Controller layer. For advanced topics related to the number of application module pools your application may need, see Section 50.4, “Deployment Environment Scenarios and Pooling.”

50.1.1.2 Database Connection Pools

The type of database connection pool the Fusion web application uses depends on the connection type that you configure for your application modules:
- JDBC URL (e.g. jdbc:oracle:thin:@penguin:1521:ORCL)
- JNDI name for a data source (e.g. java:comp/env/jdbc/YourConnectionDS)

JDeveloper configures the application module by default to use the data source connection type. A JDBC data source is a vendor-independent encapsulation of a database server connection. The JDBC data source offers advantages that the JDBC URL connection type does not. When you define a connection type based on a data source, you reconfigure the data source without changing the deployed application. The data source is also centrally defined at the application server level, whereas JDBC URL connections are not. In cases where a JDBC data source is not viable, at runtime, ADF Business Components will construct a default JDBC URL based on the data source connection information.

If you supply a JDBC URL connection while configuring your application module — which happens when you select a JDeveloper named connection which encapsulates
the JDBC URL and username information — then the ADF database connection pool will be used for managing the connection pool.

If you use the default and supply the JNDI name of a JDBC data source then the ADF database connection pool will not be used and the configuration parameters described below relating to the ADF database connection pool are not relevant.

---

**Note:** To configure the database connection pool for JDBC data sources looked-up by JNDI from your Java EE web and/or EJB container, consult the documentation for your Java EE container to understand the pooling configuration options and how to set them.

---

When using ADF database connection pooling, you have the following basic rule: One database connection pool is created for each unique `<JDBCURL, Username>` pair, in each Java VM where a `<JDBCURL, Username>` connection is requested by a root application used by the ADF Controller layer. For advanced topics related to the number of connection pools your application may need, see Section 50.4, "Deployment Environment Scenarios and Pooling."

### 50.2 Setting Pool Configuration Parameters

You control the runtime behavior of an application module pool by setting appropriate configuration parameters. You can set these declaratively in an application module configuration, supply them as Java System parameters, or set them programmatically at runtime.

#### 50.2.1 How to Set Configuration Properties Declaratively

The **Pooling and Scalability** tab of the Edit Configuration dialog shown in Figure 50–1 is used for viewing and setting parameters.

*Figure 50–1  Pooling and Scalability Tab of the Edit Configuration Dialog*
Before you begin:
It may be helpful to have an understanding of connection pooling. For more information, see Section 50.2, "Setting Pool Configuration Parameters."

You may also find it helpful to understand functionality that can be added using other Oracle ADF features.

To edit your application module's pooling configuration:
1. In the Applications window, double-click the application module.
2. In the overview editor, click the Configurations navigation tab.
3. In the Configurations page, double-click the configuration you want to edit.
4. In the Edit Configuration dialog, click the Pooling and Scalability tab and edit the desired runtime properties and click OK to save the changes for your configuration.

50.2.2 What Happens When You Set Configuration Properties Declaratively

The values that you supply through the Edit Configuration dialog are saved in an XML file named bc4j.xcfg in the ./common subdirectory relative to the application module's XML document. All of the configurations for all of the application modules in a single Java package are saved in that same file. Typically, you do not modify the bc4j.xcfg file directly and use the Edit Configuration dialog to change configuration settings for the application module.

For example, if you look at the bc4j.xcfg file in the ./src/oracle/summit/model/services/common directory of the SummitADF application workspace, you will see the two named configurations for the BackOfficeAppModule application module, as shown in Example 50–1. In this case, the BackOfficeAppModuleLocal and the BackOfficeAppModuleShared configurations specify JDBC URL connections for use by the Oracle ADF Model Tester. The connection details for the JDBC connections appear in the connections.xml file located in the ./adf/META-INF subdirectory relative to the project directory.

Example 50–1  Configuration Settings for the BackOfficeAppModule

```xml
<BC4JConfig version='11.1' xmlns='http://xmlns.oracle.com/bc4j/configuration'>
  ...
  < AppModuleConfigBag
    ApplicationName='oracle.summit.model.services.BackOfficeAppModule'>
    < AppModuleConfig
      name='BackOfficeAppModuleLocal'
      jbo.project='oracle.summit.model.Model'
      ApplicationName='oracle.summit.model.services.BackOfficeAppModule'
      DeployPlatform='LOCAL' JDBCName='summit_adf'>
      < Database jbo.TypeMapEntries='Java'/>
      < Security
        AppModuleJndiName='oracle.summit.model.services.BackOfficeAppModule'/> 
    </ AppModuleConfig>
    < AppModuleConfig
      name='BackOfficeAppModuleShared'
      jbo.project='oracle.summit.model.Model'
      ApplicationName='oracle.summit.model.services.BackOfficeAppModule'
      DeployPlatform='LOCAL' JDBCName='summit_adf'>
      < AM-Pooling jbo.ampool.maxpoolsizes='1'
        jbo.ampool.isuseexclusive='false'/>
      < Database jbo.TypeMapEntries='Java'/> 
    </ AppModuleConfig>
  </ AppModuleConfigBag> 
</ BC4JConfig>
```
Note that attributes of child elements of the `<AppModuleConfig>` tag have names beginning with `jbo` that match the names of their ADF Business Components properties (for example, the `<AM-Pooling>` tag defines the attribute `jbo.ampool.maxpoolsize` that corresponds to the property `jbo.ampool.maxpoolsize`). It’s also important to understand that if a property is currently set to its runtime default value in the Edit Configuration dialog, then JDeveloper does not write the entry to the `bc4j.xcfg` file.

50.2.3 How to Set Configuration Properties as System Parameters

As an alternative to specifying configuration properties in the `bc4j.xcfg` file, you can also set Java VM system parameters with the same property names. These system parameters will be used only if a corresponding property does not exist in the relevant `bc4j.xcfg` file for the application module in question. In other words, configuration parameters that appear in the application module configuration take precedence over parameters of the same name supplied as Java system parameters.

It may be useful to set configuration properties as Java VM system parameters when all ADF applications running on a particular Java VM require the same configuration value setting for particular parameters. In this case, you must not set the configuration properties in the `bc4j.xcfg` file and you should confirm that the Edit Configuration dialog displays no value for the desired property, as described in Section 50.2.1, "How to Set Configuration Properties Declaratively."

You typically set Java system parameters using the `-D` command line flag to the Java VM like this:

```
java -Dproperty=value -jar yourserver.jar
```

Alternatively, your Java EE container probably has a section in its own configuration files where Java system parameters can be specified for use at Java EE container startup time.

If you adopt the technique of specifying site-specific default values for Oracle ADF configuration parameters as Java system parameters, you should make sure that your application’s `bc4j.xcfg` files do not include references to these parameters unless you want to define an application-module-specific exception to these global default values.

---

**Caution:** The values of Idle Instance Timeout, Pool Polling Interval settings for both the Application Pool and the database Connection Pool are displayed and edited in this dialog as a number of seconds, but are saved to the configuration file in milliseconds. If you provide a value for any of these four parameters as a Java System parameter — or if you hand-edit the `bc4j.xcfg` file — make sure to provide these time interval values in milliseconds!
50.2.4 How to Programmatically Set Configuration Properties

When your application requires control over application module configuration properties at runtime, you can dynamically set these properties using ADF Business Components API. For example, in a typical ADF application, your application module may configure a static JDBC data source. However, when the application needs to display data, depending upon the user, from various databases, you might set the data source name and application module pool parameters at runtime.

You can set configuration properties programmatically by creating a Java class that implements the EnvInfoProvider interface in the oracle.jbo.common.ampool package. In your class, you override the getInfo() method and call put() to put values into the environment Hashtable passed in as shown in Example 50–2.

Example 50–2 Setting Environment Properties with a Custom EnvInfoProvider

```java
package devguide.advanced.customenv.view;
import java.util.Hashtable;
import oracle.jbo.common.ampool.EnvInfoProvider;
/**
 * Custom EnvInfoProvider implementation to set
 * environment properties programmatically
 */
public class CustomEnvInfoProvider implements EnvInfoProvider {
    /**
     * Overridden framework method to set custom values in the
     * environment hashtable.
     *
     * @param string - ignore
     * @param environment Hashtable of config parameters
     * @return null - not used
     */
    public Object getInfo(String string, Object environment) {
        Hashtable envHashtable = (Hashtable)environment;
        envHashtable.put("some.property.name","some value");
        return null;
    }
    /* Required to implement EnvInfoProvider */
    public void modifyInitialContext(Object object) {}
    /* Required to implement EnvInfoProvider */
    public int getNumOfRetries() {return 0;}
}
```

When creating an application module for a stateless or command-line-client, with the createRootApplicationModule() method of the Configuration class, you can pass the custom EnvInfoProvider as the optional second argument. In order to use a custom EnvInfoProvider in an ADF web-based application, you need to implement a custom session cookie factory class as shown in Example 50–3. To use your custom session cookie factory, set the jbo.ampool.sessioncookiefactoryclass configuration property to the fully qualified name of your custom session cookie factory class.

Example 50–3 Custom SessionCookieFactory to Install a Custom EnvInfoProvider

```java
package devguide.advanced.customenv.view;
import java.util.Properties;
import oracle.jbo.common.ampool.ApplicationPool;
import oracle.jbo.common.ampool.EnvInfoProvider;
import oracle.jbo.common.ampool.SessionCookie;
import oracle.jbo.http.HttpSessionCookieFactory;
```
public class CustomHttpSessionCookieFactory extends HttpSessionCookieFactory {
    public SessionCookie createSessionCookie(String appId, String sessionId, ApplicationPool pool, Properties props) {
        SessionCookie cookie = super.createSessionCookie(appId, sessionId, pool, props);
        EnvInfoProvider envInfoProv = new CustomEnvInfoProvider();
        cookie.setEnvInfoProvider(envInfoProv);
        return cookie;
    }
}

50.2.5 What You May Need to Know About Configuration Property Scopes

Each runtime configuration property used by ADF Business Components has a scope. The scope of each property indicates when the property’s value is evaluated and whether its value is effectively shared (i.e. static) in a single Java VM, or not. The ADF Business Components PropertyManager class is the registry of all supported properties. It defines the property names, their default values, and their scope. This class contains a main() method so that you can run the class from the command line to see a list of all the configuration property information.

Assuming JDEVHOME is the JDeveloper installation directory, to see this list of settings for reference, do the following:

$ java -cp JDEVHOME/BC4J/lib/bc4jmt.jar oracle.jbo.common.PropertyManager

Issuing this command will send all of the ADF Business Components configuration properties to the console. It also lists a handy reference about the different levels at which you can set configuration property values and remind you of the precedence order these levels have:

Properties loaded from following sources, in order:
1. Client environment [Provided programmatically
   or declaratively in bc4j.xcfg]
2. Applet tags
3. -D flags (appear in System.properties)
4. bc4j.properties file (in current directory)
5. /oracle/jbo/BC4J.properties resource
6. /oracle/jbo/common.jboserver.properties resource
7. /oracle/jbo/common.Diagnostic.properties resource
8. System defined default

You’ll see each property is listed with one of the following scopes:
- MetaObjectManager
  Properties at this scope are initialized once per Java VM when the ADF PropertyManager is first initialized.
- SessionImpl
Properties at this scope are initialized once per invocation of
ApplicationModule.prepareSession().

- **Configuration**
  Properties at this scope are initialized when the ApplicationModule pool is first
  created and the application module's configuration is read the first time.

- **Diagnostic**
  Properties at this scope are specific to the built-in ADF Business Components
diagnostic facility.

At each of these scopes, the layered value resolution described above is performed
when the properties are initialized. Whenever property values are initialized, if you
have specified them in the Client Environment (level 1 in the resolution order) the
values will take precedence over values specified as System parameters (level 3 in the
resolution order).

The Client Environment is a hashtable of name/value pairs that you can either
programatically populate, or which will be automatically populated for you by the
Configuration object when loaded, with the name/value pairs it contains in its
entry in the bc4j.xcfg file. The implication of this is that for any properties scoped
at MetaObjectManager level, the most reliable way to ensure that all of your
application modules use the same default value for those properties is to do both of
the following:

1. Make sure the property value does not appear in any of your application module's
   bc4j.xcfg file configuration name/value pair entries.
2. Set the property value using a Java system property in your runtime environment.

If, instead, you leave any MetaObjectManager-scoped properties in your bc4j.xcfg
files, you will have the undesirable behavior that they will take on the value specified
in the configuration of the first application module whose pool gets created after the
Java VM starts up.

### 50.2.6 What You May Need to Know About How Database and Application Module
Pools Cooperate

How ADF application module pools use the database connection pool depends on the
setting of the jbo.doconnectionpooling application module configuration
parameter. In the Pooling and Scalability page of the Edit Configuration dialog shown
in Figure 50-1, you set this parameter using the checkbox labelled Disconnect
Application Module Upon Release.

---

**Note:** The notion of *disconnecting* the application module upon
release to the pool better captures what the actual feature is doing
than the related configuration parameter name
(jbo.doconnectionpooling) does. The setting of
jbo.doconnectionpooling=false does not mean that there is no
database connection pooling happening. What it means is that the
application module is not disconnected from its JDBC connection
upon check in back to the application module pool.

---

If the default setting of jbo.doconnectionpooling=false is used, then when an
application module instance is created in any pool it acquires a JDBC connection from
the appropriate connection pool (based on the JDBC URL in the ADF case, or from the
underlying JDBC data source implementation’s pool in the case of a JNDI data source name). That application module instance holds onto the JDBC connection object that it acquired from the pool until the application module instance is removed from the application module pool. During its lifetime, that application module instance may service many different users, and ADF worries about issuing rollbacks on the database connection so that different users don’t end up getting pending database state confused. By holding onto the JDBC connection, it allows each application module instance to keep its JDBC PreparedStatement objects cached and reusable across subsequent accesses by clients, thereby providing the best performance.

If jbo.doconnectionpooling=true, then each time a user session finishes using an application module (typically at the end of each HTTP request), the application module instance disassociates itself with the JDBC connection it was using on that request and it returns it to the JDBC connection pool. The next time that application module instance is used by a user session, it will reacquire a JDBC connection from the JDBC connection pool and use it for the span of time that application module is checked out of the application module pool (again, typically the span of one HTTP request). Since the application module instance “unplugs” itself from the JDBC connection object used to create the PreparedStatements it might have used during the servicing of the current HTTP request, those PreparedStatements are no longer usable on the next HTTP request because they are only valid in the context of the Connection object in which they were created. So, when using the connection pooling mode turned on like this, the trade-off is slightly more JDBC overhead setup each time, in return for using a smaller number of overall database connections.

The key difference is seen when many application module pools are all using the same underlying database user for their application connection.

- If 50 different application module pools each have even just a single application module instance in them, with jbo.doconnectionpooling=false there will be 50 JDBC application connections in use. If the application module pooling parameters are set such that the application module pools are allowed to shrink to 0 instances after an appropriate instance idle timeout by setting jbo.ampool.minavailablesize=0, then when the application module is removed from its pool, it will put back the connection it’s holding onto.

- In contrast, if 50 different application module pools each have a single application module instance and jbo.doconnectionpooling=true, then the amount of JDBC connections in use will depend on how many of those application modules are simultaneously being used by different clients. If an application module instance is in the pool and is not currently being used by a user session, then with jbo.doconnectionpooling=true it will have released its JDBC connection back to the connection pool and while the application module instance is sitting there waiting for either another user to need it again, or to eventually be cleaned up by the application module pool monitor, it will not be "hanging on" to a JDBC connection.

**Performance Tip:** Leave the jbo.doconnectionpooling configuration parameter set to false for best performance without sacrificing scalability and reliability. Database connection pooling is still achieved through application module pooling. The only exception is when multiple application module pools (and therefore a large number of application module instances) share the same database, making the total available database connections the highest priority.

Highest performance is achieved by not disconnecting the application module instance from its database connection on each check in to the application module pool.
Accordingly, the default setting of the \texttt{jbo.doconnectionpooling} configuration parameter is \texttt{false}. The pooling of application module instances is already an effective way to optimize resource usage, and the Oracle ADF runtime is more efficient when you do not have to disconnect application module instances from their associated JDBC connection after each release to the pool. Effectively, by pooling the application modules which are related one-to-one with a JDBC connection, you are already achieving a pooling of database connections that is optimal for most Fusion web applications.

However, when minimizing the total overall number of database sessions is a priority, one situation in which it might be appropriate to use database connection pooling is when you have a large number of application module pools all needing to use database connections from the same underlying application user at the database level. In this case, the many application module pools can economize on the total overall database sessions by sharing a single, underlying database connection pool of JDBC connections, albeit at a loss of efficiency of each one. This choice would be favored only if total overall database sessions is of maximum priority. In this scenario, if a user scrolls through some, but not all rows of a view object's row set, then with \texttt{jbo.doconnectionpooling=true}, Oracle ADF will automatically passivate the pending application module state (including current row information) so that the next time the application module is used, the queried view object can be put back into the same current row with the same initial rows fetched. This passivation behavior may reduce performance.

To achieve a more ideal balance between conserving JDBC connections and keeping all application modules connected to the database, you can configure \texttt{jbo.ampool.connection_threshold}. This runtime property specifies the maximum number of connections that application modules in all application module pools combined may hold onto without releasing back to the connection pool upon checkin. Setting the maximum number of connections implies disconnecting application modules upon release is desired and automatically enables \texttt{jbo.doconnectionpooling=true}. For more details about optimizing the \texttt{jbo.doconnectionpooling} property, see Section 50.3.2, "What You May Need to Know About Optimizing Connection Pooling."

### 50.2.7 What You May Need to Know About Application Module Pool Parameters

The application module pool configuration parameters fall into three logical categories relating to pool behavior, pool sizing, and pool cleanup behavior.

#### 50.2.7.1 Pool Behavior Parameters

Table 50–1 lists the application module configuration parameters that affect the behavior of the application module pool.
### Table 50–1 Application Module Pool Behavior Configuration Parameters

<table>
<thead>
<tr>
<th>Pool Configuration Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Failover Transaction State Upon Managed Release (jbo.dofailover)</td>
<td>Specifies whether to disable or enable failover. By default, failover is disabled. To enable failover, set the parameter to <code>true</code>. When enabled, the Oracle ADF framework performs eager passivation of the pending transaction state each time an application module is released to the pool in &quot;Managed State&quot; mode. See Section 49.2.2.2, &quot;How Passivation Changes When Optional Failover Mode is Enabled&quot; for more information. The failover feature is disabled by default (jbo.dofailover=false) as a performance optimization when there is only one web server instance configured, thus reducing the need for passivation and activation. This allows for application module affinity to a specific user session. <strong>Note:</strong> When enabling application module state passivation, a failure can occur when Oracle WebLogic Server is configured to forcibly release connections back into the pool. A failure of this type produces a <code>SQLException</code> (Connection has already been closed.) that is saved to the server log. The exception is not reported through the user interface. To ensure that state passivation occurs and users' changes are saved, set an appropriate value for the <code>weblogic-application.xml</code> deployment descriptor parameter <code>inactive-connection-timeout-seconds</code> on the <code>&lt;connection-check-params&gt;</code> pool params element. Setting the deployment descriptor parameter to several minutes, in most cases, should avoid forcing the inactive connection timeout and the resulting passivation failure. Adjust the setting as needed for your environment.</td>
</tr>
</tbody>
</table>
Setting Pool Configuration Parameters

Developing Fusion Web Applications with Oracle Application Development Framework

---

### Table 50–1  (Cont.) Application Module Pool Behavior Configuration Parameters

<table>
<thead>
<tr>
<th>Pool Configuration Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Row-Level Locking Behavior Upon Release (jbo.locking.mode)</td>
<td>Specifies the locking mode (optimistic or pessimistic). The default is optimistic, which forces the application module pool not to create a pending transaction state on the database with row-level locks each time the application module is released to the pool. See Section 49.11.1, ‘How to Confirm That Applications Use Optimistic Locking’ for more information. Fusion web applications should leave the locking mode set to the default value optimistic to avoid creating the row-level locks. This parameter is not configurable in the Edit Configuration dialog. To edit the jbo.locking.mode parameter, open the Business Components page of the overview editor for the adf-config.xml file, located in the ADF META-INF folder in the Application Resources pane of the Applications window. This feature is enabled by default and set to optimistic.</td>
</tr>
<tr>
<td>Disconnect Application Module Upon Release (jbo.doconnectionpooling)</td>
<td><strong>Note:</strong> This parameter’s name is misleading and is better understood by the name Disconnect Application Module Upon Release, as shown in the Edit Configuration dialog. Specifies whether the application module instance can be disconnected from the database connection when the application module instance is returned to the application module pool. This enables an application to size the application module pool larger than the database connection pool. The default is false, which means that an application module instance can retain its database connection when the application module instance is returned to the application module pool. When set to true, the application module can release the database connection back to the database connection pool when the application module instance is returned to the application module pool. Note that before an application module is disconnected from the database connection, a rollback can be issued on that database connection to revert any pending database state. See also jbo.ampool.connection_threshold to achieve an ideal balance between conserving connections and using in-memory application module passivation. See Section 50.2.6, ‘What You May Need to Know About How Database and Application Module Pools Cooperate’ for more information. This feature is disabled by default (false).</td>
</tr>
<tr>
<td>Pool Configuration Parameter</td>
<td>Description</td>
</tr>
<tr>
<td>------------------------------</td>
<td>-------------</td>
</tr>
<tr>
<td>Disconnect Application Module Upon Reaching Maximum Connection Threshold (jbo.ampool.connection_threshold)</td>
<td>Specifies whether to force application modules to hold onto their JDBC connections so they do not release back to the connection pool upon checkin until a maximum number of JDBC connections is reached for all application modules in all application module pools combined. The default is to disable this feature (jbo.ampool.connection_threshold=0) which avoids the overhead associated with normal connection pooling. Setting a connection threshold to a limit greater than 0 enables this feature. When the threshold is reached, connections will be released on the next pool cleanup cycle starting with least recently used, available application modules. Setting a non-zero connection threshold implies disconnecting application modules upon release is desired and automatically enables jbo.doconnectionpooling=true. See Section 50.3.2, “What You May Need to Know About Optimizing Connection Pooling” for more information. Setting a non-zero connection threshold releases JDBC connections during application module pool cleanup instead of during application module checkin. To ensure JDBC connections are released efficiently, configure jbo.ampool.monitorsleepinterval to shorten the monitor sleep period. This feature is disabled by default (jbo.ampool.connection_threshold=0).</td>
</tr>
</tbody>
</table>
Setting Pool Configuration Parameters

Transaction Memory State Upon Release

(jbo.txn.disconnect_level)

Specifies whether the application module, view objects and row sets remain in memory and stay valid but allow their corresponding references to JDBC objects to be dropped. Passivation in memory is enabled by default (jbo.txn.disconnect_level=1). Upon activation, the framework reexecutes and synchronizes the cursor positions.

When used in conjunction with jbo.doconnectionpooling=true or jbo.ampool.connection_threshold, improves performance and reduces the memory overhead associated with this situation. See Section 50.3.2, "What You May Need to Know About Optimizing Connection Pooling" for more information.

Setting jbo.txn.disconnect_level=0, changes the application module passivation behavior so that the view objects and their row sets are closed and removed. In this case, view objects and their row sets will be re-created and reverted to their original state upon activation. Configuring jbo.txn.disconnect_level to 1 can prevent this behavior to avoid the passivation costs for this situation.

This feature is enabled by default (jbo.txn.disconnect_level=1).

Enable Application Module Pooling

(jbo.ampool.doampooling)

Specifies whether to enable application module pooling. By default application pooling is enabled (true).

Whenever you deploy your application in a production environment the default setting of jbo.ampool.doampooling set to true is the way you will run your application. But, as long as you run your application in a test environment, setting the property to false can play an important role in your testing. When this property is false, there is effectively no application pool. See Section 49.10, "Testing to Ensure Your Application Module is Activation-Safe" for more information.

This feature is enabled by default (true).

Support Dynamic JDBC Credentials

(jbo.ampool.dynamicjdbccredentials)

Specifies whether to enable additional pooling lifecycle events to allow developer-written code to change the database credentials (username/password) each time a new user session begins to use the application module.

This feature is enabled by default (true), however this setting is a necessary but not sufficient condition to implement the feature. The complete implementation requires additional developer-written code.
50.2.7.2 Pool Sizing Parameters

Table 50–2 lists the application module configuration parameters that affect the sizing of the application module pool.

<table>
<thead>
<tr>
<th>Pool Configuration Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initial Pool Size</td>
<td>Specifies the number of application module instances to create when the pool is initialized. The default is 0 (zero) instances. Creating application module instances during initialization reduces the cost of CPU processing by creating application module instances during the initialization instead of on-demand when additional application module instances are required. A general guideline is to configure this to 10% more than the anticipated number of concurrent application module instances required to service all users. When configuring jbo.ampool.initpoolsize, realize that any pre-initialized application module instances that are not used and that exceed the limit specified by jbo.ampool.maxinactiveage will be freed from the pool. Coordinate this parameter with jbo.ampool.minavailablesize to prevent the initialized instances from being reclaimed.</td>
</tr>
<tr>
<td>(jbo.ampool.initpoolsize)</td>
<td></td>
</tr>
<tr>
<td>Maximum Pool Size</td>
<td>Specifies the maximum number of application module instances that the pool can allocate. The pool will never create more application module instances than this limit imposes. The default is 4096 instances.</td>
</tr>
<tr>
<td>(jbo.ampool.maxpoolsize)</td>
<td></td>
</tr>
</tbody>
</table>
A single application module pool monitor per Java VM runs in a background thread and wakes up every so often to do resource reclamation. The pool monitor uses the following two, independent strategies to identify which application module instances are candidates to be removed from the pool and reclaimed as a potential new resource.

1. The application module pool monitor removes application module instances from the pool that have not been used for more than 3600000 milliseconds (which is the default value and is exactly one hour). These unused application module instances will be reclaimed regardless of the minimum available size for the pool. To override the maximum time to live for an application module, you can set the `jbo.ampool.timetolive` parameter. However, for most Fusion web applications, you will not need to reclaim unused application module instance and can set this parameter value to -1.

2. The application module pool monitor removes application module instances that have remained idle for 600000 milliseconds (which is the default value and is exactly 10 minutes). This cleanup stops when the number of instances in the pool reaches the minimum available size. You can override the idle timeout for application module instances using the `jbo.ampool.maxinactiveage` parameter.

### Table 50–2 (Cont.) Application Module Pool Sizing Configuration Parameters

<table>
<thead>
<tr>
<th>Pool Configuration Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Referenced Pool Size</td>
<td>Specifies the maximum number of application module instances in the pool that may attempt to preserve session affinity for the next request made by the session which used them last before releasing them to the pool in managed-state mode. User session affinity mechanism attempts to give back the same application module instance from the pool that the user session was using on the last request. If the application module pool is sized correctly for your typical application load, then most of the time a user session will be reunited with the application module instance it was using. The default is to allow 10 available instances to try and remain “loyal” to the affinity they have with the most recent session that released them in managed state mode. The referenced pool size should always be less than or equal to the maximum pool size. Configure this value to maintain the application module instance’s affinity to a user’s session. A general guideline is to configure this to the expected number of concurrent users that perform multiple operations with short think times. If there are no users expected to use the application with short think times, then this can be configured to 0 zero to eliminate affinity. Maintaining this affinity as much as possible will save the CPU processing cost of needing to switch an application module instance from one user session to another.</td>
</tr>
</tbody>
</table>

**50.2.7.3 Pool Cleanup Parameters**

A single application module pool monitor per Java VM runs in a background thread and wakes up every so often to do resource reclamation. The pool monitor uses the following two, independent strategies to identify which application module instances are candidates to be removed from the pool and reclaimed as a potential new resource.

1. The application module pool monitor removes application module instances from the pool that have not been used for more than 3600000 milliseconds (which is the default value and is exactly one hour). These unused application module instances will be reclaimed regardless of the minimum available size for the pool. To override the maximum time to live for an application module, you can set the `jbo.ampool.timetolive` parameter. However, for most Fusion web applications, you will not need to reclaim unused application module instance and can set this parameter value to -1.

2. The application module pool monitor removes application module instances that have remained idle for 600000 milliseconds (which is the default value and is exactly 10 minutes). This cleanup stops when the number of instances in the pool reaches the minimum available size. You can override the idle timeout for application module instances using the `jbo.ampool.maxinactiveage` parameter.
Table 50–3 lists the parameters that affect how resources are reclaimed when the pool monitor does one of its resource cleanup passes.

**Best Practice:** When you specify the length of time between application module pool cleanup passes, set all application modules to use the same **Pool Polling Interval** value. Since there is only a single application monitor pool monitor per Java VM, the value that will effectively be used for the application module pool monitor polling interval will be the value found in the application module configuration read by the first application module pool that gets created. Setting all application modules to use the same value ensures that this value is set in a predictable way.

<table>
<thead>
<tr>
<th>Pool Configuration Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pool Polling Interval</td>
<td>Specifies the length of time in milliseconds between pool resource cleanup. Configuring a higher interval results in less frequent resource cleanups. The default is to have the application module pool monitor wake up every 600000 milliseconds (which is 600 seconds, or ten minutes). Configuring a lower interval results in inactive application module instances being removed more frequently to save memory. While the number of application module instances in the pool will never exceed the maximum pool size, available instances which are candidates for getting removed from the pool do not get &quot;cleaned up&quot; until the next time the application module pool monitor wakes up to do its job.</td>
</tr>
<tr>
<td>(jbo.ampool.monitorsleepinterval)</td>
<td></td>
</tr>
</tbody>
</table>
### Setting Pool Configuration Parameters

Developing Fusion Web Applications with Oracle Application Development Framework

#### Maximum Available Size

(jbo.ampool.maxavailablesize)

Specifies the ideal maximum number of available application module instances in the pool when the server is under load.

The default maximum available size is 25 instances. A lower value generally results in more application module instances being removed from the pool on a cleanup. Configure this to leave the maximum number of available instances desired after a resource cleanup.

A general guideline is to configure this to 20% more than the pool size under normal load to allow for some additional growth. If this is set too low, then some users may see an error accessing the application if no application module instances are available.

When the pool monitor wakes up to do resource cleanup, it will try to remove available application module instances to bring the total number of available instances down to this ideal maximum. Instances that have been not been used for a period longer than the idle instance time-out will always get cleaned up at this time, then additional available instances will be removed if necessary to bring the number of available instances down to this size.

While application module pool tuning allows different values for the jbo.ampool.maxavailablesize | jbo.ampool.minavailablesize parameters, in most cases it is fine to set these minimum and maximum tuning properties to the same value.

#### Minimum Available Size

(jbo.ampool.minavailablesize)

Specifies the minimum number of available application module instances that the pool monitor should leave in the pool during a resource cleanup operation, when the server is under light load.

The default is 5 instances.

Set to 0 (zero) if you want the pool to shrink to contain no instances when all instances have been idle for longer than the idle time-out after a resource cleanup.

While application module pool tuning allows different values for the jbo.ampool.minavailablesize | jbo.ampool.maxavailablesize parameters, in most cases it is fine to set these minimum and maximum tuning properties to the same value.

---

### Table 50–3 (Cont.) Application Module Resource Management Configuration Parameters

<table>
<thead>
<tr>
<th>Pool Configuration Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Maximum Available Size</td>
<td>Specifies the ideal maximum number of available application module instances in the pool when the server is under load. The default maximum available size is 25 instances. A lower value generally results in more application module instances being removed from the pool on a cleanup. Configure this to leave the maximum number of available instances desired after a resource cleanup. A general guideline is to configure this to 20% more than the pool size under normal load to allow for some additional growth. If this is set too low, then some users may see an error accessing the application if no application module instances are available. When the pool monitor wakes up to do resource cleanup, it will try to remove available application module instances to bring the total number of available instances down to this ideal maximum. Instances that have been not been used for a period longer than the idle instance time-out will always get cleaned up at this time, then additional available instances will be removed if necessary to bring the number of available instances down to this size. While application module pool tuning allows different values for the jbo.ampool.maxavailablesize</td>
</tr>
<tr>
<td>Minimum Available Size</td>
<td>Specifies the minimum number of available application module instances that the pool monitor should leave in the pool during a resource cleanup operation, when the server is under light load. While application module pool tuning allows different values for the jbo.ampool.minavailablesize</td>
</tr>
</tbody>
</table>
When you specify a JDBC data source as your application module’s connection type, any configuration parameters that you have configured for the database connection pool will be ignored. To configure the connection pool for your data source, you must use the means provided by your Java EE container. In the case of Oracle WebLogic Server, you configure the data source using the Oracle WebLogic Server Administration Console.

The main steps for configuring JDBC data sources are:

1. Create a data source for each database that you want to connect to. When you create the data source, specify the configuration options to match the ones for ADF Business Components database connection pools described in Table 50–4. The configuration settings that you specify will depend on your database and the capacity planning that you need anticipate for your application.

For details about configuring JDBC data sources and connection pool capacity planning, see *Administering JDBC Data Sources for Oracle WebLogic Server*.

2. Optionally, configure transaction options for the data source.

3. Optionally, configure connection testing options for the data source.

4. Optionally, target the data source to additional servers and clusters.
For detailed procedures for each of these steps, see the topic "Configure JDBC data sources" in the Administration Console Online Help.

#### 50.2.9 What You May Need to Know About Database Connection Pool Parameters

If you are using a JDBC URL for your connection information so that the ADF database connection pool is used, then configuration parameters listed in Table 50–5 can be used to tune the behavior of the database connection pool. A single "database connection pool monitor" per Java VM runs in a background thread and wakes up every so often to do resource reclamation. The parameters in Table 50–3 include the ones that affect how resources are reclaimed when the pool monitor does one of its resource cleanup passes.

---

**Note:** The configuration parameters for database connection pooling have MetaObjectManager scope (described in Section 50.2.5, "What You May Need to Know About Configuration Property Scopes" earlier). This means their settings are global and will be set once when the first application module pool in your application is created. To insure the most predictable behavior, leave the values of these parameters in the Connection Pool section of the Pooling and Scalability tab at their default values — so that no entry for them is written into the bc4j.xcfg file — and to instead set the desired values for the database connection pooling tuning parameters as Java System Parameters in your Java EE container.

---

<table>

<tr>
<td>(jbo.initpoolsizex)</td>
</tr>
</tbody>
</table>
### Setting Pool Configuration Parameters

#### Tuning Application Module Pools and Connection Pools

<table>
<thead>
<tr>
<th>Pool Configuration Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Maximum Pool Size</strong></td>
<td>Specifies the maximum number of JDBC connection instances that the pool can allocate. The pool will never create more JDBC connections than this imposes. The default is 4096 instances. Each connection request will wait up to <code>jbo.poolrequesttimeout</code> and, if no connection becomes available, raises: JBO-28102: A request was timed out while waiting for a resource to be returned to the resource pool, null.</td>
</tr>
</tbody>
</table>

(jbo.maxpoolsize) |

| **Pool Polling Interval** | Specifies the length of time in milliseconds between pool resource cleanup. The default is 600000 milliseconds of idle time (which is 600 seconds, or ten minutes). Configuring a lower interval results in inactive connection instances being removed more frequently to save memory. Configuring a higher interval results in less frequent resource cleanups. While the number of JDBC connection instances in the pool will never exceed the maximum pool size, available instances which are candidates for getting removed from the pool do not get "cleaned up" until the next time the JDBC connection pool monitor wakes up to do its job. |

(jbo.poolmonitorsleepinterval) |

| **Maximum Available Size** | Specifies the ideal maximum number of JDBC connection instances in the pool when the server is under load. The default is an ideal maximum of 25 instances (when not under load). When the pool monitor wakes up to do resource cleanup, it will try to remove available JDBC connection instances to bring the total number of available instances down to this ideal maximum. Instances that have been not been used for a period longer than the idle instance time-out will always get cleaned up at this time, then additional available instances will be removed if necessary to bring the number of available instances down to this size. |

(jbo.poolmaxavailablesize) |

| **Minimum Available Size** | Specifies the minimum number of available JDBC connection instances that the pool monitor should leave in the pool during a resource cleanup operation, when the server is under light load. The default is to not let the minimum available size drop below 5 instances. Set to zero (0) if you want the pool to shrink to contain no instances when all instances have been idle for longer than the idle time-out. |

(jbo.poolminavailablesize) |
50.3 Initializing Database State and Pooling Considerations

Sometimes you may need to invoke stored procedures to initialize database state related to the current user's session. The correct place to perform this initialization is in an overridden `prepareSession()` method of your application module.

50.3.1 How to Set Database State Per User

The Fusion web application can set database state on a per-user basis. You typically create a database `CONTEXT` namespace, associate a PL/SQL procedure with it, and then use the `SYS_CONTEXT()` SQL function to reference values from the context.

For example, you can use the PL/SQL package to set and get a package-level variable that holds the name of the currently authenticated Fusion web application user as shown in Example 50–4.

**Example 50–4  CONTEXT_PKG PL/SQL Package**

```sql
create or replace package context_pkg as
  procedure set_app_user_name(username varchar2);
  function app_user_name return varchar2;
end context_pkg;
```

Then your application can define the WHERE clause of a view object to reference the `context_pkg.app_user_name` function and query the per-user state.

To set the database state, the application module framework extension class (`AppModuleImpl.java`) defines a `callStoredProcedure()` helper method similar to the ones in Section 16.5.2, "How to Invoke Stored Procedure with Only IN
Arguments." The custom application module class then extends this framework extension class and defines the setCurrentUserInPLSQLPackage() helper method shown in Example 50–5. The helper method uses the callStoredProcedure() method to invoke the context_pkg.set_app_user_name() stored procedure, passing the value of the currently authenticated user as a parameter value.

Example 50–5 Method to Call Context_Pkg.Set_App_User_Name Stored Procedure

```java
// In CustomAppModuleImpl.java
public void setCurrentUserInPLSQLPackage() {
    String user = getUserPrincipalName();
    callStoredProcedure("context_pkg.set_app_user_name(?)", new Object[]{user});
}
```

With this helper method in place, the custom application module class then overrides the prepareSession() method as shown in Example 50–6.

Example 50–6 Overridden afterConnect() and prepareSession() to Set Database State

```java
// In CustomAppModuleImpl.java
protected void prepareSession(Session session) {
    super.prepareSession(session);
    getLoggedInUser().retrieveUserInfoForAuthenticatedUser();
    setUserIdIntoUserDataHashtable();
    setCurrentUserInPLSQLPackage();
}
```

50.3.2 What You May Need to Know About Optimizing Connection Pooling

The default setting for jbo.doconnectionpooling is false. This means the application module instance hangs onto its JDBC connection while it's in the application module pool. This is the most efficient setting because the application module can keep its JDBC prepared statements open across application module checkouts/checkins. The application module instance will trigger its prepareSession() method each time a new user session begins using it.

If you set jbo.doconnectionpooling to true, then on each checkout of an application module from the pool, that application module pool will acquire a JDBC connection from the database connection pool and use it during the span of the current request. At the end of the request when the application module is released back to the application module pool, that application module pool releases the JDBC connection it was using back to the database connection pool.

It follows that with jbo.doconnectionpooling set to true the application module instance in the pool may have a completely different JDBC connection each time you check it out of the pool. In this situation, the prepareSession() method will fire each time the application module is checked out of the pool to give you a chance to reinitialize the database state.

When you set jbo.doconnectionpooling to true, the default setting for jbo.txn.disconnect_level ensures that all application modules, view objects and row sets remain in memory and stay valid after their corresponding references to JDBC connections are dropped. This configuration reduces the memory overhead associated with this situation where application module passivation is normally performed upon release. Instead, upon activation, the framework reexecutes and synchronizes the cursor positions.
To achieve a more ideal balance between conserving JDBC connections and keeping all application modules connected to the database, you can configure `jbo.ampool.connection_threshold` to specify the maximum number of connections that application modules in all application module pools combined may hold onto without releasing back to the connection pool upon checkin. Setting the threshold to a limit greater than 0, forces the cleanup monitor to release JDBC connections during application module pool cleanup instead of during application module checkin.

This is an important difference with application module connection threshold enabled; application modules are disconnected during pool cleanup, not during checkin. The cleanup monitor makes a best effort to disconnect application modules until the total number of JDBC connections falls below the specified threshold limit. Note that it may not be possible if there are not enough application modules in the available state. To ensure JDBC connections are released efficiently, you can configure `jbo.ampool.monitorsleepinterval` to shorten the monitor sleep period.

The `jbo.ampool.connection_threshold` property is not exposed by JDeveloper property editors and is intended to be configured at runtime, strictly as a Java option for Oracle WebLogic Server. For example, in your deployment environment, the system administrator may define the property as `-Djbo.ampool.connection_threshold=limit` using the startup script for Oracle WebLogic Server, such as `setWLSEnv.cmd`.

When testing your application in JDeveloper, you can specify the property as a JVM system property. For example, specify JDeveloper launch settings for JVM using the Edit Run Configuration dialog, as shown in Figure 50–2. In JDeveloper, open the Edit Run Configuration dialog from the Run/Debug page of the Project Properties dialog.

![Figure 50–2 Specifying Application Module Connection Threshold as a JDeveloper Launch Setting](image)
50.4 Deployment Environment Scenarios and Pooling

The number of pools and the type of pools that your application will utilize will depend upon how the target platform is configured. For example, will there be more than one Java Virtual Machine (JVM) available to service the web requests coming from your application users and will there be more than one Oracle WebLogic Server domain? To understand how many pools of which kinds are created for an application in both a single-JVM scenario and a multiple-JVM runtime scenario, review the following assumptions:

- Your Fusion web application makes use of two application modules HRModule and PayablesModule.
- You have a CommonLOVModule containing a set of commonly used view objects to support list of values in your application, and that both HRModule and PayablesModule aggregate a nested instance of CommonLOVModule to access the common LOV view objects it contains.
- You have configured both HRModule and PayablesModule to use the same JDeveloper connection definition named appuser.
- In both HRModule and PayablesModule you have configured jbo.passivationstore=database (the default) and configured the ADF Business Components “internal connection” (jbo.server.internal_connection) used for state management persistence to have the value of a fully qualified JDBC URL that points to a different username than the appuser connection does.

50.4.1 Single Oracle WebLogic Server Domain, Single Oracle WebLogic Server Instance, Single JVM

If you deploy this application to a single Oracle WebLogic Server domain, configured with a single Oracle WebLogic Server instance, there is only a single Java VM available to service the web requests coming from your application users.

Assuming that all the users are making use of web pages that access both the HRModule and the PayablesModule, this will give:

- One application module pool for the HRModule root application module
- One application module pool for the PayablesModule root application module
- One DB connection pool for the appuser connection
- One DB connection pool for the JDBC URL supplied for the internal connection for state management.

This gives a total of two application module pools and two database pools in this single Java VM.

---

**Note:** There is no separate application module pool for the nested instances of the reusable CommonLOVModule. Instances of CommonLOVModule are wrapped by instances of HRModule and PayablesModule in their respective application module pools.
50.4.2 Multiple Oracle WebLogic Server Domains, Multiple Oracle WebLogic Server Instance, Multiple JVMs

Next consider a deployment environment involving multiple Java VMs. Assume that you have configured four different physical machines as two Oracle WebLogic Server domains, with a hardware load-balancer in front. On these four machines, each Oracle WebLogic Server instance will have a single JVM. As users of your application access the application, their requests are shared across these two Oracle WebLogic Server domains, and within each domain, across the two JVMs that its Oracle WebLogic Server instances have available.

Again assuming that all the users are making use of web pages that access both the HRModule and the PayablesModule, this will give:

- Four application module pools for HRModule, one in each of four JVMs.
  \[(1 \text{ HRModule root application module}) \times (2 \text{ Oracle WebLogic Server domains}) \times (2 \text{ Oracle WebLogic Server JVMs each})\]

- Four application module pools for PayablesModule, one in each of four JVMs.
  \[(1 \text{ PayablesModule root application module}) \times (2 \text{ Oracle WebLogic Server domains}) \times (2 \text{ Oracle WebLogic Server JVMs each})\]

- Four DB connection pools for appuser, one in each of four JVMs.
  \[(1 \text{ appuser DB connection pool}) \times (2 \text{ Oracle WebLogic Server domains}) \times (2 \text{ Oracle WebLogic Server JVMs each})\]

- Four DB connection pools for the internal connection JDBC URL, one in each of four JVMs.
  \[(1 \text{ internal connection JDBC URL DB connection pool}) \times (2 \text{ Oracle WebLogic Server domains}) \times (2 \text{ Oracle WebLogic Server JVMs each})\]

This gives a total of eight application module pools and eight DB connection pools spread across four JVMs.

As you begin to explore the configuration parameters for the application module pools in Section 50.2.7, "What You May Need to Know About Application Module Pool Parameters," keep in mind that the parameters apply to a given application module pool for a given application module in a single JVM.

As the load balancing spreads user requests across the multiple JVMs where Oracle ADF is running, each individual application module pool in each JVM will have to support one \(\frac{n}{n}\)th of the user load — where \(n\) is the number of JVMs available to service those user requests. The appropriate values of the application module and DB connection pools need to be set with the number of Java VMs in mind. The basic approach is to base sizing parameters on load testing and the results of the application module pooling statistics, then divide that total number by the \(n\) number of pools you will have based on your use of multiple application server domains and multiple Oracle WebLogic Server instances. For example, if you decide to set the minimum number of application modules in the pool to ten and you end up with five pools due to having five Oracle WebLogic Server instances servicing this application, then you would want to configure the parameter to 2 (ten divided by five), not 10 (which would only serve a given application module in a single JVM). For details about available sizing parameters, see Table 50–2 and Table 50–5.
Part VII

Appendices

Part VII contains the following appendices:

- Appendix A, "Oracle ADF XML Files"
- Appendix B, "Oracle ADF Binding Properties"
- Appendix C, "ADF Security Permission Grants"
- Appendix D, "Most Commonly Used ADF Business Components Methods"
- Appendix E, "ADF Business Components Java EE Design Pattern Catalog"
- Appendix F, "ADF Equivalents of Common Oracle Forms Triggers"
- Appendix G, "Performing Common Oracle Forms Tasks in Oracle ADF"
- Appendix H, "Deploying ADF Applications to GlassFish"
This appendix provides a reference for the Oracle ADF metadata files that you create in your data model and user interface projects. You may use this information when you want to edit the contents of the metadata these files define.

This appendix includes the following sections:

- Section A.1, "About ADF Metadata Files"
- Section A.2, "ADF File Overview Diagram"
- Section A.3, "ADF File Syntax Diagram"
- Section A.4, "adfm.xml"
- Section A.5, "modelProjectName.jpx"
- Section A.6, "bc4j.xcfg"
- Section A.7, "DataBindings.cpx"
- Section A.8, "pageNamePageDef.xml"
- Section A.9, "adfc-config.xml"
- Section A.10, "task-flow-definition.xml"
- Section A.11, "adf-config.xml"
- Section A.12, "adf-settings.xml"
- Section A.13, "web.xml"
- Section A.14, "logging.xml"

A.1 About ADF Metadata Files

Metadata files in a Fusion web application are structured XML files used by the application to:

- Specify the parameters, methods, and return values available to your application’s Oracle ADF data control usages
- Create objects in the Oracle ADF binding context and define the runtime behavior of those objects
- Define configuration information about the UI components in JSF and Oracle ADF Faces
- Define application configuration information for the Java EE application server
In the case of ADF bindings, you can use the binding-specific editors to customize the runtime properties of the binding objects. You can open a binding editor when you display the Structure window for a page definition file and choose Go to Properties from the context menu.

Additionally, you can view and edit the contents of any metadata file in JDeveloper’s XML editor. The easiest way to work with these files is through the Structure window and Properties window. In the Structure window, you can choose an element and in the Properties window, you can define attribute values for the element, often by choosing among dropdown menu choices. Use this appendix to learn the choices you can choose in the case of the Oracle ADF-specific elements.

### A.2 ADF File Overview Diagram

The relationship between the Oracle ADF metadata files defines dependencies between the model data and the user interface projects. The dependencies are defined as file references within XML elements of the files.

Figure A–1 illustrates the hierarchical relationship of the XML metadata files that you might work with in a Fusion web application that uses an ADF Business Components application module as a service interface to JSF web pages.

**Figure A–1 Oracle ADF File Hierarchy Overview for the Fusion Web Application**
A.2.1 Oracle ADF Data Control Files

In a Fusion web application containing ADF Business Components, the data control implementation files are contained within the application. The application module and view object XML component descriptor files provide the references for the data control. These files, with the bc4j.xcfg file, provide the necessary information for the data control.

An application that uses ADF Business Components in one project and a non-ADF Business Components data control in another project may have a DataControls.dcx file, as well as supporting <sessionbeannname>.xml and <beannname>.xml files.

A.2.2 Oracle ADF Data Binding Files

These standard XML configuration files for a Fusion web application appear in your user interface project:

- adfm.xml: This file lists the DataBindings.cpx file that is available in the current project.
  See Section A.4, "adfm.xml" for more information.

- DataBindings.cpx: This file contains the page map, page definitions references, and data control references. The file is created the first time you create a data binding for a UI component (either from the Structure window or from the Data Controls panel). The DataBindings.cpx file defines the Oracle ADF binding context for the entire application. The binding context provides access to the bindings and data controls across the entire application. The DataBindings.cpx file also contains references to the <pagename>PageDef.xml files that define the metadata for the Oracle ADF bindings in each web page.
  For more information, see Section A.7, "DataBindings.cpx."

- <pagename>PageDef.xml: This is the page definition XML file. It associates web page UI components with data, or data controls. JDeveloper creates this file each time you design a new web page using the Data Controls panel or Structure window. These XML files contain the metadata used to create the bindings that populate the data in the web page’s UI components. For every web page that refers to an ADF binding, there must be a corresponding page definition file with binding definitions.
  For more information, see Section A.8, "pageNamePageDef.xml."

A.2.3 Web Configuration Files

These standard XML configuration files required for a JSF application appear in your user interface project:

- web.xml: Part of the application's configuration is determined by the contents of its Java EE application deployment descriptor, web.xml. The web.xml file defines everything about your application that a server needs to know. The file plays a role in configuring the Oracle ADF data binding by setting up the ADFBindingFilter. Additional runtime settings include servlet runtime and initialization parameters, custom tag library location, and security settings.
  For more information about ADF data binding and JSF configuration options, see Section A.13, "web.xml."
An ADF Faces application typically uses its own set of configuration files in addition to web.xml. For more information, see the "Configuration in trinidad-config.xml" section in Developing Web User Interfaces with Oracle ADF Faces.

- **adfc-config.xml**: The configuration file for an ADF unbounded task flow. The configuration file contains metadata about the activities and control flows contained in the unbounded task flow. The default name for this file is adfc-config.xml, but an end user can change the name.
  
  For more information, see Section A.9, "adfc-config.xml."

- **task-flow-definition.xml**: The configuration file for an ADF bounded task flow. The configuration file contains metadata about the activities and control flows contained in the bounded task flow. The default name for this file can be task-flow-definition.xml or whatever an end user specifies in the Create ADF Task Flow dialog. The same application can contain multiple task flow definition files.
  
  For more information, see Section A.10, "task-flow-definition.xml."

### A.3 ADF File Syntax Diagram

Figure A–2 illustrates the hierarchical relationship of the XML metadata files that you might work with in a web application that uses an ADF application module as a service interface to ADF Business Components. At runtime, the objects created from these files interact in this sequence:

1. When the first request for an ADF databound web page occurs, the servlet registers the Oracle ADF servlet filter ADFBindingFilter named in the web.xml file.

2. The binding filter creates an empty binding context.

3. When a page is rendered, the binding filter asks the binding context to load a corresponding PageDef.xml for the page.

4. The binding context creates the binding container by loading the <page> file as referenced by the <pagemap> element in the DataBindings.cpx file.

5. The adfm.xml file loads the DataBindings.cpx contents and finds the right PageDef.xml based on the <pagemap> element reference to the <pageDefinitionUsage> element.

6. The binding container's prepareModel phase prepares and refreshes all relevant executables (most are marked deferred by default).

7. An iterator binding gets executed by referencing the named method on the data control found through the data control factory named in the case of ADF Business Components in the bc4j.xcfg file.

8. The binding container also creates the bindings defined in the <bindings> section of the pagenamePageDef.xml file for the mapped web page.

9. The web page references to ADF bindings through EL using the expression #{bindings} are resolved by accessing the binding container of the page.

10. The page pulls the available data from the bindings in the binding container.
A.4 adfm.xml

The adfm.xml file contains the classpath-relative paths for the .cpx, .dcx, .jpx, and .xcfg files in each design time project that is included in the runtime deployed application. The adfm.xml file operates as a dynamically maintained "Registry of Registries" that is used to quickly find all .cpx, .dcx, .jpx, and .xcfg files (which are themselves registries of metadata).

The file registry is used extensively by the ADF Library resource catalog browsing implementations, by ADF Model layer design time, and at runtime during merge and discovery.

When a developer creates a binding on a page, JDeveloper adds metadata files (for example, page definitions) in the project source tree. The adfm.xml file then notes the location of each.

When a project is built, the adfm.xml file is put in project-root/adfmsrc/META-INF/adfm.xml. The project-level archive deployment profiles locate the file at META-INF/adfm.xml.
At runtime, the application classpath is scanned to build the list of 
\texttt{.cpx} files that 
comprise the application. The application then loads each \texttt{.cpx} as needed to create the 
binding context. For details about ADF Model layer usage, see Section 17.4.2, "What 
Happens When You Use the Data Controls Panel".

Four types of sub registries are recorded by the \texttt{adfm.xml} file:

- DataBindingRegistry (\texttt{.cpx})
- DataControlRegistry (\texttt{.dcx})
- BusinessComponentServiceRegistry (\texttt{.xcfg})
- BusinessComponentProjectRegistry (\texttt{.jpx})

### A.5 \texttt{modelProjectName.jpx}

The \texttt{.jpx} file contains configuration information that JDeveloper uses in the design 
time to allow you to create the data model project with ADF Business Components. It 
also contains metadata that defines how a shared application module is used at 
runtime. Because the shared application module can be accessed by any data model 
project in the same Fusion web application, JDeveloper maintains the scope of the 
shared application module in the ADF Business Components project configuration file.

This file is saved in the \texttt{src} directory of the project. For example, the Summit sample 
application for Oracle ADF stores the \texttt{Model.jpx} file in the 
\texttt{.src/oracle/summit/model} subdirectory of the \texttt{Model} project.

Example A–2 displays a sample default \texttt{.jpx} file.

\textbf{Example A–1 Sample \texttt{.jpx} File}

```xml
<JboProject
   xmlns="http://xmlns.oracle.com/bc4j"
   Name="Model"
   Version="12.1.2.66.11"
   SeparateXMLFiles="true"
   PackageName="oracle.summit.model">
   <DesignTime>
     <Attr Name="_appModuleNames2"
           Value="oracle=summit.model.services.BackOfficeAppModule1"/>
     <Attr Name="_appModuleName1"
           Value="oracle=summit.model.services.CustomerSelfServiceAppModule1"/>
     <Attr Name="_appModuleName0"
           Value="oracle=summit.model.services.SummitAppModule"/>
     <Attr Name="_jbo.TypeMapEntries" Value="Java'/">
     <Attr Name="_NamedConnection" Value="summit_adf'"/>
   </DesignTime>
   <Containee
     Name="assoc"
     PackageName="oracle=summit.model.entities.assoc"
     ObjectType="JboPackage">
     <DesignTime>
       <Attr Name="_AS" Value="true'"/>
     </DesignTime>
   </Containee>
   <Containee
     Name="entities"
     PackageName="oracle.summit.model.entities"
     ObjectType="JboPackage">
```

A-6 Developing Fusion Web Applications with Oracle Application Development Framework
The bc4j.xcfg file contains metadata information about application module names, the database connection used by the application module, and the runtime parameters the user has configured for the application module.

The bc4j.xcfg file is located in the ./common subdirectory relative to the application module's XML component definition. All of the configurations for all of the application modules in a single Java package are saved in that same file. For example, if you look at the bc4j.xcfg file in the /Model/src/oracle/summit/model/services/common directory of the Summit ADF sample application’s Model project, you see the configurations for its application modules. For details about editing the configurations, see Section 13.3.4, "How to Change Your Application Module’s Runtime Configuration" and Section 50.2, "Setting Pool Configuration Parameters."

Example A–2 displays a sample bc4j.xcfg file from the Summit ADF sample application.
**Example A–2 Sample bc4j.xcfg File**

```xml
<?xml version = '1.0' encoding = 'UTF-8'?>
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
  <AppModuleConfigBag ApplicationName="oracle.summit.model.services.SummitAppModule">
    < AppModuleConfig name="SummitAppModuleLocal" DeployPlatform="LOCAL" JDBCName="summit_adf" jbo.project="oracle.summit.model.Model" java.naming.factory.initial="oracle.jbo.common.JboInitialContextFactory" ApplicationName="oracle.summit.model.services.SummitAppModule">
      <Database jbo.TypeMapEntries="Java"/>
      <Security AppModuleJndiName="oracle.summit.model.services.SummitAppModule"/>
    </ AppModuleConfig>
  </ AppModuleConfigBag>
  < AppModuleConfigBag ApplicationName="oracle.summit.model.services.CustomerSelfServiceAppModule">
    < AppModuleConfig name="CustomerSelfServiceLocal" jbo.project="oracle.summit.model.Model" ApplicationName="oracle.summit.model.services.CustomerSelfServiceAppModule" DeployPlatform="LOCAL" JDBCName="summit_adf" jbo.project="oracle.summit.model.Model" java.naming.factory.initial="oracle.jbo.common.JboInitialContextFactory">
      <Database jbo.TypeMapEntries="Java"/>
      <Security AppModuleJndiName="oracle.summit.model.services.CustomerSelfServiceAppModule"/>
    </ AppModuleConfig>
  </ AppModuleConfigBag>
  < AppModuleConfigBag ApplicationName="oracle.summit.model.services.BackOfficeAppModule">
    < AppModuleConfig name="BackOfficeAppModuleLocal" jbo.project="oracle.summit.model.Model" JDBCName="summit_adf" ApplicationName="oracle.summit.model.services.BackOfficeAppModule" DeployPlatform="LOCAL" jbo.project="oracle.summit.model.Model" java.naming.factory.initial="oracle.jbo.common.JboInitialContextFactory">
      <Database jbo.TypeMapEntries="Java"/>
      <Security AppModuleJndiName="oracle.summit.model.services.BackOfficeAppModule"/>
    </ AppModuleConfig>
  </ AppModuleConfigBag>
</ BC4JConfig>

A.7 DataBindings.cpx

The DataBindings.cpx file is created in the user interface project the first time you drop a data control usage onto a web page in the visual editor. The DataBindings.cpx file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime. It is used extensively by the ADF Library resource catalog.
browsing implementations, and also by the .cpx and .dcx design time and runtime merge and discovery. When you insert a databound UI component into your document, the page will contain binding expressions that access the Oracle ADF binding objects at runtime.

The DataBindings.cpx file appears in the /src directory of the user interface project. When you double-click the file node, the binding context description appears in the XML source editor. (To edit the binding context parameters, use the Properties window and choose the desired parameter in the Structure window.)

### A.7.1 DataBindings.cpx Syntax

The top level element of the DataBindings.cpx file is `<Application>`. For example:

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<Application xmlns="http://xmlns.oracle.com/adfm/application" version="11.1.1.56.60" id="DataBindings" SeparateXMLFiles="false" Packages="oracle.summit.view" ClientType="Generic">
```

Figure A–3 shows the structure definition of the DataBindings.cpx file in the Summit standalone sample applications for Oracle ADF.

**Figure A–3 Structure of the DataBindings.cpx File**

![DataBindings.cpx - Structure](image)

- **Path Mappings**
  - path: pageMap
    - usage: oracle_summit_view_FollowPageDef

- **Page Definition Usages**
  - id: pageDefinitionUsage_FollowPageDef
    - path: oracle_summit_view_FollowPageDef"FollowPageDef"

- **Data Control Usages**
  - id: dataControlUsage_EmployeesManagement

The child elements have the following usages:

- `<definitionFactories>` registers a factory class to create the ADF binding objects associated with a particular namespace at runtime. The factory class is specific to the namespace associated with the type of ADF binding (for instance, a task flow binding).
- `<pageMap>` maps all user interface URLs and the corresponding page definition usage name. This map is used at runtime to map a URL to its page definition.
- `<pageDefinitionUsages>` maps a page definition usage (BindingContainer instance) name to the corresponding page definition. The `id` attribute represents the usage ID. The `path` attribute represents the full path to the page definition.
- `<dataControlUsages>` declares a list of data control usages (shortnames) and corresponding path to the data control definition entries in the .dcx or .xcfg file.
Table A–1 describes the attributes of the DataBindings.cpx elements.

<table>
<thead>
<tr>
<th>Element Syntax</th>
<th>Attributes</th>
<th>Attribute Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;definitionFactories&gt;</td>
<td>nameSpace</td>
<td>A URI. Identifies the location of the executable elements in the page definition usage.</td>

<td>id</td>
<td>A unique qualifier. Identifies the data control usage as is defined in the DataControls.dcx file.</td>
</tr>
<tr>
<td></td>
<td>path</td>
<td>The fully qualified package name. Identifies the location of the data control.</td>
</tr>
</tbody>
</table>

A.7.2 DataBindings.cpx Sample

Example A–3 shows the syntax for the DataBindings.cpx file in the Summit ADF sample application.

The ADF executable definition factory (factory element) is named by a className attribute and is associated with a namespace. At runtime, the factory class creates the executable definition objects that leads to the creation of the binding objects for the ADF binding container associated with a particular page definition. The factory locates the page definition through two DataBindings.cpx file elements: the pageMap element that maps the page URL to the page definition ID (usageId attribute) assigned at design time and the pageDefinitionUsages element that maps the ID to the location of the page definition from the project or project classpath.

Additionally, the ADF Business Components data control (BC4JDataControl element) is named by the id attribute. The combination of the Package attribute and the Configuration attribute is used to locate the bc4j.xcfg file in the ./common subdirectory of the indicated package. The configuration contains the information of the application module name and all the runtime parameters the user has configured.
Example A–3  Sample DataBindings.cpx File

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<Application xmlns="http://xmlns.oracle.com/adfm/application" version="11.1.1.56.60" id="DataBindings" SeparateXMLFiles="false"
    Package="oracle.summit.view" ClientType="Generic">
    <definitionFactories>
        <factory nameSpace="http://xmlns.oracle.com/adf/controller/binding"
            className="oracle.adf.controller.internal.binding.TaskFlowBindingDefFactoryImpl"/>
        <dtfactory className="oracle.adf.controller.internal.dtrt.binding.BindingDTObjectFactory"/>
        <factory nameSpace="http://xmlns.oracle.com/adfm/dvt"
            className="oracle.adfinternal.view.faces.dvt.model.binding.FacesBindingFactory"/>
    </definitionFactories>
    <pageMap>
        <page path="/index.jsf" usageId="oracle_summit_view_indexPageDef"/>

            syncMode="Immediate"
            xmlns="http://xmlns.oracle.com/adfm/datacontrol"/>
    </dataControlUsages>
</Application>
```

A.8  pageNamePageDef.xml

The `pageNamePageDef.xml` files are created each time you insert a databound component into a web page using the Data Controls panel or Structure window. These XML files define the Oracle ADF binding container for each web page in the application. The binding container provides access to the bindings within the page. You will have one XML file for each databound web page.

**Caution:** The DataBindings.cpx file maps JSF pages to their corresponding page definition files. If you change the name of a page definition file or a JSF page, JDeveloper does not automatically refactor the DataBindings.cpx file. You must manually update the page mapping in the DataBindings.cpx file.
The PageDef.xml file appears in the /src/view directory of the user interface project. The Applications window displays the file in the view package of the Application Sources node. When you double-click the file node, the page description appears in the XML source editor. To edit the page description parameters, use the Properties window and choose the desired parameter in the Structure window.

For more information, see Chapter 17.7, "Working with Page Definition Files."

There are important differences in how the page definitions are generated for methods that return a single value and a collection.

### A.8.1 PageDef.xml Syntax

The top-level element of the PageDef.xml file is `<pageDefinition>`:

```
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
  version='11.1.1.59.23' id='pagename>PageDef'
  Package='oracle.summit.view.pageDefs'>
```

where the XML namespace attribute (xmlns) specifies the URI to which the ADF binding container binds at runtime. Only the package name is editable; all other attributes should have the values shown.

Example A–4 displays the child element hierarchy of the `<pageDefinition>` element. Note that each business service for which you have created a data control will have its own `<AdapterDataControl>` definition.

#### Example A–4 PageDef.xml Element Hierarchy

```
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition version='1.0' encoding='UTF-8' ?>
  <parameters>
    ...
  </parameters>
  <executables>
    ...
  </executables>
  <bindings>
    ...
  </bindings>
</pageDefinition>
```

The child elements have the following usages:

- `<parameters>` defines page-level parameters that are EL accessible. These parameters store information local to the web page request and may be accessed in the binding expressions.
- `<executables>` defines the list of items (methods, view objects, and accessors) to execute during the `prepareModel` phase of the ADF page lifecycle. Methods to be executed are defined by `<methodIterator>`. The lifecycle performs the execute in the sequence listed in the `<executables>` section. Whether or not the method or operation is executed depends on its `Refresh` or `RefreshCondition` attribute value. Built-in operations on the data control are defined by:
  - `<page>`: definition for a nested page definition (binding container)
  - `<iterator>`: definition to a named collection in `DataControls`
  - `<_accessorIterator>`: definition to get an accessor in a data control hierarchy
- `<methodIterator>`: definition to get to an iterator returned by an invoked method defined by a `methodAction` in the same file
- `<variableIterator>`: internal iterator that contains variables declared for the binding container
- `<invokeAction>`: definition of which method to invoke as an executable

**Note:** Only use `invokeAction` when your application does not use the ADF Controller module from the Fusion web application technology stack. If your application uses the ADF Controller module, Oracle recommends that you use a task flow method call activity, as described in Section 21.5, "Using Method Call Activities."

- `<bindings>` refers to an entry in `<executables>` to get to the collection from which bindings extract/submit attribute level data.

Table A–2 describes the attributes of the top-level `<pageDefinition>` element.

<table>
<thead>
<tr>
<th>Element Syntax</th>
<th>Attributes</th>
<th>Attribute Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>&lt;pageDefinition&gt;</code></td>
<td>ControllerClass</td>
<td>Fully qualified class name to create when controller requests a PageController object for this bindingContainer.</td>
</tr>
<tr>
<td></td>
<td>EnableTokenValidation</td>
<td>Enables currency validation for this bindingContainer when a postback occurs. This is to confirm that the web tier state matches the state that particular page was rendered with.</td>
</tr>
<tr>
<td></td>
<td>FindMode</td>
<td>FindMode is for legacy (10.1.2) use only and indicates whether this bindingContainer should start out in findMode when initially prepared.</td>
</tr>
</tbody>
</table>
Table A–3 describes the attributes of the child element of `<parameters>`.

<table>
<thead>
<tr>
<th>Element Syntax</th>
<th>Attributes</th>
<th>Attribute Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>&lt;parameter&gt;</code></td>
<td>evaluate</td>
<td>Specifies when the parameter should be evaluated: eachUse, firstUse, or inPrepareModel.</td>
</tr>
<tr>
<td>id</td>
<td></td>
<td>Unique identifier. May be referenced by ADF bindings.</td>
</tr>
<tr>
<td>option</td>
<td></td>
<td>Indicates the usage of the variable within the binding container:</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ Final indicates that this parameter cannot be passed in by a usage of this binding container. It must use the default value in the definition.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ Optional indicates that the variable value need not be provided.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ Mandatory specifies that the parameter value must be provided at runtime using Java or an EL expression. Failure to provide a value for a mandatory parameter or binding leads to an exception being thrown during binding validation.</td>
</tr>
<tr>
<td>readonly</td>
<td></td>
<td>Indicates whether the parameter value may be modified or not. Set to true when you do not want the application to modify the parameter value.</td>
</tr>
<tr>
<td>value</td>
<td></td>
<td>A default value, which can be an EL expression.</td>
</tr>
</tbody>
</table>
Table A–4 describes the attributes of the `PageDef.xml <executables>` elements.

### Table A–4  Attributes of the `PageDef.xml File <executables>` Element

<table>
<thead>
<tr>
<th>Element Syntax</th>
<th>Attributes</th>
<th>Attribute Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>&lt;accessorIterator&gt;</code></td>
<td>Accessor</td>
<td>Specifies any other accessor defined by this binding.</td>
</tr>
<tr>
<td></td>
<td>Binds</td>
<td>Specifies the view or action to which the iterator is bound.</td>
</tr>
<tr>
<td>BeanClass</td>
<td></td>
<td>Identifies the Java type of beans in the associated iterator or collection.</td>
</tr>
<tr>
<td>CacheResults</td>
<td></td>
<td>If <code>true</code>, manages the data collection between requests.</td>
</tr>
<tr>
<td>ChangeEventRate</td>
<td></td>
<td>Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.</td>
</tr>
<tr>
<td>DataControl</td>
<td></td>
<td>Interprets and returns the collection referred to by this iterator binding.</td>
</tr>
<tr>
<td>id</td>
<td></td>
<td>Unique identifier. May be referenced by any ADF value binding.</td>
</tr>
<tr>
<td>MasterBinding</td>
<td></td>
<td>Reference to the <code>methodIterator</code> (or iterator) that binds the data collection that serves as the master to the accessor iterator’s detail collection.</td>
</tr>
<tr>
<td>ObjectType</td>
<td></td>
<td>Used for ADF Business Components only. A boolean value determines whether the collection is an object type or not.</td>
</tr>
<tr>
<td>RangeSize</td>
<td></td>
<td>Specifies the number of data objects in a range to fetch from the bound collection. The range defines a window you can use to access a subset of the data objects in the collection. Typically, when you create a component by dragging an object from the Data Controls panel, the range size is set to 25. Use <code>RangeSize</code> when you want to work with an entire set or when you want to limit the number of data objects to display in the page. Note that the values <code>-1</code> and <code>0</code> have specific meaning: the value <code>-1</code> returns all available objects from the collection, while the value <code>0</code> will return the same number of objects as the collection uses to retrieve from its data source. If the <code>RangeSize</code> attribute is not specified at all, all available objects are returned.</td>
</tr>
</tbody>
</table>
Table A–4  (Cont.) Attributes of the PageDef.xml File <executables> Element

<table>
<thead>
<tr>
<th>Element Syntax</th>
<th>Attributes</th>
<th>Attribute Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Refresh</td>
<td></td>
<td>Determines when to invoke the executable. Oracle recommends that you do not change from the default value (deferred) for the Refresh attribute and that you do use an EL expression for the RefreshCondition attribute to determine if an executable should be refreshed. For completeness’ sake, the following is the list of valid attribute values:</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ always: Invokes the executable each time the binding container is prepared. This occurs when the page displays and when the user submits changes, or when the application posts back to the page.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ deferred: Refresh occurs when another binding requires or refers to this executable. Since refreshing an executable may impact performance, you can set the refresh to occur only if deferred is used in a binding that is being rendered. This is the default value for ADF Faces applications.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ &lt;default&gt;: Always set to deferred by default.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ ifNeeded: Whenever the framework needs to refresh the executable because it has not been refreshed to this point. For example, when you have an accessor hierarchy such that a detail is listed first in the page definition, the master could be refreshed twice (once for the detail and again for the master’s iterator). Using ifNeeded avoids duplicate refreshes. This is the default value for all view technologies other than ADF Faces.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ never: The application itself calls refresh on the executable during one of the controller phases and does not want the framework to refresh the executable at all.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ prepareModel: Invokes the executable each time the page’s binding container is prepared.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ prepareModelIfNeeded: Invokes the executable during the Prepare Model phase if this executable has not been refreshed to this point. See also ifNeeded.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ renderModel: Invokes the executable each time the page is rendered.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>■ renderModelIfNeeded: Invokes the executable during the page’s Render Model phase on the condition that it is needed. See also ifNeeded.</td>
</tr>
<tr>
<td>RefreshCondition</td>
<td>An EL expression that determines if the executable should be refreshed. Use with the executable’s Refresh attribute to make the refresh of the executable predictable. The Refresh attribute is evaluated if the EL expression that you set for RefreshCondition returns true.</td>
<td></td>
</tr>
<tr>
<td>RefreshAfter</td>
<td>Use to handle dependencies between executables. For example, you can set a condition so that this executable refreshes after another executable.</td>
<td></td>
</tr>
</tbody>
</table>
### RowCountThreshold
Specify a value to determine if a result set returns the number of rows you specify as a value. If you set RowCountThreshold to 0, the iterator returns the estimated row count in the result set by executing the count query. If you set RowCountThreshold to less than 0, the iterator does not execute the count query.

Set RowCountThreshold to a value greater than 0 if you want the iterator to execute the count query with the maximum value equal to the value you specify for RowCountThreshold. If the estimated row count is less than the value of RowCountThreshold, return the number of rows in the estimated row count. If the estimated row count is greater than the value of RowCountThreshold, return -1.

### Sortable
Specifies whether the iterator is sortable or not.

### <invokeAction>
Only use `<invokeAction>` when your application does not use the ADF Controller module from the Fusion web application technology stack. Oracle recommends that you use a task flow method call activity, as described in Section 21.5, “Using Method Call Activities,” if your application uses the ADF Controller module.

### Binds
Determines the action to invoke. This may be on any actionBinding. Additionally, in the case, of the EJB session facade data control, you may bind to the finder method exposed by the data control. Built-in actions supported by the EJB session facade data control include:

- **Execute** executes the bound action defined by the data collection.
- **Find** retrieves a data object from a collection.
- **First** navigates to the first data object in the data collection range.
- **Last** navigates to the first data object in the data collection range.
- **Next** navigates to the first data object in the data collection range. If the current range position is already on the last data object, then no action is performed.
- **Previous** navigates to the first data object in the data collection range. If the current position is already on the first data object, then no action is performed.
- **setCurrentRowWithKey** passes the row key as a String converted from the value specified by the input field. The row key is used to set the currency of the data object in the bound data collection. When passing the key, the URL for the form will not display the row key value. You may use this operation when the data collection defines a multipart attribute key.
- **setCurrentRowWithKeyValue** is used as above, but when you want to use a primary key value instead of the stringified key.

### id
Unique identifier. May be referenced by any ADF action binding.

### Refresh
See Refresh for `<accessorIterator>`.

### RefreshCondition
See RefreshCondition for `<accessorIterator>`.

| <graph>        | type               | Identifies the graph type.                                                           |
|                | ChangeEventPolicy  | Identifies the update policy for the component. Valid values are none, ppr, and push. The default is ppr. |
|                | xmlns              | Used internally by ADF.                                                               |
|                | CustomInputHandle  | This is the class name for a oracle.jbo.uicli.binding.JUCtrlValueHandle implementation that is used to process the inputValue for a given value binding. |
|                | id                 | Unique identifier. May be referenced by any ADF action binding.                      |
|                | IterBinding        | Refers to the iteratorBinding instance in this bindingContainer to which this binding is associated. |
|                | NullValueId        | Refers to the entry in the message bundle for this bindingContainer that contains the String to indicate the null value in a list display. |
|                | graphDataMap       | Wraps the data binding XML for the ADF Faces graph component.                        |

<p>| &lt;list&gt;         | ApplyValidation    | Set to true by default. When true, controlBinding executes validators defined on the binding. You can set to false in the case of ADF Business Components, when running in local mode and when the same validators are already defined on the corresponding attribute. |
|                | BindingClass       | This is for backward compatibility to indicate which class implements the runtime for this binding definition. This is used by earlier versions of JDeveloper. |
|                | ControlClass       | Used internally by ADF.                                                               |</p>

</tr>
</tbody>
</table>
The `adfc-config.xml` file is the source file for the ADF unbounded task flow that JDeveloper creates by default when you create an application using the ADF Fusion Web Application template. By default, JDeveloper stores the `adfc-config.xml` file in the following directory:

```
application_root\ViewController\Web Content\WEB-INF
```

If you create additional unbounded task flows, JDeveloper proposes the following file name for the source files of the additional unbounded task flows:

```
adfc-configN.xml
```
where $N$ is a number that increments each time you create a new unbounded task flow. Alternatively, you choose the file name you want for an unbounded task flow’s source file.

Each source file for an unbounded task flow contains the metadata for activities, control flow rules, and managed beans that you added to an unbounded task flow so that end users can interact with the Fusion web application to complete a task.

The XML schema definition file (XSD) that defines valid metadata entries for the `adfc-config.xml` file is `adfc-config_1_0.xsd`. The `adfc-config_1_0.xsd` file is stored in the `adf-controller-schema.jar` file in the following directory of your JDeveloper installation:

```
jdev_install\oracle_common\modules\oracle.adf.model_12.1.2
```

Use JDeveloper’s XSD Visual Editor to view the `adfc-config_1_0.xsd` file. Using this editor, you can identify the valid metadata elements and attributes for the `adfc-config.xml` file.

**Example A–5** shows the source file for an unbounded task flow where view activities, control flow rules, and so on have yet to be added.

**Example A–5  Sample adfc-config.xml file with no entries**

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
</adfc-config>
```

**Figure A–4** shows the Diagram view of the Summit sample application for ADF task flows’ `adfc-config.xml` file. **Example A–6** shows the corresponding source view of the unbounded task flow that appears in **Figure A–4**.

For more information about unbounded task flows, see Chapter 20, "Getting Started with ADF Task Flows."

**Figure A–4  Diagram View of Summit ADF Task Flow Sample Application’s adfc-config.xml File**

---

**Example A–6  Source View of Summit ADF Task Flow Sample Application’s adfc-config.xml File**

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <view id="index">
    <page>/index.jsf</page>
  </view>
  <managed-bean id="__1">
    <managed-bean-name>login</managed-bean-name>
    <managed-bean-class>oracle.summit.bean.LoginBean</managed-bean-class>
    <managed-bean-scope>request</managed-bean-scope>
  </managed-bean>
  <managed-bean id="__2">
    <managed-bean-name>WelcomePageBean</managed-bean-name>
    <managed-bean-class>oracle.summit.bean.WelcomePageBean</managed-bean-class>
  </managed-bean>
</adfc-config>
```
A.10  task-flow-definition.xml

The default file name that JDeveloper proposes for the source file of the first ADF bounded task flow that you create is task-flow-definition.xml. This file stores the metadata for a bounded task flow. It contains entries for each view activity, method call activity, task flow call, and so on that you add to the bounded task flow.

JDeveloper proposes the following file name for subsequent bounded task flows that you create:

task-flow-definitionN.xml

where N is a number that increments each time you create a new bounded task flow. Alternatively, you choose the file name you want for a bounded task flow’s source file. By default, JDeveloper stores the task-flow-definition.xml file in the following directory:

application_root\ViewController\Web Content\WEB-INF

The XML schema definition files (XSD) that define the valid metadata entries for the source file of a bounded task flow are stored in the adf-controller-schema.jar file in the following directory of your JDeveloper installation:

jdev_install\oracle_common\modules\oracle.adf.model_12.1.2

Use JDeveloper’s XSD Visual Editor to view these XSD files and identify the valid metadata elements and attributes for the source file of a bounded task flow.

Example A–7 shows the content of a source file when you create a new bounded task flow using the Create Task Flow dialog. The <task-flow-definition> element identifies this file as a bounded task flow. JDeveloper generates the <task-flow-definition> element when you select the Create as Bounded Task Flow checkbox in the Create Task Flow dialog. The value of the <task-flow-definition> element’s id attribute (task-flow-definition) corresponds to the value that you enter in the Task Flow ID field of the Create Task Flow dialog. The <use-page-fragments/> element indicates that all view activities in this bounded task flow must be associated with page fragments. JDeveloper generates this entry when you select the Create with Page Fragments checkbox in the Create Task Flow dialog.

Example A–7  Sample task-flow-definition.xml with no entries

<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <task-flow-definition id="task-flow-definition">
    <use-page-fragments/>
  </task-flow-definition>
</adfc-config>

Example A–8 shows the Summit ADF task flow sample application’s customers-task-flow-definition.xml file. You can view entries for the activities shown in the Structure window in Figure A–5.

For more information about bounded task flows, see Chapter 20, “Getting Started with ADF Task Flows.”
Figure A–5  Structure View of the customers-task-flow-definition.xml File

Example A–8  Source View of the customers-task-flow-definition.xml File

```xml
<?xml version="1.0" encoding="windows-1252" >
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
<task-flow-definition id="customer-task-flow-definition">
  <default-activity id="__1">isCustomerLogin</default-activity>
  <managed-bean id="__11">
    <managed-bean-name id="__9">CustomersBackingBean</managed-bean-name>
    <managed-bean-class id="__10">oracle.summit.backing.CustomersBackingBean</managed-bean-class>
    <managed-bean-scope id="__8">backingBean</managed-bean-scope>
  </managed-bean>
  <view id="Customers">
    <page>/customers/Customers.jsff</page>
  </view>
  <method-call id="SetCurrentRowWithKeyValue">
    <method>#{bindings.setCurrentRowWithKeyValue.execute}</method>
    <outcome>
      <fixed-outcome>setCurrentRowWithKey</fixed-outcome>
    </outcome>
  </method-call>
  <router id="isCustomerLogin">
    <case id="__4">
      <expression>${securityContext.userInRole['Application Customer Role']}</expression>
      <outcome>customerLogin</outcome>
    </case>
    <default-outcome>notCustomerLogin</default-outcome>
  </router>
  <control-flow-rule id="__2">
    <from-activity-id>SetCurrentRowWithKeyValue</from-activity-id>
    <control-flow-case id="__3">
      <from-outcome>setCurrentRowWithKey</from-outcome>
      <to-activity-id>Customers</to-activity-id>
    </control-flow-case>
  </control-flow-rule>
  <control-flow-rule id="__5">
    <from-activity-id>isCustomerLogin</from-activity-id>
    <control-flow-case id="__6">
      <from-outcome>notCustomerLogin</from-outcome>
      <to-activity-id>Customers</to-activity-id>
    </control-flow-case>
  </control-flow-rule>
</task-flow-definition>
</adfc-config>
```
A.11  adf-config.xml

JDeveloper generates the adf-config.xml file when you create an application using the ADF Fusion Web Application template. JDeveloper stores this application-level descriptor file in the following directory:

application_root\adf\META-INF

In JDeveloper, you can locate the file in the Application Resources panel of the Applications window by expanding the Descriptors > ADF META-INF nodes.

The adf-config.xml file specifies application-level settings that you define during development. You can use a deployment profile to specify settings that are used at application deploy time. You can change some of the settings at runtime using Oracle Enterprise Manager.

Examples of tasks that you can accomplish by changing settings in the adf-config.xml file include the following:

- Enable or disable the validation of ADF Controller metadata
- Replicate memory scope if you deploy your Fusion web application in a clustered environment
- Configure an integer value for the root-view-port-request-lock-timeout property that specifies the number of seconds a request can hold a lock on the root view port before timing out and allowing other requests to acquire the lock. The default value is 600 seconds. For more information about the root view port, see Section 23.1.2, "About View Ports and ADF Regions."
- Configure properties to manage the caching of resource bundles where your application uses EL expressions to retrieve strings at runtime from resource bundles

The properties that you can configure are:

- **initial-size**
  
  Specifies the initial number of resource bundles that your application can cache. The default value is 100.

- **max-size**
  
  Specifies the maximum number of resource bundles that your application can cache. The default value is 100.

- **load-factor**
  
  The default value is 0.75.

- **expire-time**
  
  The default value is 43200 seconds (12 hours).
You specify these properties as attribute values of the `<resource-bundle-cache>` element in the `adf-config.xml` file. Example A–9 demonstrates how you might configure these values for your application in the `adf-config.xml` file.

As an alternative to configuring the caching of resource bundles in the `adf-config.xml` file, you can specify the resource bundle caching properties as parameters for the Java Virtual Machine (JVM). If you specify the properties as parameters for the JVM, the changes apply to all applications managed by the JVM. For this reason, consider configuring the resource bundle caching properties in the `adf-config.xml` file for your application. Use the following property names if you decide to specify the resource bundle caching properties as parameters for the JVM:

- resource-bundle-cache-initial-size
- resource-bundle-cache-max-size
- resource-bundle-cache-load-factor
- resource-bundle-cache-expire-time

At runtime, the Fusion web application loads the `adf-config.xml` file from the `META-INF` directory. If the Fusion web application finds more than one `adf-config.xml` file, it stops loading the file and logs a warning.

The following tasks modify or require you to modify the `adf-config.xml` file:

- Creating task flows
  For more information, see Chapter 20, "Getting Started with ADF Task Flows."

- Enabling implicit save points
  For more information, see Section 24.7.7, "How to Enable Implicit Save Points."

- Specify a bounded task flow that does not require authorization to invoke when a user attempts to invoke a bounded task flow in a region for which they do not have security permissions. For more information, see Section 23.12, "Handling Access to Secured Task Flows by Unauthorized Users."

- Disable automatic partial page rendering as the default behavior for an application. This requires you to change the value for the `changeEventPolicy` attribute from the default value of `ppr`:

  ```xml
  <defaults changeEventPolicy="ppr"/>
  ```
  
  For more information, see Section 27.2.1, "What You May Need to Know About Partial Page Rendering and Iterator Bindings."

- Persisting saved searches in MDS
  For more information, see Section 33.2.4, "How to Persist Saved Searches into MDS."

- Configuring ADF Business Components global settings
  For more information, see Section 9.1.1, "Limiting the Maximum Number of Records Fetched for a View Object" and Section 3.2.3, "How to Initialize the Data Model Project With a Database Connection."

- Enabling or disabling Oracle ADF Security
  For more information, see Section 41.3, "Enabling ADF Security" and Section 41.10, "Disabling ADF Security."
Enabling seeded customizations

For more information, see Section 45.2.4, "How to Enable Seeded Customizations for User Interface Projects" and Section 45.2.5, "How to Enable Seeded Customizations in Existing Pages."

Configuring change persistence

For more information, see Section 46.2.1, "How to Enable User Customizations."

Enabling user customizations

For more information, see Section 46.2.2, "What Happens When You Enable User Customizations."

Example A–9 shows example entries for an application’s adf-config.xml file.

Example A–9  Sample adf-config.xml File

```xml
<adf-config version="1.0" encoding="windows-1252" ?>
  <adf-config xmlns="http://xmlns.oracle.com/adf/config">
    <sec:adf-security-child>
      <CredentialStoreContext credentialStoreClass="oracle.adf.share.security.providers.jps.CSFCredentialStore"
        credentialStoreLocation="../../src/META-INF/jps-config.xml"/>
      <JaasSecurityContext initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
        jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
        authorizationEnforce="true"
        authenticationRequire="true"/>
    </sec:adf-security-child>
    <savepoint-datasource>java:comp/env/jdbc/summit_adfDS</savepoint-datasource>
    <enable-implicit-savepoints>true</enable-implicit-savepoints>
    <unauthorized-region-taskflow>/WEB-INF/task-flow-definition.xml</unauthorized-region-taskflow>
  </adf-controller-config>
</adf-config>
```

`<taglib config xmlns="http://xmlns.oracle.com/adf/faces/config">
  <tag name="calendar">
    <attribute name="activeDay">
      <persist-changes>true</persist-changes>
    </attribute>
  </tag>
  <tag name="table">
    <attribute name="filterVisible">
      <persist-changes>true</persist-changes>
    </attribute>
  </tag>
</taglib>`
The `adf-settings.xml` file holds project-level and library-level settings such as ADF Faces help providers and ADF Controller phase listeners.

The configuration settings for `adf-settings.xml` are fixed and cannot be changed during or after application deployment. There can be multiple `adf-settings.xml` files in an application. The users of `adf-settings.xml` files are responsible for merging the contents of their configuration.

JDeveloper creates an `adf-settings.xml` file when you:

- Create an application using the ADF Fusion Web Application template
- Add ADF Page Flow (ADF Controller) as a feature to an existing project

By default, JDeveloper stores the `adf-settings.xml` file in the following directory:

`application_root\ViewController\src\META-INF`

The following tasks modify or require you to modify the `adf-settings.xml` file:

- Registering a phase listener
  
  For more information, see Section 27.4.2, "How to Register a Listener Globally."

- Creating help for ADF Faces components
  
  For more information, see the "Displaying Help for Components" section in Developing Web User Interfaces with Oracle ADF Faces.
For information about how to edit the adf-settings.xml file, see the "How to Configure for ADF Faces in adf-settings.xml" section in Developing Web User Interfaces with Oracle ADF Faces.

Example A–10 shows a sample adf-settings.xml file with settings configured for a phase listener and a help provider.

Example A–10  Sample adf-settings.xml File

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adf-settings xmlns="http://xmlns.oracle.com/adf/config">
  <adfc-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
    <lifecycle>
      <phase-listener>
        <listener-id>SummitPhaseListener</listener-id>
        <class>oracle.summit.listeners.SummitPhaseListener</class>
      </phase-listener>
    </lifecycle>
  </adfc-controller-config>
  <adf-faces-config>
    <help-provider prefix="MYAPP">
      <help-provider-class>oracle.summit.MyHelpProvider</help-provider-class>
      <property>
        <property-name>myCustomProperty</property-name>
        <value>someValue</value>
      </property>
    </help-provider>
  </adf-faces-config>
</adf-settings>
```

A.13 web.xml

Oracle ADF has specific configuration settings for the standard web.xml deployment descriptor file.

When you create a project in JDeveloper that uses JSF technology, a starter web.xml file with default settings is created for you in the /WEB-INF folder. To edit the file, double-click web.xml in the Applications window to open it in the XML editor.

The following must be configured in web.xml for all applications that use JSF and ADF Faces:

- ADF Library resource servlet and mapping: Serves up web application resources (images, style sheets, JavaScript libraries) from ADF Library JAR files on the application class path.

By default, static web application resources (including resources in ADF Libraries), such as images, have a staleness period setting of 364 days. This staleness period setting requests that the client not make a request to the server to validate the static web application resources until one of the following events occur:

- Staleness period expires
- Browser cache no longer contains the static resource
- User executes a page refresh

If the client does make a request to the server and the resources have not changed, the server returns a HTTP 304 response (Not Modified) with no body.
You can override the staleness period setting of 364 days for all static web application resources in ADF Libraries by adding initialization parameters to the `web.xml` file. **Example A–11** demonstrates how to set these initialization parameters using a number of examples.

**Example A–11  Staleness Settings for Static Resources in web.xml**

```
<!-- Expires all static resources in 30 days -->
<init-param>
  <param-name>expires</param-name>
  <param-value>60*60*24*30</param-value>
</init-param>

<!-- Expires static resources with the .js file extension in 1 day -->
<init-param>
  <param-name>expires.js</param-name>
  <param-value>60*60*24</param-value>
</init-param>

<!-- Turns off staleness setting. Use for testing -->
<init-param>
  <param-name>expires</param-name>
  <param-value>OFF</param-value>
</init-param>
```

**Example A–12** shows the default file extensions. You can add additional file extensions by configuring the `extensions` parameter value to include the file extensions that you want. Note that you must prepend and append "." to the file extension. **Example A–12** also shows how you specify visibility for cache control.

**Example A–12  Specifying Additional File Extensions and Cache Control**

```
<!-- Specify file extensions for a number of different file formats -->
<init-param>
  <param-name>extensions</param-name>
  <param-value>.png.jpg.jpeg.gif.js.css.</param-value>
</init-param>

<!-- Specify visibility for cache control, for example -->
<init-param>
  <param-name>visibility</param-name>
  <param-value>Public</param-value>
</init-param>
```

- JSF servlet and mapping: The servlet `javax.faces.webapp.FacesServlet` that manages the request-processing lifecycle for web applications utilizing JSF to construct the user interface.
- ADF Faces filter and mapping: A servlet filter to ensure that ADF Faces is properly initialized by establishing a `AdfFacesContext` object. This filter also processes file uploads.

The JSF servlet and mapping configuration settings are automatically added to the starter `web.xml` file when you first create a JSF project. When you insert an ADF Faces component into a JSF page for the first time, JDeveloper automatically inserts the configuration settings for ADF Faces filter and mapping, and resource servlet and mapping.

For more information, see the "ADF Faces Configuration" appendix in *Developing Web User Interfaces with Oracle ADF Faces*.
A.14 logging.xml

ADF Logger is a diagnostic tool that you can use in JDeveloper to capture runtime traces messages when you debug an application. You configure the use of this tool by editing the logging.xml file.

For more information about the logging.xml file and using the ADF Logger, see Section 42.6, "Using the ADF Logger."
This appendix describes the properties of the ADF bindings that you use can access at runtime in an Oracle ADF application. Table B–1 shows the properties that you can use in EL expressions to access values of the ADF binding objects at runtime. The properties appear in alphabetical order.

<table>

</table>
| displayHints           | Returns a list of name-value pairs for UI hints for all display attributes to which the binding is associated. The map contains the following elements:  
  - label: The label to display for the current attribute.  
  - tooltip: The tooltip to display for the current attribute.  
  - displayHint: The display hint for the current attribute.  
  - displayHeight: The height in lines for the current attribute.  
  - displayWidth: The width in characters for the current attribute.  
  - controlType: The control type hint for the current attribute.  
  - format: The format to be used for the current attribute. | n/a      | n/a    | n/a      | yes    | yes  | n/a   | n/a  |
<p>| enabled                | Use the operationEnabled property.                                          | n/a      | n/a    | n/a      | n/a    | n/a  | n/a   | n/a  |
| enabledString          | Returns disabled if the action binding is not ready to be invoked. Otherwise, returns an empty string (&quot;&quot;). | n/a      | yes    | n/a      | n/a    | n/a  | n/a   | n/a  |
| error                  | Returns any exception that was cached while updating the associated attribute value for a value binding or when invoking an operation bound by an operation binding. | yes      | yes    | yes      | yes    | yes  | yes   | yes  |
| estimatedRowCount      | Returns the maximum row count of the rows in the collection with which this iterator binding is associated. | yes      | n/a    | n/a      | n/a    | n/a  | yes   | yes  |
| findMode               | Returns true if the iterator is currently operating in find mode. Otherwise, returns false. | yes      | n/a    | n/a      | n/a    | n/a  | n/a   | n/a  |
| fullName               | Returns the fully qualified name of the binding object in the Oracle ADF binding context. | yes      | yes    | yes      | yes    | yes  | yes   | yes  |</p>

### Table B–1 (Cont.) EL Properties of Oracle ADF Bindings

<table>
<thead>
<tr>
<th>Runtime Property</th>
<th>Description</th>
<th>Iterator</th>
<th>Action</th>
<th>Attribute</th>
<th>Button</th>
<th>List</th>
<th>Table</th>
<th>Tree</th>
</tr>
</thead>
</table>
| rangeSet         | Returns a list of map elements over the range of rows from the associated iterator binding. The elements in this list are wrapper objects over the indexed row in the range that restricts access to the attributes to which the binding is bound. The properties returned on the reference object are:   
   - index: The range index of the row this reference is pointing to.  
   - key: The key of the row this reference is pointing to.  
   - keyStr: The string format of the key of the row this reference is pointing to.  
   - currencyString: The current indexed row as a string. Returns "*" if the current entry belongs to the current row; otherwise, returns " ". This property is useful in JSP applications to display the current row.  
   - attributeValues: The array of applicable attribute values from the row. You may also access an attribute value by name on a range set like rangeSet.dname if dname is a bound attribute in the range binding. | n/a      | n/a    | n/a      | n/a    | n/a  | yes   | yes  |
| rangeSize        | Returns the range size of the ADF iterator binding's row set. This allows you to determine the number of data objects to bind from the data source.                                                                 | yes      | n/a    | n/a      | n/a    | n/a  | yes   | yes  |
| rangeStart       | Returns the absolute index in a collection of the first row in range. See the javadoc for oracle.jbo.RowSetIterator.getRangeStart().                                                                                                                                  | yes      | n/a    | n/a      | n/a    | n/a  | yes   | yes  |
| result           | Returns the result of a method that is bound and invoked by a method action binding.                                                                                                                      | n/a      | yes    | n/a      | n/a    | n/a  | n/a   | n/a  |
| rootNodeBinding  | Returns the root node of a tree binding.                                                                                                                                                                   | n/a      | n/a    | n/a      | n/a    | n/a  | n/a   | yes  |

ADF Security Permission Grants

This appendix lists the security-aware components of Oracle ADF and the actions that their Permission implementation classes define.

Table C–1 shows the ADF components and their permission grants that you can define to create ADF security policies. You add grants to the policy store using the overview editor for ADF security policies. A permission grant specifies the fully qualified permission class name, the fully qualified resource name, the action that can be performed against the resource, and the application role target of the grant. When you enable ADF security to enforce authorization checking against the security policies of the policy store, the operations supported by ADF components will be inaccessible to users who do not possess sufficient access rights as defined by grants to their application role.

For complete details about defining ADF security policies in Fusion web applications, see Chapter 41, "Enabling ADF Security in a Fusion Web Application."

Most Commonly Used ADF Business Components Methods

This appendix lists the most commonly used methods in the interfaces and classes of the ADF Business Components layer of Oracle ADF.

This appendix contains the following sections:

- Section D.1, "Methods for Creating Your Own Layer of Framework Base Classes"
- Section D.2, "Methods Used in the Client Tier"
- Section D.3, "Methods Used in the Business Service Tier"

D.1 Methods for Creating Your Own Layer of Framework Base Classes

Before you begin to develop application-specific business components, you can create a layer of classes that extend all of the ADF Business Components framework base implementation classes described in this appendix. An example of a customized framework base class for application module components might look like this:

```java
package com.yourcompany.adfextensions;
import oracle.jbo.server.ApplicationModuleImpl;
public class CustomApplicationModuleImpl extends ApplicationModuleImpl {
    /*
    * We might not yet have any custom code to put here yet, but
    * the first time we need to add a generic feature that all of
    * our company’s application modules need, we will be very happy
    * that we thought ahead to leave ourselves a convenient place
    * in our class hierarchy to add it so that all of the application
    * modules we have created will instantly benefit by that new feature,
    * behavior change, or even perhaps, bug workaround.
    */
}
```

A common set of customized framework base classes in a package name of your own choosing like `com.yourcompany.adfextensions`, each importing the `oracle.jbo.server.*` package, would consist of the following classes:

- public class CustomEntityImpl extends EntityImpl
- public class CustomEntityDefImpl extends EntityDefImpl
- public class CustomViewObjectImpl extends ViewObjectImpl
- public class CustomViewRowImpl extends ViewRowImpl
- public class CustomApplicationModuleImpl extends ApplicationModuleImpl
Methods Used in the Client Tier

- public class CustomDBTransactionImpl extends DBTransactionImpl2
- public class CustomDatabaseTransactionFactory extends DatabaseTransactionFactory

For completeness, you may also want to create customized framework classes for the following classes as well:
- public class CustomViewDefImpl extends ViewDefImpl
- public class CustomEntityCache extends EntityCache
- public class CustomApplicationModuleDefImpl extends ApplicationModuleDefImpl

Overriding anything in these classes would be a fairly rare requirement.

D.2 Methods Used in the Client Tier

All of the interfaces described in this section are designed so that you may expose method for use in the client tier. These interface methods part of the oracle.jbo.* package.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components interfaces.

Note: The corresponding implementation classes for these oracle.jbo.* interfaces are intentionally designed to not be directly accessed by client code. Section D.3, "Methods Used in the Business Service Tier" shows that the implementation classes reside in the oracle.jbo.server.* package and generally have the suffix Impl in their name to help remind you not to use them in your client-layer code.

D.2.1 ApplicationModule Interface

An application module is a business service component that acts as a transactional container for other ADF components and coordinates with them to implement a number of Java EE design patterns important to business application developers. These design pattern implementations enable your client code to work easily with updatable collections of value objects, based on fast-lane reader SQL queries that retrieve only the data needed by the client, in the way the client wants to view it. Changes made to these value objects are automatically coordinated with your persistent business domain objects in the business service tier to enforce business rules consistently and save changes back to the database. Table D–1 describes the operations that you can perform on an application module using the ApplicationModule interface.

Note: For the complete list of design patterns that ADF Business Components implements, see Appendix E, "ADF Business Components Java EE Design Pattern Catalog."
Methods Used in the Client Tier

In addition to generic application module access, JDeveloper can generate a custom YourApplicationModuleName interface containing service-level custom methods that you’ve chosen to expose to the client. You use the Client Interface page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.

D.2.2 Transaction Interface

The Transaction interface exposes methods allowing the client to manage pending changes in the current transaction. Table D–2 describes the operations that you can perform on the transaction using the Transaction interface.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this ApplicationModule interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Access an existing view object instance using the assigned instance name (for example, MyVOInstanceName)</td>
<td>findViewObject()</td>
</tr>
<tr>
<td>Create a new view object instance from an existing definition</td>
<td>createViewObject()</td>
</tr>
<tr>
<td>Create a new view object instance from a SQL Statement</td>
<td>createViewObjectFromQueryStmt()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This incurs runtime overhead to describe the &quot;shape&quot; of the dynamic query's SELECT list. Use this method only when you cannot know the SELECT list for the query at design time. Furthermore, if you are creating the dynamic query based on some kind of custom runtime repository, you can follow the steps to create (both read-only and updatable) dynamic view objects without the runtime-describe overhead, as described in Section 10.6, &quot;Creating a View Object with Multiple Updatable Entities.&quot; If only the WHERE needs to be dynamic, create the view object at design time, then set the WHERE clause dynamically as needed using ViewObject APIs.</td>
</tr>
<tr>
<td>Access a nested application module instance by name</td>
<td>findApplicationModule()</td>
</tr>
<tr>
<td>Create a new nested application module instance from an existing definition</td>
<td>createApplicationModule()</td>
</tr>
<tr>
<td>Find a view object instance in a nested application module using a dot-notated name (for example, MyNestedAMInstanceName.OneOfItsVONames)</td>
<td>findViewObject()</td>
</tr>
<tr>
<td>Notes:</td>
<td>You can use this method to find an instance of a view object belonging to a nested application module in a single method call. This way you do not need to first call findApplicationModule() to find the nested application module, before calling findViewObject() on that nested application module.</td>
</tr>
<tr>
<td>Access the current transaction object</td>
<td>getTransaction()</td>
</tr>
</tbody>
</table>

In addition to generic application module access, JDeveloper can generate a custom YourApplicationModuleName interface containing service-level custom methods that you’ve chosen to expose to the client. You use the Client Interface page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.
### D.2.3 ViewObject Interface

A view object is a component that encapsulates a database query and simplifies working with the row set of results it produces. You use view objects to project, filter, join, or sort business data using SQL from one or more tables to cast the data into exactly the format that the user should see on the page or panel. You can create "master-detail" hierarchies of any depth or complexity by connecting view objects together using view links. View objects can produce read-only query results, or when associated with one or more entity objects at design time, can be fully updatable. Updatable view objects can support insertion, modification, and deletion of rows in the result collection, with automatic delegation to the correct business domain objects.
Every view object contains a "default row set" for simplifying the 90 percent of use cases where you work with a single row set of results for the view object’s query. A view object implements all the methods on the RowSet interface by delegating them to this default RowSet. That means you can invoke any RowSet methods on any view object as well.

Every view object implements the StructureDef interface to provide information about the number and types of attributes in a row of its row sets. So you can call StructureDef methods directly on any view object.

Table D–3 describes the operations that you can perform on a view object using the ViewObject interface.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this ViewObject interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Set an additional runtime WHERE clause on the row set</td>
<td>setWhereClause()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This WHERE clause augments any WHERE clause specified at design time in the base view object. It does not replace it.</td>
</tr>
<tr>
<td>Set a dynamic ORDER BY clause</td>
<td>setOrderByClause()</td>
</tr>
<tr>
<td>Create a Query-by-Example criteria collection</td>
<td>createViewCriteria()</td>
</tr>
<tr>
<td>Notes:</td>
<td>You then create one or more ViewCriteriaRow objects using the createViewCriteriaRow() method on the ViewCriteria object you created. Then you add() these view criteria rows to the view criteria collection and apply the criteria using the applyViewCriteria() method.</td>
</tr>
<tr>
<td>Apply a Query-by-Example criteria collection</td>
<td>applyViewCriteria()</td>
</tr>
<tr>
<td>Set a query optimizer hint</td>
<td>setQueryOptimizerHint()</td>
</tr>
<tr>
<td>Access the attribute definitions for the key attributes in the view object</td>
<td>getKeyAttributeDefs()</td>
</tr>
<tr>
<td>Add a dynamic attribute to rows in this view object’s row sets</td>
<td>addDynamicAttribute()</td>
</tr>
<tr>
<td>Clear all row sets produced by a view object</td>
<td>clearCache()</td>
</tr>
<tr>
<td>Remove a view object instance and its resources</td>
<td>remove()</td>
</tr>
<tr>
<td>Set an upper limit on the number of rows that the view object will attempt to fetch from the database</td>
<td>setMaxFetchSize()</td>
</tr>
<tr>
<td>Notes:</td>
<td>Default is -1, which means to impose no limit on how many rows would be retrieved from the database if you iterated through them all. By default, as you iterate through them, they are fetched lazily.</td>
</tr>
</tbody>
</table>

In addition to generic ViewObject access, JDeveloper can generate you a custom YourViewObjectName interface containing view object-level custom methods that you’ve chosen to expose to the client. You use the Client Interface page of the Edit View Object dialog to select the methods that you want to appear in your client interface.
D.2.4 RowSet Interface

A row set is an object that contains a set of rows, typically produced by executing a view object's query.

Every RowSet aggregates a "default row set iterator" for simplifying the 90 percent of use cases where you need only a single iterator over the row set. A RowSet object implements all the methods on the RowSetIterator interface by delegating them to this default RowSetIterator. This means you can invoke any RowSetIterator method on any RowSet object (or view object, since it implements RowSet, as well for its default RowSet).

Table D–4 describes the operations that you can perform on a row set using the RowSet interface.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSet interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Set a WHERE clause bind variable value</td>
<td>setWhereClauseParams()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>Bind variable ordinal positions are zero-based.</td>
<td></td>
</tr>
<tr>
<td>Avoid view object row caching if data is being read only once</td>
<td>setForwardOnly()</td>
</tr>
<tr>
<td>Force a row set's query to be (re)executed (in the case of exclusive view object instances) or potentially executed (in the case of shared view object instances)</td>
<td>executeQuery()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>The behavior of this method differs depending on whether the view object belongs to a shared application module or not. When reexecuting the query for an exclusive view object (not an instance of a shared module), a new query collection is created. Before executing the query for a shared view object instance, a check is performed to determine whether the results already exist. Already cached results will be reused for the shared view object instance instead of reexecuting the query. If you want to ensure that the results for a shared view object instance are refreshed, you can invoke the forceExecuteQueryOfSharedVO() method. However, if at the time of invoking force execute a user is iterating over the collection of a shared view object instance, then the behavior is undefined and exceptions may result.</td>
<td></td>
</tr>
<tr>
<td>Estimate the number of rows in a view object's query result</td>
<td>getEstimatedRowCount()</td>
</tr>
<tr>
<td>Produce an XML document for rows in a view object row set</td>
<td>writeXML()</td>
</tr>
<tr>
<td>Process all rows from an incoming XML document</td>
<td>readXML()</td>
</tr>
<tr>
<td>Set whether a row set will automatically see new rows based on the same entity object created through other row sets</td>
<td>setAssociationConsistent()</td>
</tr>
</tbody>
</table>
D.2.5 RowSetIterator Interface

A row set iterator is an iterator over the rows in a row set. By default it allows you to iterate both forward and backward through the rows. Table D–5 describes the operations that you can perform on a row set using the RowSetIterator interface.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSetIterator interface method</th>
<th>Notes:</th>
</tr>
</thead>
<tbody>
<tr>
<td>Create a secondary iterator to use for programmatic iteration</td>
<td><code>createRowSetIterator()</code></td>
<td>If you plan to find and use the secondary iterator by name later, then pass in a string name as the argument; otherwise, pass <code>null</code> for the name and make sure to close the iterator when done iterating by calling its <code>closeRowSetIterator()</code> method.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSetIterator interface method</th>
<th>Notes:</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the first row of the iterator's row set</td>
<td><code>first()</code></td>
<td></td>
</tr>
<tr>
<td>Test whether there are more rows to iterate</td>
<td><code>hasNext()</code></td>
<td></td>
</tr>
<tr>
<td>Get the next row of an iterator's row set</td>
<td><code>next()</code></td>
<td></td>
</tr>
<tr>
<td>Find a row in this iterator's row set with a given key value</td>
<td><code>findByKey()</code></td>
<td>It's important that the Key object that you pass to <code>findByKey</code> be created using the exact same data types as the attributes that comprise the key of the rows in the view object you're working with.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSetIterator interface method</th>
<th>Notes:</th>
</tr>
</thead>
<tbody>
<tr>
<td>Create a new row to populate for insertion</td>
<td><code>createRow()</code></td>
<td>The new row will already have default values set for attributes which either have a static default value supplied at the entity object or view object level, or if the values have been populated in an overridden <code>create()</code> method of the underlying entity object(s).</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSetIterator interface method</th>
<th>Notes:</th>
</tr>
</thead>
<tbody>
<tr>
<td>Create a view row with an initial set of foreign key and/or discriminator attribute values</td>
<td><code>createAndInitRow()</code></td>
<td>You use this method when working with view objects that can return one of a &quot;family&quot; of entity object subtypes. By passing in the correct discriminator attribute value in the call to create the row, the framework can create you the correct matching entity object subtype underneath.</td>
</tr>
</tbody>
</table>
Methods Used in the Client Tier

Table D–5 (Cont.) RowSetIterator Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSetIterator interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Insert a new row into the iterator’s row set</td>
<td>insertRow()</td>
</tr>
<tr>
<td>Notes:</td>
<td>It’s a good habit to always immediately insert a newly created row into the rowset. That way you will avoid a common gotcha of creating the row but forgetting to insert it into the rowset.</td>
</tr>
<tr>
<td>Get the last row of the iterator’s row set</td>
<td>last()</td>
</tr>
<tr>
<td>Get the previous row of the iterator’s row set</td>
<td>previous()</td>
</tr>
<tr>
<td>Reset the current row pointer to the slot before the first row</td>
<td>reset()</td>
</tr>
<tr>
<td>Close an iterator when done iterating</td>
<td>closeRowSetIterator()</td>
</tr>
<tr>
<td>Set a given row to be the current row</td>
<td>setCurrentRow()</td>
</tr>
<tr>
<td>Remove the current row</td>
<td>removeCurrentRow()</td>
</tr>
<tr>
<td>Remove the current row to later insert it at a different location in the same iterator</td>
<td>removeCurrentRowAndRetain()</td>
</tr>
<tr>
<td>Remove the current row from the current collection but do not remove it from the transaction.</td>
<td>removeCurrentRowFromCollection()</td>
</tr>
<tr>
<td>Set/change the number of rows in the range (a “page” of rows the user can see)</td>
<td>setRangeSize()</td>
</tr>
<tr>
<td>Scroll to view the nth page of rows (1-based)</td>
<td>scrollToRangePage()</td>
</tr>
<tr>
<td>Scroll to view the range of rows starting with row number n</td>
<td>scrollRangeTo()</td>
</tr>
<tr>
<td>Set row number n in the range to be the current row</td>
<td>setCurrentRowAtRangeIndex()</td>
</tr>
<tr>
<td>Get all rows in the range as a row array</td>
<td>getAllRowsInRange()</td>
</tr>
</tbody>
</table>

D.2.6 Row Interface

A row is generic value object. It contains attributes appropriate in name and Java type for the view object that it is related to. Table D–6 describes the operations that you can perform on a view object row using the Row interface.

Table D–6 Row Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this Row interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the value of an attribute by name</td>
<td>getAttribute()</td>
</tr>
<tr>
<td>Set the value of an attribute by name</td>
<td>setAttribute()</td>
</tr>
<tr>
<td>Produce an XML document for a single row</td>
<td>writeXML()</td>
</tr>
<tr>
<td>Eagerly validate a row</td>
<td>validate()</td>
</tr>
<tr>
<td>Read row attribute values from XML</td>
<td>readXML()</td>
</tr>
<tr>
<td>Remove the row</td>
<td>remove()</td>
</tr>
<tr>
<td>Flag a newly created row as temporary (until updated again)</td>
<td>setNewRowState(Row.STATUS_INITIALIZED)</td>
</tr>
</tbody>
</table>
In addition to generic Row access, JDeveloper can generate a custom YourViewObjectNameRow interface containing your type-safe attribute getter and setter methods, as well as any desired row-level custom methods that you’ve chosen to expose to the client. You use the Client Row Interface page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

### D.2.7 StructureDef Interface

The StructureDef interface provides access to runtime metadata about the structure of a Row object.

In addition, for convenience every view object implements the StructureDef interface as well, providing access to metadata about the attributes in the resulting view rows that its query will produce.

Table D–7 describes the operations that you can perform on a view object row using the StructureDef interface.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this StructureDef interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Access attribute definitions for all attributes in the view object row</td>
<td>getAttributeDefs()</td>
</tr>
<tr>
<td>Find an attribute definition by name</td>
<td>findAttributeDef()</td>
</tr>
<tr>
<td>Get attribute definition by index</td>
<td>getAttributeDef()</td>
</tr>
<tr>
<td>Get number of attributes in a row</td>
<td>getAttributeCount()</td>
</tr>
</tbody>
</table>

### D.2.8 AttributeDef Interface

The AttributeDef interface provides attribute definition information for any attribute of a view object row or entity object instance like attribute name, Java type, and SQL type. It also provides access to custom attribute-specific metadata properties that can be inspected by generic code you write, as well as UI hints that can assist in rendering an appropriate user interface display for the attribute and its value. Table D–8 describes the operations that you can perform on an attribute using the AttributeDef interface.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this AttributeDef interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the Java type of the attribute</td>
<td>getJavaType()</td>
</tr>
<tr>
<td>Get the SQL type of the attribute</td>
<td>getSQLType()</td>
</tr>
</tbody>
</table>

**Notes:**

The int value corresponds to constants in the JDBC class java.sql.Types.
D.2.9 AttributeHints Interface

The AttributeHints interface exposes UI hint information that you can use to render an appropriate user interface display for the attribute and its value. Table D–9 describes the operations that you can perform on an attribute using the AttributeHints interface.

### Table D–9 AttributeHints Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this AttributeHints interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Determine the kind of attribute</td>
<td>getAttributeKind()</td>
</tr>
<tr>
<td>Get the Java type of elements contained in an Array-valued attribute</td>
<td>getElemJavaType()</td>
</tr>
<tr>
<td>Get the SQL type of elements contained in an Array-valued attribute</td>
<td>getElemSQLType()</td>
</tr>
<tr>
<td>Get the name of the attribute</td>
<td>getName()</td>
</tr>
<tr>
<td>Get the index position of the attribute</td>
<td>getIndex()</td>
</tr>
<tr>
<td>Get the precision of a numeric attribute or the maximum length of a string attribute</td>
<td>getPrecision()</td>
</tr>
<tr>
<td>Get the scale of a numeric attribute</td>
<td>getScale()</td>
</tr>
<tr>
<td>Get the underlying column name corresponding to the attribute</td>
<td>getColumnNameForQuery()</td>
</tr>
<tr>
<td>Get attribute-specific custom property values</td>
<td>getProperty(), getProperties()</td>
</tr>
<tr>
<td>Get the UI AttributeHints object for the attribute</td>
<td>getUIHelper()</td>
</tr>
<tr>
<td>Test whether the attribute is mandatory</td>
<td>isMandatory()</td>
</tr>
<tr>
<td>Test whether the attribute is queriable</td>
<td>isQueriable()</td>
</tr>
<tr>
<td>Test whether the attribute is part of the primary key for the row</td>
<td>isPrimaryKey()</td>
</tr>
<tr>
<td>Get the formatted value of the attribute, using any format mask supplied</td>
<td>getFormattedAttribute()</td>
</tr>
</tbody>
</table>
## Methods Used in the Business Service Tier

### D.3 Methods Used in the Business Service Tier

The implementation classes corresponding to the `oracle.jbo.*` interfaces, as described in Section D.2, "Methods Used in the Client Tier," are intentionally designed to not be directly accessed by client code. They reside in a different package named `oracle.jbo.server.*` and have the `Impl` suffix in their name to help remind you not to use them in your client-layer code.

In your business service tier implementation code, you can use any of the same methods that are available to clients, but in addition you can also:

- Safely cast any `oracle.jbo.*` interface to its `oracle.jbo.server.*` package implementation class and use any methods on that `Impl` class as well.
- Override any of the public or protected methods for the base framework implementation classes and write custom code in your component subclass before or after calling `super.methodName()` to augment or change the default functionality.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components classes.

### D.3.1 Controlling Custom Java Files for Your Components

Before examining the specifics of individual classes, it’s important to understand how you can control which custom Java files each of your components will use. When you don’t need a customized subclass for a given component, you can just let the base framework class handle the implementation at runtime.

Each business component you create comprises a single XML component descriptor, and zero or more related custom Java implementation files. Each component that supports Java customization has a Java page in its component overview editor in the JDeveloper IDE. By selecting or deselecting the different Java classes, you control which ones will be created for your component. If none of the classes is specified, then your component will be an XML-only component, which simply uses the base framework class as its Java implementation. Otherwise, tick the checkbox of the related Java classes for the current component that you need to customize. JDeveloper will create a custom subclass of the framework base class in which you can add your code.

#### Table D–9 (Cont.) AttributeHints Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this AttributeHints interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the display hint for the attribute</td>
<td><code>getDisplayHint()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>The display hint will have a string value of either Display or Hide.</td>
</tr>
<tr>
<td>Get the preferred control type for the attribute</td>
<td><code>getControlType()</code></td>
</tr>
<tr>
<td>Parse a formatted string value using any format mask supplied for the attribute</td>
<td><code>parseFormattedAttribute()</code></td>
</tr>
</tbody>
</table>

### Notes:

- You can set up global IDE preferences for the Java classes to be generated by default for each ADF business component type by choosing **Tools > Preferences > Business Components** and ticking the checkboxes to indicate what you want your defaults to be.
A best practice is to *always* generate entity object and view row classes, even if you don’t require any custom code in them other than the automatically generated getter and setter methods. These getter and setter methods offer you compile-time type checking that prevents errors surfacing at runtime in response to an attribute having been set to an incorrect kind of value.

### D.3.2 ApplicationModuleImpl Class

The `ApplicationModuleImpl` class is the base class for application module components. Since the application module is the ADF component used to implement a business service, think of the application module class as the place where you can write your service-level application logic. The application module coordinates with view object instances to support updatable collections of value objects that are automatically "wired" to business domain objects. The business domain objects are implemented as ADF entity objects.

#### D.3.2.1 Methods You Typically Call on ApplicationModuleImpl

Table D–10 describes the operations that you can perform on an application module using the `ApplicationModuleImpl` class.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method of the <code>ApplicationModuleImpl</code> class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform any of the common application module operations from inside your class, which can also be done from the client</td>
<td>For a list of these methods, see Section D.2.1, &quot;ApplicationModule Interface.&quot;</td>
</tr>
<tr>
<td>Access a view object instance that you added to the application module’s data model at design time</td>
<td><code>getViewObjectInstanceName()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>JDeveloper generates this type-safe view object instance getter method for you to reflect each view object instance in the application module’s design time data model.</td>
</tr>
<tr>
<td>Access the current <code>DBTransaction</code> object</td>
<td><code>getDBTransaction()</code></td>
</tr>
<tr>
<td>Access a nested application module instance that you added to the application module at design time</td>
<td><code>getAppModuleInstanceName()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>JDeveloper generates this type-safe application module instance getter method for you to reflect each nested application module instance added to the current application module at design time.</td>
</tr>
</tbody>
</table>

#### D.3.2.2 Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass

Table D–11 describes the operations that you can perform on an application module using your custom `ApplicationModuleImpl` class.
Methods Used in the Business Service Tier

Table D–11  Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your custom ApplicationModuleImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Invoke a database stored procedure</td>
<td>someCustomMethod()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>Use the appropriate method on the</td>
<td></td>
</tr>
<tr>
<td>DBTransaction interface to create a JDBC</td>
<td></td>
</tr>
<tr>
<td>PreparedStatement. If the stored procedure</td>
<td></td>
</tr>
<tr>
<td>has OUT parameters, then create a CallableStatement instead.</td>
<td></td>
</tr>
<tr>
<td>For sample code that demonstrates</td>
<td></td>
</tr>
<tr>
<td>encapsulating a call to a PL/SQL stored</td>
<td></td>
</tr>
<tr>
<td>procedure inside your application module,</td>
<td></td>
</tr>
<tr>
<td>see Section 16.5, &quot;Invoking Stored Procedures and Functions.&quot;</td>
<td></td>
</tr>
</tbody>
</table>

| Expose custom business service methods on  | someCustomMethod()                                                  |
| your application module                   |                                                                     |
| Notes:                                     |                                                                     |
| Select the method name on the Client       |                                                                     |
| Interface page of the Edit Application Module dialog to expose it for client access if required. |

JDeveloper can generate a custom YourApplicationModuleName interface containing service-level custom methods that you’ve chosen to expose to the client. You can use the Client Interface page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.

D.3.2.3 Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

Table D–12 describes the operations that you can override on an application module using your custom ApplicationModuleImpl class.

Table D–12  Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom ApplicationModuleImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform custom setup code the first time an application module is created and each subsequent time</td>
<td>prepareSession()</td>
</tr>
<tr>
<td>it gets used by a different client session.</td>
<td></td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>This is the method you’d use to set up per-client context info for the current user in order to use</td>
<td></td>
</tr>
<tr>
<td>Oracle’s Virtual Private Database (VPD) features. It can also be used to set other kinds of PL/SQL</td>
<td></td>
</tr>
<tr>
<td>package global variables, whose values might be client-specific, on which other stored procedures</td>
<td></td>
</tr>
<tr>
<td>might rely.</td>
<td></td>
</tr>
<tr>
<td>This method is also useful to perform setup code that is specific to a given view object instance</td>
<td></td>
</tr>
<tr>
<td>in the application module. If instead of the view object setup code being instance-specific, you</td>
<td></td>
</tr>
<tr>
<td>want it to be initialized for every instance ever created of that view object component, then put</td>
<td></td>
</tr>
<tr>
<td>the setup logic in an overridden create() method in your ViewObjectImpl subclass instead.</td>
<td></td>
</tr>
</tbody>
</table>
Table D–12 (Cont.) Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom ApplicationModuleImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform custom setup code after the application module's transaction is associated with a database connection from the connection pool</td>
<td>afterConnect()</td>
</tr>
<tr>
<td>Notes:</td>
<td>Can be a useful place to write a line of code that uses getDBTransaction().executeCommand( ) to perform an ALTER SESSION SET SQL TRACE TRUE to enable database SQL trace logging for the current application connection. These logs can then be processed with the TKPROF utility to study the SQL statements being performed and the query optimizer plans that are getting used. For details about working with the TKPROF utility, see section &quot;Understanding SQL Trace and TKPROF&quot; in the &quot;Using Application Tracing Tools&quot; chapter of the Oracle Database Performance Tuning Guide.</td>
</tr>
<tr>
<td>Perform custom setup code before the application module's transaction releases its database connection back to the database connection pool</td>
<td>beforeDisconnect()</td>
</tr>
<tr>
<td>Notes:</td>
<td>If you have set jbo.doconnectionpooling to true, then the connection is released to the database connection pool each time the application module is returned to the application module pool.</td>
</tr>
<tr>
<td>Write custom application module state to the state management XML snapshot</td>
<td>passivateState()</td>
</tr>
<tr>
<td>Read and restore custom application module state from the state management XML snapshot</td>
<td>activateState()</td>
</tr>
</tbody>
</table>

D.3.3 DBTransactionImpl2 Class

The DBTransactionImpl2 class — which extends the base DBTransactionImpl class, and is constructed by the DatabaseTransactionFactory class — is the base class that implements the DBTransaction interface, representing the unit of pending work in the current transaction.

D.3.3.1 Methods You Typically Call on DBTransaction

Table D–13 describes the operations that you can perform on a transaction using the DBTransaction class.

Table D–13 Methods You Typically Call on DBTransaction

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method on the DBTransaction class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Commit the transaction</td>
<td>commit()</td>
</tr>
<tr>
<td>Roll back the transaction</td>
<td>rollback()</td>
</tr>
<tr>
<td>Eagerly validate any pending invalid changes in the transaction</td>
<td>validate()</td>
</tr>
</tbody>
</table>
**Methods Used in the Business Service Tier**

**D.3.3.2 Methods You Typically Override in Your Custom DBTransactionImpl2 Subclass**

Table D–14 describes the operations that you can perform on a transaction using your custom DBTransactionImpl2 subclass.

**Table D–14**  
**Methods You Typically Override in Your Custom DBTransactionImpl2 Subclass**

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom DBTransactionImpl2 class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform custom code before or after the transaction commit operation</td>
<td>commit()</td>
</tr>
<tr>
<td>Perform custom code before or after the transaction rollback operation</td>
<td>rollback()</td>
</tr>
</tbody>
</table>

In order for your custom DBTransactionImpl2 subclass to be used at runtime, there are you must follow these steps:

1. Create a custom subclass of DatabaseTransactionFactory that overrides the create method to return an instance of your custom DBTransactionImpl2 subclass like this:

   ```java
   package com.yourcompany.adfextensions;
   import oracle.jbo.server.DBTransactionImpl2;
   import oracle.jbo.server.DatabaseTransactionFactory;
   import com.yourcompany.adfextensions.CustomDBTransactionImpl;
   public class CustomDatabaseTransactionFactory extends DatabaseTransactionFactory {
      /**
       * Return an instance of our custom CustomDBTransactionImpl class
       * instead of the default implementation.
       * @return An instance of our custom DBTransactionImpl2 implementation.
       */
      public DBTransactionImpl2 create() {
         return new CustomDBTransactionImpl();
      }
   }
   ```

2. Tell the framework to use your custom transaction factory class by setting the value of the TransactionFactory configuration property to the fully qualified class name of your custom transaction factory. As with other configuration properties, if not supplied in the configuration XML file, it can be provided alternatively as a Java system parameter of the same name.
D.3.4 EntityImpl Class

The EntityImpl class is the base class for entity objects, which encapsulate the data, validation rules, and business behavior for your business domain objects.

D.3.4.1 Methods You Typically Call on EntityImpl

Table D–15 describes the operations that you can perform on an entity object using the EntityImpl class.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in the EntityImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the value of an attribute</td>
<td>getAttributeName()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This code-generated getter method calls getAttributeInternal(), but provides compile-time type checking.</td>
</tr>
<tr>
<td>Set the value of an attribute</td>
<td>setAttributeInternal()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This code-generated setter method calls setAttributeInternal(), but provides compile-time type checking.</td>
</tr>
<tr>
<td>Get the value of an attribute by name</td>
<td>getAttributeInternal()</td>
</tr>
<tr>
<td>Set the value of an attribute by name</td>
<td>setAttributeInternal()</td>
</tr>
<tr>
<td>Eagerly perform entity object validation</td>
<td>validate()</td>
</tr>
<tr>
<td>Refresh the entity from the database</td>
<td>refresh()</td>
</tr>
<tr>
<td>Populate the value of an attribute without marking it as being changed, but sending notification of its being changed so that the UI refreshes the value on the screen/page</td>
<td>populateAttributeAsChanged()</td>
</tr>
<tr>
<td>Access the Definition object for an entity</td>
<td>getDefinitionObject()</td>
</tr>
<tr>
<td>Get the Key object for an entity</td>
<td>getKey()</td>
</tr>
<tr>
<td>Determine the state of the entity instance, irrespective of whether it has already been posted (but not yet committed) in the current transaction</td>
<td>getEntityState()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This method will return one of the constants STATUS_UNMODIFIED, STATUS_INITIALIZED, STATUS_NEW, STATUS_MODIFIED, STATUS_DELETED, or STATUS_DEAD, indicating the status of the entity instance in the current transaction.</td>
</tr>
<tr>
<td>Determine the state of the entity instance</td>
<td>getPostState()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This method is typically relevant only if you are programmatically using the postChanges() method to post but not yet commit, entity changes to the database and need to detect the state of an entity with regard to its posting state.</td>
</tr>
<tr>
<td>Get the value originally read from the database for a given attribute</td>
<td>getPostedAttribute()</td>
</tr>
</tbody>
</table>
Table D–15  (Cont.) Methods You Typically Call on EntityImpl

If you want to... | Call this method in the EntityImpl class
---|---
Eagerly lock the database row for an entity instance | lock()  

D.3.4.2 Methods You Typically Write in Your Custom EntityImpl Subclass

Table D–16 describes the operations that you can perform on an entity object using your custom EntityImpl subclass.

Table D–16  Methods You Typically Write in Your Custom EntityImpl Subclass

If you want to... | Write a method like this in your custom EntityImpl subclass
---|---
Perform attribute-specific validation | public boolean validateSomething(AttrType value)  
Notes:  
Register the attribute validator method by adding a MethodValidator rule on the correct attribute in the Validation page of the Edit Entity Object dialog.

Perform entity-level validation | public boolean validateSomething()  
Notes:  
Register the entity-level validator method by adding a MethodValidator rule on the entity in the Validation panel of the Edit Entity Object dialog.

Calculate the value of a transient attribute | Add your calculation code to the generated getAttributeName() method.

D.3.4.3 Methods You Typically Override in Your Custom EntityImpl Subclass

Table D–17 describes the operations that you can override on an entity object using your custom EntityImpl subclass.

Table D–17  Methods You Typically Override in Your Custom EntityImpl Subclass

If you want to... | Override this method in your EntityImpl subclass
---|---
Set calculated default attribute values, including programatically populating the primary key attribute value of a new entity instance | create()  
Notes:  
After calling super.create(), call the appropriate setAttrName() method(s) to set the default values for the attributes.

Modify attribute values before changes are posted to the database | prepareForDML()  

Augment or change the standard INSERT, UPDATE, or DELETE DML operation that the framework will perform on your entity object's behalf to the database | doDML()  
Notes:  
This method checks the value of the operation flag to the constants DML_INSERT, DML_UPDATE, or DML_DELETE to test what DML operation is being performed.
### Table D–17 (Cont.) Methods You Typically Override in Your Custom EntityImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your EntityImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform complex, SQL-based validation after all entity instances have been posted to the database but before those changes are committed</td>
<td>beforeCommit()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This method is invoked for each entity row in the transaction.</td>
</tr>
<tr>
<td>Perform custom processing after all entity instances have been committed to the database</td>
<td>afterCommit()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This method is invoked for each entity row in the transaction list of pending changes.</td>
</tr>
<tr>
<td>Insure that a related, newly created, parent entity gets posted to the database before the current child entity on which it depends</td>
<td>postChanges()</td>
</tr>
<tr>
<td>Notes:</td>
<td>If the parent entity is related to this child entity via a composition association, then the framework already handles posting the changes automatically. If they are only associated (but not composed), then you need to override postChanges() to force a newly created parent entity to post before the current, dependent child entity. For an example of the code you typically write in your overridden postChanges() method to accomplish this, see Section 4.14.7.3, &quot;Overriding postChanges() to Control Post Order.&quot;</td>
</tr>
<tr>
<td>Programmatical ly define default attribute values or to perform custom initialization before a modified row is refreshed back to its initialization state or after the row is first created</td>
<td>initDefaultExpressionAttributes()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This method is invoked just before the end of the initialization cycle, which makes it suitable for executing custom code.</td>
</tr>
</tbody>
</table>

**Note:** It is possible to write attribute-level validation code directly inside the appropriate setAttributeName method of your EntityImpl class; however, adopting the MethodValidator approach suggested in Table D–16 conveniently places all the validations in effect on the Validation Rules page of the overview editor for the attributes of the entity object.
WARNING: It is also possible to override the `validateEntity()` method to write entity-level validation code; however, if you want to maintain the benefits of the ADF bundled exception mode — where the framework collects and reports a maximal set of validation errors back to the client user interface — use the `MethodValidator` approach suggested in Table D–16. This allows the framework to automatically collect all of your exceptions that your validation methods throw without your having to understand the bundled exception implementation mechanism. Overriding the `validateEntity()` method directly shifts the responsibility onto your own code to correctly catch and bundle the exceptions that Oracle ADF would have caught by default, which is nontrivial and a chore to remember and hand-code each time.

### D.3.5 EntityDefImpl Class

The `EntityDefImpl` class is a singleton, shared metadata object for all entity objects of a given type in a single Java VM. For instance, if the Java VM contains two instances of the `EntityDefImpl` class, one with the customers XML data and one with the orders, there would only ever be one instance of each. This class defines the structure of the entity instances and provides methods to create new entity instances and find existing instances by their primary key.

#### D.3.5.1 Methods You Typically Call on EntityDefImpl

Table D–18 describes the operations that you can perform on an entity object using the `EntityDefImpl` class.

<table>
<thead>
<tr>
<th>If you want to…</th>
<th>Call this method in the EntityDefImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Find an entity object of a given type by its primary key</td>
<td><code>findByPrimaryKey()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>For a tip about getting <code>findByPrimaryKey()</code> to find entity instances of subtype entities as well, see Section 4.19.4.2, &quot;Subtype Entity Objects and the findByPrimaryKey() Method.&quot;</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Access the current DBTransaction object</th>
<th><code>getDBTransaction()</code></th>
</tr>
</thead>
<tbody>
<tr>
<td>Find any EntityDefImpl object by its fully qualified name</td>
<td><code>findDefObject()</code> (static method)</td>
</tr>
<tr>
<td>Retrieve the value of an entity object's custom property</td>
<td><code>getProperty()</code>, <code>getProperties()</code></td>
</tr>
<tr>
<td>Set the value of an entity object's custom property</td>
<td><code>setProperty()</code></td>
</tr>
<tr>
<td>Create a new instance of an entity object</td>
<td><code>createInstance2()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>Alternatively, you can expose custom <code>createXXX()</code> methods with your own expected signatures in that same custom EntityDefImpl subclass. See Section D.3.5.2, &quot;Methods You Typically Write in Your Custom EntityDefImpl Class&quot; for details.</td>
</tr>
</tbody>
</table>
Methods Used in the Business Service Tier

Table D–18 (Cont.) Methods You Typically Call on EntityDefImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in the EntityDefImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Iterate over the entity instances in the cache of this entity type</td>
<td>getAllEntityInstancesIterator()</td>
</tr>
<tr>
<td>Access an array list of entity definition objects for entities that extend the current one.</td>
<td>getExtendedDefObjects()</td>
</tr>
</tbody>
</table>

D.3.5.2 Methods You Typically Write in Your Custom EntityDefImpl Class

Table D–19 describes the operations that you can perform on an entity object using your custom EntityDefImpl class.

Table D–19 Methods You Typically Write on EntityDefImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your custom EntityDefImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Allow other classes to create an entity instance with an initial type-safe set of attribute values or setup information</td>
<td>createXXX(Type1arg1, ..., TypeNargN)</td>
</tr>
</tbody>
</table>

Notes:
Internally, using this method would create and populate an instance of a NameValuePairs object (which implements AttributeList) and call the protected method createInstance(), passing that NameValuePairs object. Make sure that the method is public if other classes need to be able to call it.

D.3.5.3 Methods You Typically Override in Your Custom EntityDefImpl

Table D–20 describes the operations that you can perform on an entity object using the EntityDefImpl class.

Table D–20 Methods You Typically Override on EntityDefImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom EntityDefImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform custom metadata initialization when this singleton metaobject is loaded</td>
<td>createDef()</td>
</tr>
<tr>
<td>Avoid using the RETURNING INTO clause to support refresh-on-insert or refresh-on-update attributes</td>
<td>isUseReturningClause()</td>
</tr>
<tr>
<td>Notes: Set this method to return false to disable the use of RETURNING INTO, necessary sometimes when your entity object is based on a view with INSTEAD OF triggers that don’t support RETURNING INTO at the database level.</td>
<td></td>
</tr>
<tr>
<td>Control whether the UPDATE statements issued for this entity update only changed columns or for all columns</td>
<td>isUpdateChangedColumns()</td>
</tr>
<tr>
<td>Notes: Defaults to true.</td>
<td></td>
</tr>
<tr>
<td>Find any EntityDefImpl object by its fully qualified name</td>
<td>findDefObject()</td>
</tr>
<tr>
<td>Notes: Static method.</td>
<td></td>
</tr>
</tbody>
</table>
D.3.6 

**ViewObjectImpl Class**

The `ViewObjectImpl` class is the base class for view objects.

### D.3.6.1 Methods You Typically Call on ViewObjectImpl

**Table D–21** describes the operations that you can perform on a view object using the `ViewObjectImpl` class.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in the <code>ViewObjectImpl</code> class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform any of the common view object, row set, or row set iterator operations from inside your class, which can also be done from the client</td>
<td>For more information about operations at the view object, row set, or row set iterator level, see Section D.2.3, &quot;ViewObject Interface,&quot; Section D.2.4, &quot;RowSet Interface,&quot; and Section D.2.5, &quot;RowSetIterator Interface.&quot;</td>
</tr>
<tr>
<td>Search a view instance’s in-memory row set without changing the default row set</td>
<td><code>findByViewCriteria()</code></td>
</tr>
<tr>
<td>Fetch all the rows from the database and then determine the total row count in the view object row set</td>
<td><code>getRowCount()</code></td>
</tr>
<tr>
<td>Determine the total number of rows in view object row set after each invocation by the client</td>
<td><code>getQueryHitCount()</code></td>
</tr>
<tr>
<td>Determine the total number of rows in the view object row set</td>
<td><code>getEstimatedRowCount()</code></td>
</tr>
<tr>
<td>Define a named bind parameter</td>
<td><code>defineNamedWhereClauseParam()</code></td>
</tr>
</tbody>
</table>

Notes:

- Use this method carefully: Performance may be affected when a large number of rows is involved.
- This is the preferred way to find row count since it requires only one database query (after the count is obtained, it will be maintained as rows are added and removed).
### Table D–22 (Cont.) Methods You Typically Call on ViewObjectImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in the ViewObjectImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Remove a named bind parameter</td>
<td>removeNamedWhereClauseParam()</td>
</tr>
<tr>
<td>Set bind variable values on the default row set by name</td>
<td>setNamedWhereClauseParam()</td>
</tr>
<tr>
<td>Notes: Only works when you have formally defined named bind variables on your view object.</td>
<td></td>
</tr>
<tr>
<td>Set bind variable values on the default row set</td>
<td>setWhereClauseParams()</td>
</tr>
<tr>
<td>Notes: Use this method for view objects with binding style of &quot;Oracle Positional&quot; or &quot;JDBC Positional&quot; when you have not formally defined named bind variables.</td>
<td></td>
</tr>
<tr>
<td>Retrieve a subset of rows in a view object's row set based on evaluating an in-memory filter expression</td>
<td>getFilteredRows()</td>
</tr>
<tr>
<td>Retrieve a subset of rows in the current range of a view object's row set based on evaluating an in-memory filter expression</td>
<td>getFilteredRowsInRange()</td>
</tr>
<tr>
<td>Override the runtime display of criteria items that appear inside an ADF query component. Subclasses may override to return custom AttributeHints implementation for the given criteria item. Returns null by default.</td>
<td>getCriteriaItemAttributeHints()</td>
</tr>
<tr>
<td>Set the number of rows that will be fetched from the database per roundtrip for this view object</td>
<td>setSize()</td>
</tr>
<tr>
<td>Notes: The default fetch size is a single row at a time. This is definitely not optimal if your view object intends to retrieve many rows, so you should either set the fetch size higher at design time on the Tuning page of the Edit View Object dialog, or set it at runtime using this method.</td>
<td></td>
</tr>
<tr>
<td>Force a row set's query to be (re)executed specifically on a lookup view object instance in a shared application module</td>
<td>forceExecuteQueryOfSharedVO()</td>
</tr>
<tr>
<td>Notes: Reexecuting the query forces a new query collection and will prevent the application module cache from being used. You should only use this method when you are sure that you are accessing the shared application module during setup and not during runtime. This method when used during normal runtime may have unintended side-effects that disrupt the navigation of users accessing the collection concurrently. If you want to refresh the collection from the cache without creating a new query collection, call executeQuery() instead.</td>
<td></td>
</tr>
</tbody>
</table>

### D.3.6.2 Methods You Typically Write in Your Custom ViewObjectImpl Subclass

Table D–22 describes the operations that you can perform on a view object using your custom ViewObjectImpl subclass.
JDeveloper can generate a custom *YourViewObjectName* interface containing view object custom methods that you’ve chosen to expose to the client. You can use the **Client Interface** page of the Edit View Object to select the methods that you want to appear in your client interface.

### D.3.6.3 Methods You Typically Override in Your Custom ViewObjectImpl Subclass

**Table D–23** describes the operations that you can perform on a view object using your custom ViewObjectImpl subclass.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom ViewObjectImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initialize custom view object class members (not row attributes) when the view object instance is created for the first time</td>
<td><code>create()</code></td>
</tr>
<tr>
<td>Notes: This method is useful to perform set up logic that is applicable to every instance of a view object that will ever get created, in the context of any application module. If instead of <em>generic</em> view object setup logic, you need to perform logic specific to a given view object <em>instance</em> in an application module, then override the <code>prepareSession()</code> method of your application module’s <code>ApplicationModuleImpl</code> subclass and perform the logic there after calling <code>findViewObject()</code> to find the view object instance whose properties you want to set.</td>
<td></td>
</tr>
<tr>
<td>Write custom view object instance state to the state management XML snapshot</td>
<td><code>passivateState()</code></td>
</tr>
<tr>
<td>Read and restore custom view object instance state from the state management XML snapshot</td>
<td><code>activateState()</code></td>
</tr>
</tbody>
</table>
### Table D–23 (Cont.) Methods You Typically Override in Your Custom ViewObjectImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom ViewObjectImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Customize the execution of the view object query to utilize an alternative data source</td>
<td>executeQueryForCollection()</td>
</tr>
<tr>
<td>Notes:</td>
<td>By default view objects read their data from the database and automate the task of working with the JDBC layer to process the database result sets. However, by overriding appropriate methods in its custom Java class, you can create a view object that programmatically retrieves data from alternative data sources, as described in Section 10.5, “Using Programmatic View Objects for Alternative Data Sources.” It is not correct to override <code>executeQueryForCollection()</code> to make changes to WHERE clauses and parameters. By the time the method is called, ADF Business Components assumes that the parameters are already calculated and that row filters are constructed. If you change the query before it gets executed each time, ADF Business Components could never reuse an existing cached statement handle. Instead, when you want to specify bind parameters before the query is executed, you can override <code>prepareRowSetForQuery()</code> on ViewObjectImpl since it provides access to the row set that is being executed.</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and determine whether the query collection has more rows to fetch from the query execution</td>
<td>hasNextForCollection()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and log bind parameter names and values used in the query</td>
<td>bindParametersForCollection()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and populate each row of the retrieved data</td>
<td>createRowFromResultSet()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and return a count of the number of rows that will be retrieved</td>
<td>getCountHitCount()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and to determine whether the query would return more rows than the capped value specified by a global row fetch limit.</td>
<td>getCappedQueryHitCount()</td>
</tr>
<tr>
<td>Customize the programmatic view object to access the row set that is being executed and change the view object WHERE clause and specify bind parameter values before the query is executed. This is the recommended hook point for overriding query and setting bind parameters. This method is invoked by the framework every time a row set is about to be executed.</td>
<td>prepareRowSetForQuery()</td>
</tr>
</tbody>
</table>
Table D–23 (Cont.) Methods You Typically Override in Your Custom ViewObjectImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom ViewObjectImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and release any resources that may be associated with a row set that is being closed</td>
<td>releaseUserDataForCollection()</td>
</tr>
<tr>
<td>Change or augment the way that the ViewCriteria collection of ViewCriteriaRows is converted into a Query-by-Example WHERE clause</td>
<td>getViewCriteriaClause(boolean)</td>
</tr>
<tr>
<td>Customize the programmatic view object to implement range paging.</td>
<td>buildRangePagingQuery()</td>
</tr>
</tbody>
</table>
| Customize the programmatic view object to implement range paging and pass in parameters to control the range start and size for the current range of rows to fetch from a data source. | bindRangePagingParams()                                                       

D.3.7 ViewRowImpl Class

The ViewRowImpl class is the base class for view row objects.

D.3.7.1 Methods You Typically Call on ViewRowImpl

Table D–24 describes the operations that you can perform on a view object row using your custom ViewRowImpl class.

Table D–24 Methods You Typically Call on ViewRowImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in your custom ViewRowImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform any of the common view row operations from inside your class, which can also be done from the client</td>
<td>For more information about the row-level operations, see Section D.2.6, &quot;Row Interface.&quot;</td>
</tr>
<tr>
<td>Get the value of an attribute</td>
<td>getAttrName()</td>
</tr>
<tr>
<td>Set the value of an attribute</td>
<td>setAttrName()</td>
</tr>
<tr>
<td>Access the underlying entity instance to which this view row is delegating attribute storage</td>
<td>getEntityUsageAliasName()</td>
</tr>
</tbody>
</table>

Notes:
You can change the name of the entity usage alias name on the Entity Objects page of the Edit View Object dialog.

D.3.7.2 Methods You Typically Write in Your Custom ViewRowImpl Class

Table D–25 describes the operations that you can perform on a view object row using your custom ViewRowImpl class.
### Table D–25  Methods You Typically Write on ViewRowImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your custom ViewRowImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Calculate the value of a view object-level transient attribute</td>
<td>getAttrName()</td>
</tr>
<tr>
<td>Notes:</td>
<td>JDeveloper generates the skeleton of the method for you, but you need to write the custom calculation logic inside the method body.</td>
</tr>
<tr>
<td>Perform custom processing of the setting of a view row attribute</td>
<td>setAttrName()</td>
</tr>
<tr>
<td>Notes:</td>
<td>JDeveloper generates the skeleton of the method for you, but you need to write the custom logic inside the method body if required.</td>
</tr>
<tr>
<td>Determine the updateability of an attribute in a conditional way</td>
<td>isAttributeUpdateable()</td>
</tr>
<tr>
<td>Expose logical operations on the current row, optionally callable by clients</td>
<td>doSomething()</td>
</tr>
<tr>
<td>Notes:</td>
<td>Often these view-row-level custom methods simply turn around and delegate to a method call on the underlying entity object related to the current row.</td>
</tr>
</tbody>
</table>

JDeveloper can generate a custom `YourViewObjectNameRow` interface containing view row custom methods that you’ve chosen to expose to the client. You can use the Client Row Interface page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

### D.3.7.3 Methods You Typically Override in Your Custom ViewRowImpl Subclass

Table D–26 describes the operations that you can perform on a view object row using your custom ViewRowImpl subclass.

### Table D–26  Methods You Typically Override in Your Custom ViewRowImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your ViewRowImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Determine the updateability of an attribute in a conditional way</td>
<td>isAttributeUpdateable()</td>
</tr>
</tbody>
</table>
This appendix summarizes the Java Platform, Enterprise Edition (Java EE) design patterns that the ADF Business Components layer implements for you.

By using the Oracle Application Development Framework's business components building-blocks and related design time extensions to JDeveloper, you get a prescriptive architecture for building richly functional and cleanly layered Java EE business services with great performance.

Table E–1 provides a brief overview of the numerous design patterns that the ADF Business Components layer implements for you. Some are the familiar patterns from Sun’s Java EE BluePrints and some are design patterns that ADF Business Components adds to the list. For details about Java EE BluePrints, see the BluePrints page at the Oracle Technology Network website at http://www.oracle.com/technetwork/java/index-jsp-136701.html.

<table>
<thead>
<tr>
<th>Pattern Name and Description</th>
<th>How ADF Business Components Implements It</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model/View/Controller</td>
<td>The ADF application module provides a generic implementation of a Model/View/Controller “application object” that simplifies exposing the application data model for any application or service, and facilitates declaratively specifying the boundaries of a logical unit of work. Additional UI-centric frameworks and tag libraries provided in JDeveloper help you implement the view and controller layers.</td>
</tr>
<tr>
<td>Interface / Implementation Separation</td>
<td>ADF Business Components enforces a logical separation of client-tier accessible functionality (via interfaces) and its business tier implementation. JDeveloper handles the creation of custom interfaces and client proxy classes automatically.</td>
</tr>
<tr>
<td>Service Locator</td>
<td>ADF application modules are looked up using a simple configuration object which hides the low-level details of finding the service instance behind the scenes. For Fusion web applications, it also hides the implementation of the application module pool usage, a lightweight pool of service components that improves application scalability.</td>
</tr>
</tbody>
</table>
Inversion of Control
A containing component orchestrates the lifecycle of the components it contains, invoking specific methods that you can override at the appropriate times, so as to be able to focus more on what the code should do, instead of when it should be executed.

Dependency Injection
Simplifies application code, and increases configuration flexibility by deferring component configuration and assembly to the container.

Active Record
Avoids the complexity of "anything to anything" object/relational mapping, by providing an object that wraps a row in a database table or view, encapsulates the database access, and adds domain logic on that data.

Data Access Objects
Prevents unnecessary marshalling overhead by implementing dependent objects as lightweight, persistent classes instead of each as an individual enterprise bean. Isolates persistence details into a single, easy-to-maintain class.

Session Facade
Prevents inefficient client access of entity beans and inadvertent exposure of sensitive business information by wrapping entity beans with a session bean.

<table>
<thead>
<tr>
<th>Pattern Name and Description</th>
<th>How ADF Business Components Implements It</th>
</tr>
</thead>
<tbody>
<tr>
<td>Inversion of Control</td>
<td>ADF components contain a number of easy-to-override methods that the framework invokes as needed during the course of application processing.</td>
</tr>
<tr>
<td>Dependency Injection</td>
<td>ADF Business Components configures all its components from externalized XML metadata definition files. At runtime, the framework automatically injects dependent objects like view object instances into your application module service component and entity objects into your view rows, implementing lazy loading. It supports runtime factory substitution of components by any customized subclass of that component to simplify onsite application customization scenarios. Much of the ADF Business Components functionality is implemented via dynamic injection of validator and listener subscriptions that coordinate the framework interactions depending on what declarative features have been configured for each component in their XML metadata.</td>
</tr>
<tr>
<td>Active Record</td>
<td>ADF entity objects handle the database mapping functionality you use most frequently, including inheritance, association, and composition support, so you don’t have to focus on object/relational mapping. They also provide a place to encapsulate both declarative business rules and one-off programmatic business domain.</td>
</tr>
<tr>
<td>Data Access Objects</td>
<td>ADF view objects automate the implementation of data access for reading data using SQL statements. ADF entity objects automate persistent storage of lightweight business entities. ADF view objects and entity objects cooperate to provide a sophisticated, performant data access objects layer, where any data queried through a view object can optionally be made fully updatable without requiring that you write any &quot;application plumbing&quot; code.</td>
</tr>
<tr>
<td>Session Facade</td>
<td>ADF application modules are designed to implement a coarse-grained &quot;service facade&quot; architecture in any of their supported deployment modes. When deployed as a service interface, they provide an implementation of the Session Facade pattern automatically.</td>
</tr>
</tbody>
</table>
### Table E–1 (Cont.) Java EE Design Patterns Implemented by ADF Business Components

<table>
<thead>
<tr>
<th>Pattern Name and Description</th>
<th>How ADF Business Components Implements It</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Value Object</strong></td>
<td>ADF Business Components provides an implementation of a generic <code>Row</code> object, which is a metadata-driven container of any number and kind of attributes that need to be accessed by a client. The developer can work with the generic <code>Row</code> interface and do late-bound <code>getAttribute(&quot;Price&quot;)</code> and <code>setAttribute(&quot;Quantity&quot;)</code> calls, or optionally generate early-bound row interfaces like <code>OverdueOrdersRow</code>, to enable type-safe method calls like <code>getPrice()</code> and <code>setQuantity()</code>. Smarter than just a simple &quot;bag 'o attributes&quot;, the ADF <code>Row</code> object can be introspected at runtime to describe the number, names, and types of the attributes in the row, enabling sophisticated, generic solutions to be implemented.</td>
</tr>
<tr>
<td><strong>Page-by-Page Iterator</strong></td>
<td>ADF Business Components provides an implementation of a generic <code>RowSet</code> interface which manages result sets produced by executing view object SQL queries. The <code>RowSet</code> interface allows you to set a desired page size, for example 10 rows, and page up and down through the query results in these page-sized chunks. Since data is retrieved lazily, only data the user actually visits will ever be retrieved from the database on the backend, and in the client tier the number of rows in the page can be returned over the network in a single roundtrip.</td>
</tr>
<tr>
<td><strong>Fast-Lane Reader</strong></td>
<td>ADF view objects read data directly from the database for best performance; however, they give you a choice regarding data consistency. If updateability and/or consistency with pending changes is desired, you need only associate your view object with the appropriate entity objects whose business data is being presented. If consistency is not a concern, view objects can simply perform the query with no additional overhead. In either case, you never have to write JDBC data access code. You need only provide appropriate SQL statements in XML descriptors.</td>
</tr>
<tr>
<td><strong>(Bean) Factory</strong></td>
<td>All ADF component instantiation is done based on XML configuration metadata through factory classes allowing runtime substitution of specialized components to facilitate application customization.</td>
</tr>
<tr>
<td><strong>Entity Facade</strong></td>
<td>ADF view objects can surface any set of attributes and methods from any combination of one or more underlying entity objects to furnish the client with a single, logical value object to work with.</td>
</tr>
</tbody>
</table>
Table E–1  (Cont.) Java EE Design Patterns Implemented by ADF Business Components

<table>
<thead>
<tr>
<th>Pattern Name and Description</th>
<th>How ADF Business Components Implements It</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Value Messenger</strong></td>
<td>The ADF Business Components value object implementation coordinates with a client-side value object cache to batch attribute changes to the EJB tier and receive batch attribute updates which occur as a result of middle-tier business logic. The ADF Value Messenger implementation is designed to not require any kind of asynchronous messaging to achieve this effect.</td>
</tr>
<tr>
<td><strong>Continuations</strong></td>
<td>ADF Business Components application module pooling and state management functionality combine to deliver this value-add. Application module pooling eliminates the need to dedicate application server tier resources to individual users and supports a &quot;stateless with user affinity&quot; optimization that you can tune.</td>
</tr>
</tbody>
</table>

Continuations

Gives you the simplicity and productivity of a stateful programming model with the scalability of a stateless web solution.
ADF Equivalents of Common Oracle Forms Triggers

This appendix provides a summary of how basic tasks performed with the most common Oracle Forms triggers are accomplished using Oracle ADF.

This appendix includes the following sections:

- Section F.1, "Validation and Defaulting (Business Logic)"
- Section F.2, "Query Processing"
- Section F.3, "Database Connection"
- Section F.4, "Transaction "Post" Processing (Record Cache)"
- Section F.5, "Error Handling"

F.1 Validation and Defaulting (Business Logic)

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>WHEN-VALIDATE-RECORD</td>
<td>In the custom EntityImpl class for your entity object, write a public method</td>
</tr>
<tr>
<td></td>
<td>returning a boolean type with a method name like validateXXXX() and have it</td>
</tr>
<tr>
<td></td>
<td>return true if the validation succeeds or false if the validation fails. Then,</td>
</tr>
<tr>
<td></td>
<td>add a Method validator for this validation method to your entity object at the</td>
</tr>
<tr>
<td></td>
<td>entity level. When doing that, you can associate a validation failure message</td>
</tr>
<tr>
<td></td>
<td>with the rule.</td>
</tr>
<tr>
<td>WHEN-VALIDATE-ITEM</td>
<td>In the custom EntityImpl class for your entity object, write a public method</td>
</tr>
<tr>
<td></td>
<td>returning a boolean type and accepting a single argument of the same data type</td>
</tr>
<tr>
<td></td>
<td>as your attribute, having a method name like validateXXXX(). Have it return</td>
</tr>
<tr>
<td></td>
<td>true if the validation succeeds or false if the validation fails. Then, add a</td>
</tr>
<tr>
<td></td>
<td>Method validator for this validation method to the entity object at the</td>
</tr>
<tr>
<td></td>
<td>appropriate attribute. When doing that, you can associate a validation</td>
</tr>
<tr>
<td></td>
<td>failure message with the rule.</td>
</tr>
<tr>
<td>WHEN-DATABASE-RECORD</td>
<td>Override the addToTransactionManager() method of your entity object. Write</td>
</tr>
<tr>
<td></td>
<td>code after calling the super.</td>
</tr>
<tr>
<td>Execute code when a row in the data block is marked for insert or update</td>
<td></td>
</tr>
</tbody>
</table>
Table F–2  ADF Equivalents for Oracle Forms Query Processing Triggers

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>WHEN–CREATE–RECORD</td>
<td>Override the create() method of your entity object and after calling the super, use appropriate setAttrName() methods to set default values for attributes as necessary. To immediately set a primary key attribute to the value of a sequence, construct an instance of the SequenceImpl helper class and call its getSequenceNumber() method to get the next sequence number. Assign this value to your primary key attribute. If you want to wait to assign the sequence number until the new record is saved, but still without using a database trigger, you can use this technique in an overridden prepareForDML() method in your entity object. If instead you want to assign the primary key from a sequence using your own BEFOREINSERTFOREARCHROW database trigger, then use the special data type called DBSequence for your primary key attribute instead of the regular Number type.</td>
</tr>
<tr>
<td>WHEN–REMOVE–RECORD</td>
<td>Override the remove() method of your entity object and write code either before or after calling the super.</td>
</tr>
</tbody>
</table>

F.2 Query Processing

Table F–2  ADF Equivalents for Oracle Forms Query Processing Triggers

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>PRE–QUERY</td>
<td>Override the executeQueryForCollection() method on your view object class and write code before calling the super.</td>
</tr>
<tr>
<td>ON–COUNT</td>
<td>Override default behavior to count the query hits for a data block. Override the getQueryHitCount() method in your view object and do something instead of calling the super.</td>
</tr>
<tr>
<td>POST–QUERY</td>
<td>Generally instead of using a POST–QUERY style technique to fetch descriptions from other tables based on foreign key values in the current row, in ADF it’s more efficient to build a view object that has multiple participating entity objects, joining in all the information you need in the query from the main table, as well as any auxiliary or lookup-value tables. This way, in a single roundtrip to the database you get all the information you need. If you still need a per-fetched-row trigger like POST–QUERY, override the createInstanceFromResultSet() method in your view object class.</td>
</tr>
<tr>
<td>ON–LOCK</td>
<td>Override default behavior to attempt to acquire a lock on the current row in the data block. Override the lock() method in your entity object class and do something instead of calling the super.</td>
</tr>
</tbody>
</table>
F.3 Database Connection

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>POST-LOGON</td>
<td>Execute logic after logging into the database</td>
</tr>
<tr>
<td></td>
<td>Override the afterConnect() method on your custom application module. Since</td>
</tr>
<tr>
<td></td>
<td>application module instances can stay connected while serving different</td>
</tr>
<tr>
<td></td>
<td>logical client sessions, you can override the prepareSession() method, which</td>
</tr>
<tr>
<td></td>
<td>is fired after initial login, as well as after any time the application module</td>
</tr>

This appendix describes how common Oracle Forms tasks are implemented in Oracle ADF. In Oracle Forms, you do some tasks in the data block, and others in the UI. For this reason, the appendix is divided into two sections: tasks that relate to data, and tasks that relate to the UI.

This appendix includes the following sections:

- Section G.1, "Concepts Familiar to Oracle Forms Developers"
- Section G.2, "Performing Tasks Related to Data"
- Section G.3, "Performing Tasks Related to the User Interface"

### G.1 Concepts Familiar to Oracle Forms Developers

ADF Business Components implements all of the data-centric aspects of Oracle Forms runtime functionality, but in a way that is independent of the user interface. Responsibilities between the querying and entity-related functions are cleanly separated, resulting in better reuse, as described in Table G–1.

<table>
<thead>
<tr>
<th>This concept</th>
<th>Maps to Oracle ADF</th>
<th>With these similarities</th>
</tr>
</thead>
<tbody>
<tr>
<td>Headless Form Module</td>
<td>Application Module</td>
<td>The application module component is the “data portion” of the form. The application module is a smart data service containing a data model of master-detail-related queries that your client interface needs to work with. It also provides a transaction and database connection used by the components it contains. It can contain form-level procedures and functions, referred to as service methods, that are encapsulated within the service implementation. You can decide which of these procedures and functions should be private and which ones should be public.</td>
</tr>
<tr>
<td>Forms Record Manager</td>
<td>Entity Object</td>
<td>The entity object component implements the “validation and database changes” portion of the data block functionality. In the Forms runtime, this duty is performed by the record manager. The record manager is responsible for keeping track of which of the rows in the data block have changed, for firing the block-level and item-level validation triggers when appropriate, and for coordinating the saving of changes to the database. This is exactly what an entity object does for you. The entity object is a component that represents your business domain entity through an underlying database table. The entity object gives you a single place to encapsulate business logic related to validation, defaulting, and database modification behavior for that business object.</td>
</tr>
</tbody>
</table>
Performing Tasks Related to Data

G.2 Performing Tasks Related to Data

In Oracle Forms, tasks that relate solely to data are performed in the data block. In Oracle ADF, these tasks are done on the business components that persist data (entity objects) and on the objects that query data (view objects).

G.2.1 How to Retrieve Lookup Display Values for Foreign Keys

In Oracle Forms, an editable table often has foreign key lookup columns to other tables. The user-friendly display values corresponding to the foreign key column values exist in related tables. You often need to present these related display values to the user.

In Oracle Forms, this was a complicated task that required adding nondatabase items to the data block, adding a block-level `POST-QUERY` trigger to the data block, and writing a SQL select statement for each foreign key attribute. Additionally, if the user changed the data, you needed to sync the foreign key values with an item-level `WHEN-VALIDATE-ITEM` trigger. This process is much easier in Oracle ADF.

Implementation of the task in Oracle ADF

1. Create a view object that includes the following:
   - The main, editable entity object as the primary entity usage
   - Secondary "reference" entity usages for the one or more associated entities whose underlying tables contain the display text

   For more information, see Section 5.6.1, "How to Create Joins for Entity-Based View Objects."

2. Select the desired attributes (at least the display text) from the secondary entity usages as described in Section 5.6.3, "How to Select Additional Attributes from Reference Entity Usages."

   At runtime, the data for the main entity and all related lookup display fields is retrieved from the database in a single join.

   If the user can change the data, no additional steps are required. If the user changes the value of a foreign key attribute, the reference information is automatically retrieved for the new, related row in the associated table.

G.2.2 How to Get the Sysdate from the Database

In Oracle Forms, when you wanted to get the current date and time, you retrieved the `sysdate` from the database. In Oracle ADF, you also have the option of getting the system date using a Java method or a Groovy expression.

Table G–1 (Cont.) Concepts for Oracle Forms Developers

<table>
<thead>
<tr>
<th>This concept</th>
<th>Maps to Oracle ADF</th>
<th>With these similarities</th>
</tr>
</thead>
<tbody>
<tr>
<td>Data Block</td>
<td>View Object</td>
<td>The view object component performs the &quot;data retrieval&quot; portion of the data block functionality. Each view object encapsulates a SQL query, and at runtime each one manages its own query result set. If you connect two or more view objects in master-detail relationships, that coordination is handled automatically. While defining a view object, you can link any of its query columns to underlying entity objects. By capturing this information, the view object and entity object can cooperate automatically for you at runtime to enforce your domain business logic, regardless of the &quot;shape&quot; of the business data required by the user’s task.</td>
</tr>
</tbody>
</table>

**G-2** Developing Fusion Web Applications with Oracle Application Development Framework
Performing Tasks Related to Data

Implementation of the task in Oracle ADF
To get the system date from the database, you can use the following Groovy expression at the entity level:

`DBTransaction.currentDbTime`

**Note:** The `DBTransaction` reference is for entity-level Groovy expressions only.

If you want to assign a default value to an attribute using this Groovy expression, see Section 4.10.7, "How to Define a Default Value Using an Expression."

To get the system date from Java, you call the `getCurrentDate()` method. For more information, see Section 12.10, "Accessing the Current Date and Time."

G.2.3 How to Implement an Isolation Mode That Is Not Read Consistent

In Oracle Forms, you might have been concerned with read consistency, that is, the ability of the database to deliver the state of the data at the time the SQL statement was issued.

**Implementation of the task in Oracle ADF**

If you use an entity-based view object, the query sees the changes currently in progress by the current user's session in the pending transaction. This is the default behavior, and the most accurate.

If instead, you want a snapshot of the data on the database without considering the pending changes made by the current user, you can use a read-only view object and reexecute the query to see the latest committed database values. For more information on read-only view objects, see Section 5.8.1, "How to Create an Expert Mode View Object."

G.2.4 How to Implement Calculated Fields

Calculated fields are often used to show the sum of two values, but they could also be used for the concatenated value of two or more fields, or the result of a method call.

**Implementation of the task in Oracle ADF**

Calculated attributes are usually not stored in the database, as their values can easily be obtained programmatically. Attributes that are used in the middle tier, but that are not stored in the database are called *transient attributes*. Transient attributes can be defined at the entity object level or the view object level.

If a transient attribute will be used by more than one view object that might be based on an entity object, then define the attribute at the entity object level. Otherwise, define the transient attribute at the view object level for a particular view object.

To define transient attributes at the entity object level, see Section 4.11, "Adding Transient and Calculated Attributes to an Entity Object." To define transient attributes at the view object level, see Section 5.4, "Adding Calculated and Transient Attributes to a View Object."
G.2.5 How to Implement Mirrored Items

In Oracle Forms, you may be used to using mirrored items to show two or more fields that share identical values.

**Implementation of the task in Oracle ADF**

There is no need to have mirrored items in Oracle ADF, because the UI and data are separated. The same view object can appear on any number of pages, so you don’t need to create mirrored items that have the same value. Likewise, a form could have the same field represented in more than one place and it would not have to be mirrored.

G.2.6 How to Use Database Columns of Type CLOB or BLOB

If you are used to working with standard database types, you may be wondering how to use the CLOB and BLOB types in Oracle ADF.

**Implementation of the task in Oracle ADF**

In Oracle ADF, use the built-in data types ClobDomain or BlobDomain. These are automatically created when you reverse-engineer entity objects or view objects from existing tables with these column types. ADF Business Components also supports data types for Intermedia column types: OrdImage, OrdAudio, OrdDoc, and OrdVideo. For more information, see Section 4.10.1, "How to Set Database and Java Data Types for an Entity Object Attribute."

G.3 Performing Tasks Related to the User Interface

In Oracle ADF, common UI-related tasks (such as master-detail screens, popup list of values, and page layout) are handled quite differently than they were in Oracle Forms.

G.3.1 How to Lay Out a Page

Oracle Forms is based on an absolute pixel or point-based layout, as compared to the container-based approach of JSE, and the Layout Manager approach in ADF Swing.

**Implementation of the task in Oracle ADF**

See Developing Web User Interfaces with Oracle ADF Faces for information on how to lay out a page in Oracle ADF.

G.3.2 How to Stack Canvases

In Oracle Forms, stacked canvases were often used to hide and display areas of the screen.

**Implementation of the task in Oracle ADF**

The analog of stacked canvases in Oracle ADF is panels (layout containers) with the rendered property set to true or false. See Developing Web User Interfaces with Oracle ADF Faces for more information.

G.3.3 How to Implement a Master-Detail Screen

Master-detail relationships in Oracle ADF are coordinated through a view link. A view link is conceptually similar to an Oracle Forms relation.
Performing Tasks Related to the User Interface

G.3.4 How to Implement an Enter Query Screen
In Oracle Forms, another common task was creating an enter query screen. That is, a screen that starts in Find mode.

Implementation of the task in Oracle ADF
In Oracle ADF, this accomplished with a search form. Complete information on how to create a search form is covered in Chapter 33, "Creating ADF Databound Search Forms." In particular, you may want to look at Section 33.3.1, "How to Set Search Form Properties on the View Criteria."

G.3.5 How to Implement an Updatable Multi-Record Table
In Oracle Forms, you may be used to creating tables where you can edit and insert many records at the same time. This can be slightly more complicated when using a JSF page in Oracle ADF, because the operations to edit an existing record and to create a new record are not the same.

Implementation of the task in Oracle ADF
In Oracle ADF, this is done using an input table. To create an input table, see Section 29.4, "Creating an Input Table."

G.3.6 How to Create a Popup List of Values
In Oracle Forms, it was simple to create a list of values (LOV) object and then associate that object with a field in a declarative manner. This LOV would display a popup window and provide the following capabilities:

- Selection of modal values
- Query area at the top of the LOV dialog
- Display of multiple columns
- Automatic reduction of LOV contents, possibly based on the contents of the field that launched the LOV
- Automatic selection of the list value when only one value matches the value in the field when the LOV function is invoked
- Validation of the field value based on the values cached by the LOV
- Automatic popup of the LOV if the field contents are not valid

Implementation of the task in Oracle ADF
To implement a popup list in Oracle ADF, you configure one of the view object’s attributes to be of LOV type, and select Input Text with List of Values as the style for its UI hint. For a description of how to do this, see Section 5.12, "Working with List of Values (LOV) in View Object Attributes."
G.3.7 How to Implement a Dropdown List as a List of Values

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement an LOV (lookup-value) screen with a search item, usable for a lookup field with many possible values.

Implementation of the task in Oracle ADF

To implement a dropdown list in Oracle ADF, you configure one of the view object’s attributes to be of LOV type, and select **Input Text with List of Values** as the style for its UI hint. For a description of how to do this, see Section 5.12, "Working with List of Values (LOV) in View Object Attributes."

G.3.8 How to Implement a Dropdown List with Values from Another Table

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement a dropdown list with string values from a different table. These string values populate the field with an id code that is valid input in the table that the screen is based on.

Implementation of the task in Oracle ADF

To implement a dropdown list of this type in Oracle ADF, you configure one of the view object’s attributes to be of LOV type, and select **Choice List** as the style for its UI hint. For a description of how to do this, see Section 5.12, "Working with List of Values (LOV) in View Object Attributes."

G.3.9 How to Implement Immediate Locking

In Oracle ADF, you can lock a record in the database at the first moment it is obvious that the user is going to change a specific record.

Implementation of the task in Oracle ADF

Immediate row locking can be configured in ADF Business Components, although it is not the default and is typically not used in web application scenarios. For web applications, use the default configuration setting `jbo.locking.mode=optimistic`. For more information, see Section 49.11.1, "How to Confirm That Applications Use Optimistic Locking."

G.3.10 How to Throw an Error When a Record Is Locked

When a record has been locked by a user, it’s helpful to throw an error to let other users know that the record is not currently updatable.

Implementation of the task in Oracle ADF

Locking rows and throwing an exception if the row is already locked is built-in ADF Business Components functionality. There are a couple of different ways that you can handle the error message, depending on whether you want a static error message or a custom message with information about the current row.

- To throw a static message, register a custom message bundle in your data model project to substitute the default `RowAlreadyLockedException`’s error message with something more meaningful or user-friendly.

- To throw a message that contains information about the row, override the `lock()` method on the entity object, using a try/catch block to catch the
RowAlreadyLocked exception. After you catch the exception, you can throw an error message that might contain more specific information about the current row.
This appendix describes how to deploy Oracle ADF applications to a GlassFish application server. It describes how to create deployment profiles, how to create deployment descriptors, and how to deploy the application.

This chapter includes the following sections:

- Section H.1, "About Deploying ADF Applications to GlassFish Server"
- Section H.2, "Running an ADF Application in Integrated WebLogic Server"
- Section H.3, "Preparing the Application"
- Section H.4, "Deploying the Application"
- Section H.5, "Testing the Application and Verifying Deployment"

### H.1 About Deploying ADF Applications to GlassFish Server

Deployment is the process of packaging application files as an archive file and transferring that file to a target GlassFish application server. You can use JDeveloper to deploy ADF applications directly to the GlassFish Server, or indirectly to an archive file as the deployment target, and then install this archive file to the target GlassFish Server. For application development, you can also use JDeveloper to run an application in Integrated WebLogic Server.

You can use JDeveloper to:

- Run applications in Integrated WebLogic Server
  
  You can run and debug applications using Integrated WebLogic Server and then deploy to standalone GlassFish Server.

- Deploy directly to the standalone GlassFish Server
  
  You can deploy applications directly to the standalone GlassFish Server by creating a connection to the server and choosing the name of that server as the deployment target.

- Deploy to an archive file
  
  You can deploy applications indirectly by choosing an EAR file as the deployment target. The archive file can subsequently be installed on the target GlassFish Server.

### H.1.1 Developing Applications with Integrated WebLogic Server

If you are developing an application in JDeveloper and you want to run the application in Integrated WebLogic Server, you do not need to perform the tasks...
required for deploying directly to Oracle WebLogic Server or to an archive file. JDeveloper has a default connection to Integrated WebLogic Server and does not require any deployment profiles or descriptors. Integrated WebLogic Server has a preconfigured domain that includes the ADF libraries, as well as the -Djps.app.credential.overwrite.allowed=true setting, that are required to run ADF applications. You can run an application by choosing Run from the JDeveloper main menu.

You debug the application using the features described in Chapter 42, "Testing and Debugging ADF Components."

### H.1.2 Developing Applications to Deploy to Standalone GlassFish Server

Typically, for deployment to standalone application servers, you test and develop your application by running it in Integrated WebLogic Server. You can then test the application further by deploying it to standalone GlassFish Server.

In general, you use JDeveloper to prepare the application or project for deployment by:

- Creating a connection to the target GlassFish Server
- Creating deployment profiles (if necessary)
- Creating deployment descriptors that are specific to GlassFish
- Updating application.xml and web.xml to be compatible with the GlassFish Server (if required)

You must already have an installed GlassFish Server. For instructions on obtaining and installing GlassFish, see [http://glassfish.java.net/downloads/3.1.2-final.html](http://glassfish.java.net/downloads/3.1.2-final.html)

You must also prepare the GlassFish Server for ADF application deployment. For more information, see the "Configuring GlassFish Server" appendix in *Administering Oracle ADF Applications*.

- Installing the ADF runtime into the GlassFish Server installation:
- Setting JVM cache size and simple option
- Enabling Secure Admin on the GlassFish Server to allow for remote logins and remote connections in order for JDeveloper to run on a different machine than GlassFish.
- Creating a global JDBC data source for applications that require a connection to a data source

After the application and the GlassFish Server have been prepared, you can:

- Use JDeveloper to:
  - Directly deploy to the GlassFish Server using the deployment profile and the application server connection.
  - Deploy to an EAR file using the deployment profile. For ADF applications, WAR files can be deployed only as part of an EAR file.
- Use the GlassFish Server’s administration tools to deploy the EAR file created in JDeveloper.
H.2 Running an ADF Application in Integrated WebLogic Server

JDeveloper is installed with Integrated WebLogic Server which you can use to test and develop your application. For most development purposes, Integrated WebLogic Server will suffice. When your application is ready to be tested, you can select the run target and then choose the Run command from the main menu.

**Note:** The first time you run an application in Integrated WebLogic Server, the Configure Default Domain dialog appears for you to define an administrative password for the new domain.

When you run the application target, JDeveloper detects the type of Java EE module to deploy based on artifacts in the projects and workspace. JDeveloper then creates an in-memory deployment profile for deploying the application to Integrated WebLogic Server. JDeveloper copies project and application workspace files to an "exploded EAR" directory structure. This file structure closely resembles the EAR file structure that you would have if you were to deploy the application to an EAR file. JDeveloper then follows the standard deployment procedures to register and deploy the "exploded EAR" files into Integrated WebLogic Server. The "exploded EAR" strategy reduces the performance overhead of packaging and unpackaging an actual EAR file.

In summary, when you select the run target and run the application in Integrated WebLogic Server, JDeveloper:

- Detects the type of Java EE module to deploy based on the artifacts in the project and application
- Creates a deployment profile in memory
- Copies project and application files into a working directory with a file structure that would simulate the "exploded EAR" file of the application.
- Performs the deployment tasks to register and deploy the simulated EAR into Integrated WebLogic Server

**Note:** JDeveloper ignores the deployment profiles that were created for the application when you run the application in Integrated WebLogic Server.

The application will run in the base domain in Integrated WebLogic Server. This base domain has the same configuration as a base domain in a standalone WebLogic Server instance. In other words, this base domain will be the same as if you had used the Oracle Fusion Middleware Configuration Wizard to create a base domain with the default options in a standalone WebLogic Server instance.

JDeveloper will extend this base domain with the necessary domain extension templates, based on the JDeveloper technology extensions. For example, if you have installed JDeveloper Studio, JDeveloper will automatically configure the Integrated WebLogic Server environment with the ADF runtime template (JRF Fusion Middleware runtime domain extension template).

You can explicitly create a default domain for Integrated WebLogic Server. You can use the default domains to run and test your applications. Open the Application Servers window, right-click **IntegratedWebLogicServer** and choose Create Default Domain.
H.2.1 How to Run an Application in Integrated WebLogic Server

You can test an application by running it in Integrated WebLogic Server. You can also set breakpoints and then run the application within the ADF Declarative Debugger.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you run an application in Integrated WebLogic Server. For more information, see Section H.2, "Running an ADF Application in Integrated WebLogic Server."

**To run an application in Integrated WebLogic Server:**
1. In the Applications window, select the project, unbounded task flow, JSF page, or file as the run target.
2. Right-click the run target and choose Run or Debug.
   
   The Configure Default Domain dialog displays the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

H.3 Preparing the Application

Before you deploy an ADF application to a standalone GlassFish Server, you must perform prerequisite tasks within JDeveloper to prepare the application for deployment.

The tasks are:

- **Section H.3.1, "How to Create a Connection to the Target Application Server"**
- **Section H.3.2, "How to Create Deployment Profiles"**
- **Section H.3.3, "How to Create and Edit Deployment Descriptors"**
- **Section H.3.4, "How to Enable JDBC Data Source for GlassFish"**
- **Section H.3.5, "How to Change Initial Context Factory"**

**Note:** ADF Security is not supported on ADF Essentials for GlassFish. You should configure GlassFish-specific security within the ADF application. For more information about configuring GlassFish security, see [http://docs.oracle.com/cd/E18930_01/html/821-2418/beabg.html#scrolltoc](http://docs.oracle.com/cd/E18930_01/html/821-2418/beabg.html#scrolltoc).

H.3.1 How to Create a Connection to the Target Application Server

You can deploy applications to the GlassFish Server via JDeveloper application server connections.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you create an application server connection. For more information, see Section H.3, "Preparing the Application."

You will need to complete this task:

- Install the GlassFish Server.
To create a connection to an application server:

1. Launch the Application Server Connection wizard.
   
   You can:
   
   ■ In the Application Servers window, right-click Application Servers and choose New Application Server.
   
   ■ In the New Gallery, expand General, select Connections and then Application Server Connection, and click OK.
   
   ■ In the Resources window, choose New > IDE Connections > Application Server.

2. In the Create Application Server Connection dialog, on the Usage page, select Standalone Server.

3. On the Name and Type page, enter a connection name.

4. In the Connection Type dropdown list, choose:
   
   ■ GlassFish 3.1 to create a connection to the GlassFish Server

5. Click Next.

6. On the Authentication page, enter a user name and password for the administrative user authorized to access the GlassFish Server.

7. Click Next.

8. On the Configuration page, enter the information for the GlassFish Server:
   
   ■ Host Name: Enter the name of the machine where the GlassFish Server is running. If no name is entered, the name defaults to localhost.
   
   ■ RMI Port: If necessary, change to the RMI port number for the server. The default is 8686.
   
   ■ HTTP Port: By default, GlassFish listens to port 8080 for HTTP requests. If necessary, you can change the port number here.
   
   ■ Admin HTTP Port: By default, GlassFish uses port 4848 for administration. If necessary, you can change the port number here.
   
   ■ Secure Admin Enabled: select if you want GlassFish to to allow remote logins and remote connections

9. Click Next.

10. On the Test page, click Test Connection to test the connection.

   JDeveloper performs several types of connections tests. The JSR-88 test must pass for the application to be deployable. If the test fails, return to the previous pages of the wizard to fix the configuration.

11. Click Finish.

---

Note: If you are using GlassFish 3.1.2 and you are running JDeveloper on a different machine than GlassFish, you need to enable Secure Admin in GlassFish to allow remote logins. You do not need to enable Secure Admin if both JDeveloper and GlassFish are on the same machine.
H.3.2 How to Create Deployment Profiles

A deployment profile defines the way the application is packaged into the archive that will be deployed to the target environment. The deployment profile:

- Specifies the format and contents of the archive file that will be created
- Lists the source files, deployment descriptors, and other auxiliary files that will be packaged
- Describes the type and name of the archive file to be created
- Highlights dependency information, platform-specific instructions, and other information

You need a WAR deployment profile for each web user interface project that you want to deploy in your application. You need an application-level EAR deployment profile and you must select the projects (such as WAR profiles) to include from a list. When the application is deployed, the EAR file will include all the projects that were selected in the deployment profile.

Note: If you create your project or application using the ADF Fusion Web Application template, JDeveloper automatically creates default WAR and EAR deployment profiles. Typically, you would not need to edit or create deployment profiles manually.

For ADF applications, you can deploy the application only as an EAR file. The WAR files that are part of the application should be included in the EAR file when you create the deployment profile.

H.3.2.1 Creating a WAR Deployment Profile

You will need to create a WAR deployment profile for each web-based project you want to package into the application. Typically, the WAR profile will include the dependent data model projects it requires.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a WAR deployment profile. For more information, see Section H.3, "Preparing the Application."

You will need to complete this task:

Create web-based projects. If you used the ADF Fusion Web Application template, you should already have a default WAR deployment profile.

To create WAR deployment profiles for an application:

1. In the Applications window, right-click the web project that you want to deploy and choose New and then From Gallery.

   You will create a WAR profile for each web project.

2. In the New Gallery, expand General, select Deployment Profiles and then WAR File, and click OK.

   If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- WAR File dialog, enter a name for the project deployment profile and click OK.
4. In the Edit WAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog. Note that some items list below may not be in your particular application.

- Ensure that ADF Faces Runtime 11, JSTL 1.2, and the ADFm, ADFc, and ADFv libraries are marked deployed in the WEB-INF/lib/Contributors panel.
- Select File Groups > Web Files > Filters > WEB-INF and deselect weblogic.xml.
- Select File Groups > Web Files/Classes > Filters > META-INF and deselect ejb-jar.xml.
- Select File Groups > Web Files/Classes > Filters > path and deselect serviceinterface.
- You might also want to change the Java EE web context root setting. To do so, choose General in the left pane.
  By default, when Use Project's Java EE Web Context Root is selected, the associated value is set to the project name, for example, Application1-Project1-context-root. You need to change this if you want users to use a different name to access the application.
- Select Glassfish 3.1 as the Platform

5. Click OK to exit the Deployment Profile Properties dialog.
6. Click OK again to exit the Project Properties dialog.
7. Repeat Steps 1 through 6 for all web projects that you want to deploy.

H.3.2.2 Creating an Application-Level EAR Deployment Profile

The EAR file contains all the necessary application artifacts for the application to run in the application server. If you used the ADF Fusion Web Application template, you should already have a default EAR deployment profile. For more information about the EAR file, see Section H.4.5, "What You May Need to Know About EAR Files and Packaging."

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create an application-level EAR deployment profile. For more information, see Section H.3, "Preparing the Application."

You will need to complete this task:

Create the WAR deployment profiles, as described in Section H.3.2.1, "Creating a WAR Deployment Profile."

To create an EAR deployment profile for an application:
1. In the Applications window, right-click the application and choose New and then From Gallery.
  You will create an EAR profile for the application.
2. In the New Gallery, expand General, select Deployment Profiles and then EAR File, and click OK.
If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- EAR File dialog, enter a name for the application deployment profile and click OK.

4. In the Edit EAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.
   - Select File Groups > Application Descriptors > Filters and deselect weblogic-application.xml.
   - Select Application Assembly and then in the Java EE Modules list, select all the project profiles that you want to include in the deployment, including any WAR profiles.
   - Select Platform, select the application server you are deploying to, and then select the target application connection from the Target Connection dropdown list. For GlassFish, select GlassFish 3.1.

5. Click OK again to exit the Edit EAR Deployment Profile Properties dialog.

6. Click OK again to exit the Application Properties dialog.

---

Note: To verify that your customization classes are put correctly in the EAR class path, you can deploy the EAR profile to file system. Then you can examine the EAR to make sure that the customization class JAR is available in the EAR class path (the EAR/lib directory) and not available in the WAR class path (the WEB-INF/lib and WEB-INF/classes directories).

---

H.3.2.3 Viewing and Changing Deployment Profile Properties

After you have created a deployment profile, you can view and change its properties.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you view and change deployment profile properties. For more information, see Section H.3, “Preparing the Application.”

To view, edit, or delete a project’s deployment profile:
1. In the Applications window, right-click the project and choose Project Properties.
2. In the Project Properties dialog, click Deployment.
   - The Deployment Profiles list displays all profiles currently defined for the project.
3. In the list, select a deployment profile.
4. To edit or delete a deployment profile, click Edit or Delete.

H.3.3 How to Create and Edit Deployment Descriptors

Deployment descriptors are server configuration files that define the configuration of an application for deployment and that are deployed with the Java EE application as needed. The deployment descriptors that a project requires depend on the technologies the project uses and on the type of the target application server. Deployment descriptors are XML files that can be created and edited as source files, but for most descriptor types, JDeveloper provides dialogs or an overview editor that
you can use to view and set properties. If you cannot edit these files declaratively, JDeveloper opens the XML file in the source editor for you to edit its contents.

In addition to the standard Java EE deployment descriptors (for example, application.xml and web.xml), you can also have deployment descriptors that are specific to your target application server.

**H.3.3.1 Creating Deployment Descriptors**

JDeveloper automatically creates many of the required deployment descriptors for you. If they are not present, or if you need to create additional descriptors, you can use JDeveloper to create them.

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you create deployment descriptors. For more information, see Section H.3, "Preparing the Application."

You will need to complete this task:

Check to see whether JDeveloper has already generated deployment descriptors.

**To create a deployment descriptor:**

1. In the Applications window, expand the user interface project, select WEB-INF and click **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, choose **XML Document** and click **OK**.
3. In the Create XML File dialog, enter a name for your descriptor and click **OK**.
   
   For instance, you may want to create a **glassfish-web.xml** to define GlassFish-specific information.
4. In the overview editor, add entries for GlassFish.

Example H–1 show a sample glassfish-web.xml descriptor.

The glassfish-web.xml descriptor can be used to add additional settings that are not defined in web.xml or to modify the settings that are already defined in web.xml. For instance, you can override the jdbc/Connections1DS setting defined in web.xml as shown in Example H–2 by adding the entries res-ref-name and jndi-name to glassfish-web.xml as shown in Example H–1. After setting glassfish-web.xml, jdbc/NewConnections1DS will be used instead of jdbc/Connections1DS. Note that the res-ref-name section is optional.

**Example H–1  Sample glassfish-web.xml**

```xml
<glassfish-web-app>
  <context-root>DeptApp-ViewController-context-root</context-root>
  <resource-ref>
    <res-ref-name>jdbc/Connection1DS</res-ref-name>
    <jndi-name>jdbc/NewConnection1DS</jndi-name>
  </resource-ref>
  <class-loader delegate="false"/>
  <property value="true" name="useBundledJsf"/>
</glassfish-web-app>
```
H.3.3.2 Viewing or Modifying Deployment Descriptor Properties
After you have created a deployment descriptor, you can change its properties by using JDeveloper dialogs or by editing the file in the source editor. The deployment descriptor is an XML file (for example, application.xml) typically located under the Application Sources node.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you view or modify deployment descriptors. For more information, see Section H.3, "Preparing the Application."

**To view or change deployment descriptor properties:**
1. In the Applications window or in the Application Resources panel, double-click the deployment descriptor.
2. In the overview editor, select either the **Overview tab** or the **Source tab**, and configure the descriptor by setting property values.
   If the overview editor is not available, JDeveloper opens the file in the source editor.

H.3.3.3 Configuring the application.xml File for Application Server Compatibility
You may need to configure your application.xml file to be compliant with your Java EE 1.5.

**Note:** Typically, your project has an application.xml file that is compatible and you would not need to perform this procedure.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you configure the application.xml file. For more information, see Section H.3, "Preparing the Application."

**To configure the application.xml file:**
1. In the Applications window, right-click the application and choose **New** and then **From Gallery**.
Preparing the Application

Deploying ADF Applications to GlassFish

2. In the New Gallery, expand General, select Deployment Descriptors and then Java EE Deployment Descriptor Wizard, and click OK.

3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select application.xml and click Next.

4. On the Select Version page, select 5.0 to be compatible with Java EE 5.0 or higher and click Next.

5. On the Summary page, click Finish.

6. Edit the application.xml file with the appropriate values.

H.3.3.4 Configuring the web.xml File for GlassFish Server Compatibility

You may need to configure your web.xml file to be compliant with your Java EE version.

Example H–2 shows a web.xml file with a setting for a JDBC connection. For more information and other settings that are required, see Section A.13, "web.xml."

Example H–2 Sample Partial web.xml File

```xml
<resource-ref>
  <description>DB Connection</description>
  <res-ref-name>jdbc/Connection1DS</res-ref-name>
  <res-type>javax.sql.DataSource</res-type>
  <res-auth>Container</res-auth>
</resource-ref>
```

Note: Typically, your project has a web.xml file that is compatible and you would not need to perform this procedure. JDeveloper creates a starter web.xml file when you create a project.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you configure the web.xml file. For more information, see Section H.3, "Preparing the Application."

To configure the web.xml file:

1. In the Applications window, right-click the project and choose New and then From Gallery.

2. In the New Gallery, expand General, select Deployment Descriptors and then Java EE Deployment Descriptor, and click OK.

3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select web.xml and click Next.

4. On the Select Version page, select the version you want to use and click Next.

   Version 3.0 is compatible with Java EE 6.0 or higher, and version 2.5 is compatible with Java EE 5.0.

5. On the Summary page, click Finish.

6. Open the web.xml file in the overview editor.

7. Select the Filters tab and remove JpsFilter.
H.3.4 How to Enable JDBC Data Source for GlassFish

If you are using ADF Business Components in your application, you may need to check that the data source defined for the ADF Business Components as part of the application matches the data source defined in the GlassFish container.

You can configure the ADF application to use a JDBC Data Source in the application by editing the application’s `bc4j.xcfg` file.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you configure JDBC. For more information, see Section H.3, "Preparing the Application."

**To configure the bc4j.xcfg file to enable JDBC data source:**

1. In the Applications window, expand the model project and click the application module.
2. In the overview editor for the application module, choose Configurations and click `bc4j.xcfg`.
3. In the overview editor for `bc4j.xcfg`, select the Source tab.
4. Check that the Custom JDBCDataSource entry defined in the file matches the JDBC datasource defined for the GlassFish Server as described in the "Configuring GlassFish Server" appendix in Administering Oracle ADF Applications.

For instance, the following example shows the JDBCDataSource property defined in the `bc4j.xcfg` file:

```xml
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
  <AppModuleConfigBag ApplicationName="model.AppModule">
    < AppModuleConfig name="AppModuleLocal" jbo.project="model.Model" ApplicationName="model.AppModule" DeployPlatform="LOCAL">
      <Database jbo.TypeMapEntries="OracleApps"/>
      <Security AppModuleJndiName="model.AppModule"/>
      <Custom xmlns:ns0="http://xmlns.oracle.com/bc4j/configuration">
        <ns0:JDBCDataSource value="jdbc/OracleDS"/>
      </Custom>
    </AppModuleConfig>
    < AppModuleConfig name="AppModuleShared" jbo.project="model.Model" ApplicationName="model.AppModule" DeployPlatform="LOCAL">
      <AM-Pooling jbo.ampool.maxpoolsize="1" jbo.ampool.isuseexclusive="false"/>
      <Database jbo.TypeMapEntries="OracleApps"/>
      <Security AppModuleJndiName="model.AppModule"/>
      <Custom xmlns:ns0="http://xmlns.oracle.com/bc4j/configuration">
        <ns0:JDBCDataSource value="jdbc/OracleDS"/>
      </Custom>
    </AppModuleConfig>
  </AppModuleConfigBag>
</BC4JConfig>
```

H.3.5 How to Change Initial Context Factory

If your application requires JNDI lookup, such as in EJB-based applications, you need to change the initial context factory class name to the GlassFish context factory.

**To change the initial context factory:**

1. In the Applications window, expand the model project and double-click the `DataControls.dcx` file.
2. In the overview editor, click the **Source** tab.

3. Edit the `initial-context-factory` entry to be

   ```
   initial-context-factory="com.sun.enterprise.naming.SerialInitContextFactory"
   ```

**H.4 Deploying the Application**

You can use JDeveloper to deploy ADF applications directly to the GlassFish Server or you can create an archive file and use other tools to deploy to the application server.

---

**Note:** Before you begin to deploy applications that use Oracle ADF to the standalone application server, you need to prepare the GlassFish Server environment by performing tasks such as installing the ADF runtime libraries and setting configuration values. For more information, see the “Configuring GlassFish Server” appendix in *Administering Oracle ADF Applications*.

---

Table H–1 describes some common deployment techniques that you can use during the application development and deployment cycle. The deployment techniques are listed in order from deploying on development environments to deploying on production environments. It is likely that in the production environment, the system administrators deploy applications by using the GlassFish Administration Console or scripts.

**Table H–1 Deployment Techniques for Development or Production Environments**

<table>
<thead>
<tr>
<th>Deployment Technique</th>
<th>Environment</th>
<th>When to Use</th>
</tr>
</thead>
</table>
| Run directly from JDeveloper | Test or Development | When you are developing your application. You want deployment to be quick because you will be repeating the editing and deploying process many times.  
JDeveloper contains Integrated WebLogic Server, on which you can run and test your application.  
Note that you are testing your application in an integrated WebLogic Server and not in an Integrated GlassFish Server. After testing on the Integrated WebLogic Server, you can test further by deploying to the standalone GlassFish Server. |
| Use JDeveloper to directly deploy to the target GlassFish Server | Test or Development | When you are ready to deploy and test your application on an application server in a test environment.  
You can also use the test environment to develop your deployment scripts, for example, using Ant. |
| Use JDeveloper to deploy to an EAR file, then use the target GlassFish Server’s tools for deployment | Test or Development | When you are ready to deploy and test your application on an application server in a test environment. As an alternative to deploying directly from JDeveloper, you can deploy to an EAR file and then use other tools to deploy to the application server.  
You can also use the test environment to develop your deployment scripts, for example, using Ant. |
| Use GlassFish `asadmin` commands or GlassFish Administration Console. | Production | When your application is in a test and production environment. In production environments, system administrators usually use GlassFish `asadmin` commands or the GlassFish Administration Console. |
H.4.1 How to Deploy to the Application Server from JDeveloper

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you deploy to the application server from JDeveloper. For more information, see Section H.3, "Preparing the Application."

You will need to complete this task:

Create an application-level deployment profile that deploys to an EAR file.

To deploy to the target application server from JDeveloper:
1. In the Applications window, right-click the application and choose Deploy > deployment profile.
   Make sure you choose a GlassFish deployment profile.
2. In the Deploy wizard, on the Deployment Action page, select Deploy to Application Server and click Next.
3. On the Select Server page, select the application server connection, and click Next.
4. Click Finish.
   During deployment, you can see the process steps displayed in the deployment Log window. You can inspect the contents of the modules (archives or exploded EAR) being created by clicking on the links that are provided in the log window. The archive or exploded EAR file will open in the appropriate editor or directory window for inspection.

Note: If you are deploying a Java EE application, click the application menu next to the Java EE application in the Applications window.

For more information on creating application server connections, see Section H.3.1, "How to Create a Connection to the Target Application Server."

H.4.2 What You May Need to Know About Deploying from JDeveloper

When you deploy an application using the EAR deployment profile created for GlassFish, JDeveloper:

- Inserts the required ADF Model, ADF Controller, and ADF View library JARs into the EAR file.
- Inserts adf-share-glassfish.jar into the WAR.
- Inserts an entry for the GlassFish application lifecycle listener ADFGlassFishAppLifeCycleListener into the web.xml file.

H.4.3 How to Create an EAR File for Deployment

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using GlassFish Administration Console.
Although an ADF application is encapsulated in an EAR file (which usually includes WAR components), it may have parts that are not deployed with the EAR.

**Before you begin:**
It may be helpful to have an understanding of the options that are available to you when you create an EAR file for deployment. For more information, see Section H.3, "Preparing the Application."

You will need to complete this task:

Create an application-level deployment profile that deploys to an EAR file.

**To create an EAR archive file:**

- In the Applications window, right-click the application containing the deployment profile, and choose **Deploy > deployment profile > to EAR file.**

If an EAR file is deployed at the application level, and it has dependencies on a JAR file in the data model project and dependencies on a WAR file in the user interface project, then the files will be located in the following directories by default:

- `ApplicationDirectory/deploy/EARdeploymentprofile.EAR`
- `ApplicationDirectory/ModelProject/deploy/JARdeploymentprofile.JAR`
- `ApplicationDirectory/ViewControllerProject/deploy/WARdeploymentprofile.WAR`

**Tip:** Choose **View > Log** to see messages generated during creation of the archive file.

**H.4.4 What You May Need to Know About ADF Libraries**

An ADF Library is a JAR file that contains JAR services registered for ADF components such as ADF task flows, pages, or application modules. If you want the ADF components in a project to be reusable, you create an ADF Library deployment profile for the project and then create an ADF Library JAR based on that profile.

An application or project can consume the ADF Library JAR when you add it using the Resources window or manually by adding it to the library classpath. When the ADF Library JAR is added to a project, it will be included in the project’s WAR file if the **Deployed by Default** option is selected.

For more information, see Chapter 44, "Reusing Application Components."

**H.4.5 What You May Need to Know About EAR Files and Packaging**

When you package an ADF application into an EAR file, it can contain the following:

- **WAR files:** Each web-based view controller project should be packaged into a WAR file.
- **ADF Library JAR files:** If the application consumes ADF Library JARs, these JAR files may be packaged within the EAR.
- **Other JAR files:** The application may have other dependent JAR files that are required. They can be packaged within the EAR.
H.4.6 How to Deploy to the Application Server using asadmin Commands

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you deploy to the application server from JDeveloper. For more information, see Section H.3, "Preparing the Application."

To deploy to the target application server using asadmin command:
1. Start an asadmin shell for GlassFish Server.
2. Invoke the deploy command.
   For instance, the following command deploys application1.ear to the GlassFish Server.
   
   ```
   deploy --target=server --force /path/application1.ear
   ```

H.4.7 How to Deploy the Application Using Scripts and Ant

You can deploy the application using commands and automate the process by putting those commands in scripts. The ojdeploy command can be used to deploy an application without JDeveloper. You can also use Ant scripts to deploy the application. JDeveloper has a feature to help you build Ant scripts. Depending on your requirements, you may be able to integrate regular scripts with Ant scripts.

For more information about commands, scripts, and Ant, see Administering Oracle ADF Applications.

H.5 Testing the Application and Verifying Deployment

After you deploy the application, you can test it from the application server. To test-run your ADF application, open a browser window and enter a URL:

- For non-Faces pages: http://<host>:port/<context root>/<page>
- For Faces pages: http://<host>:port/<context root>/faces/<view_id>

where <view_id> is the view ID of the ADF task flow view activity.

Tip: The context root for an application is specified in the user interface project settings by default as ApplicationName/ProjectName/context-root. You can shorten this name by specifying a name that is unique across the target application server. Right-click the user interface project, and choose Project Properties. In the Project Properties dialog, select Java EE Application and enter a unique name for the context root.

Note: /faces has to be in the URL for Faces pages. This is because JDeveloper configures your web.xml file to use the URL pattern of /faces in order to be associated with the Faces Servlet. The Faces Servlet does its per-request processing, strips out /faces part in the URL, then forwards the URL to the JSP. If you do not include the /faces in the URL, then the Faces Servlet is not engaged (since the URL pattern doesn’t match). Your JSP is run without the necessary JSF per-request processing.
action binding
A binding for command components, such as buttons or links, to built-in or custom methods on the data control, or to built-in collection-level operations (such as, Create, Delete, Next, or Previous). An action binding object encapsulates the details of how to invoke a method and what parameters (if any) the method is expecting.

activity
A piece of work that is performed when an ADF Controller task flow runs, for example, a method call or view.

ADF
See Oracle ADF.

ADF binding filter
A servlet filter that ADF web applications use to preprocess any HTTP requests that may require access to the binding context.

ADF Business Components
A framework that simplifies the development, delivery, and customization of business applications for the Java EE platform. You use ADF Business Components to define associations between entity objects, view objects, and application modules to reflect the foreign keys present in the underlying tables.

ADF Controller layer
A mechanism that provides an enhanced navigation and state management model on top of JSF. This mechanism declaratively defines navigation using control flow rules.

ADF Faces Rich Client (RC)
A set of standard JSF components that include built-in AJAX functionality.

ADF Model layer
A layer that implements service abstraction called the data control.

application module
A transactional component that UI clients use to work with application data. It defines an updatable data model and top-level procedures and functions (called service methods) related to a logical unit of work. This unit of work is related to an end-user task.
**binding context**
A container object that holds a list of available data controls and data binding objects. The DataBindings.cpx file defines the binding context for the application. See also data control.

**bounded task flow**
A specialized form of ADF Controller task flow that has a single entry point and zero or more exit points. It contains its own set of private control flow rules, activities, and managed beans. A bounded task flow allows reuse, parameters, transaction management, and reentry. When dropped on a page, it becomes a region.

**control flow**
An ADF Controller activity that enables navigation between other activities in an ADF task flow. The control flow links one activity to another in a task flow.

**data control**
XML configuration files that describe a service. At design time, JDeveloper uses the metadata to declaratively bind an operation or data collection to a UI component.

**Data Controls panel**
A panel in JDeveloper that lists all the data controls that have been created for the application’s business services and exposes all the collections (row sets of data objects), methods, and built-in operations that are available for binding to UI components.

**entity object**
An object that represents a row in a database table and that simplifies modifying its data by handling all data manipulation language operations for you. Entity objects are ADF Business Components that provide the mapping to underlying data structures.

**invoke action**
An action that binds to a method that invokes the operations or methods defined in an action or a method action binding during any phase of the page lifecycle. See also action binding.

**iterator binding**
A binding to an iterator that iterates over view object collections. There is one iterator binding for each collection used on the page. All of the value bindings on the page must refer to an iterator binding in order for the component values to be populated with data at runtime.

Contrast with variable iterator and method iterator.

**list of values (LOV)**
See LOV.

**LOV**
Input components that allow a user to enter values by picking from a list that is generated by a query.

**MDS**
An application server and Oracle relational database that keep metadata in these areas: a file-based repository data, dictionary tables (accessed by built-in functions) and a metadata registry. One of the primary uses of MDS is to store customizations and persisted personalization for Oracle applications.
**method iterator**
A binding to an iterator that iterates over the collections returned by custom methods in the data control. An iterator binding that is always related to a method action binding object. The method action binding encapsulates the details about how to invoke the method and what parameters the method is expecting. The method action binding is itself bound to the method iterator, which provides the data.

**Oracle ADF**
An end-to-end application framework that builds on Java EE standards and open-source technologies to simplify and accelerate implementing service-oriented applications.

**Oracle Application Development Framework (Oracle ADF)**
See Oracle ADF.

**Oracle Metadata Services (MDS)**
See MDS.

**page definition file**
A file that defines the binding objects that populate the data in UI components at runtime. For every page that has ADF bindings, there must be a corresponding page definition file that defines the binding objects used by that page.

**region**
A UI component whose content is based on a task flow definition. When first rendered, the region’s content is that of the first view activity in a task flow. See also activity.

**task flow**
A set of ADF Controller activities, control flow rules and managed beans that interact to allow a user to complete a task.

**unbounded task flow**
A set of activities, ADF control flow rules, and managed beans that interact to allow a user to complete a task. An unbounded task flow has one or more points of entry.

**value binding**
A binding used by ADF Faces components that display data. Value bindings range from the most basic variety that work with a simple text field to more sophisticated list and tree bindings that support the additional needs of list, table, and tree UI controls.

**value iterator**
An ADF Model iterator pointing to a collection that contains only one data object whose attributes are the binding container variable. Contrast with method iterator and value iterator iterator.

**variable iterator**
A binding to an iterator that exposes all the variables in the binding container to the other bindings. While there is an iterator binding for each collection, there is only one variable iterator binding for all variables used on the page. Contrast with method iterator and value iterator iterator.
**view accessor**

An ADF Business Components object that points from an entity object attribute (or **view object**) to a destination view object or shared view instance in the same application workspace. The view accessor returns a row set that by default contains all the rows from the destination view object.

**view object**

An ADF Business Components object that represents a SQL query and simplifies working with its results. The SQL language is used to join, project, filter, sort, and aggregate data into the shape required by the end-user task being represented in the user interface.
