authenticated user has view access granted on the requested page’s ADF security-aware resource.

- In an **explicit authentication** scenario, your application has a public page that displays a login link, which, when clicked, triggers an authentication challenge to log in the user. The login link may optionally specify some other target page that should be displayed (assuming the authenticated user has access) after the successful authentication.

The implicit and explicit authentication scenarios are handled for you by default when you run the Configure ADF Security wizard, as described in *What You May Need to Know About ADF Authentication*. However, when you customize the default, generated login page (or supply your own page) to use ADF Faces components, you will need to configure the container-managed deployment descriptor (`web.xml` file).

To explicitly handle user authentication:

1. Create a login link component and add it to the public home web page for your application.

2. Create a managed bean using API specific to Servlet 3.0 to handle the login attempts by the user.

3. Create a JSF login page using ADF Faces components.

4. Ensure that the login page’s resources are accessible.

For more information about implicit and explicit authentication, see *What Happens at Runtime: How ADF Security Handles Authentication*.

### 47.7.1 How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication

You can create a standard login link component that can be added to any page in your application to enable users to authenticate or subsequently log off. This component keeps track of the authenticated state of the user and returns the appropriate login or logout URLs and icons. The login link component will redirect users back to a specific page once they are authenticated. Hence, using this login link component provides you with a single, consistent object.

To the unauthenticated user, the login link component will look similar to *Figure 47-16*.

**Figure 47-16  Component Before User Logs In**

![Click here to log in](Figure 47-16)

Then when the user clicks the login link and logs in as a user with the appropriate credentials, the component will look similar to *Figure 47-17*.

**Figure 47-17  Component After User Logs In**

![Click here to log out](Figure 47-17)

Before you begin:
It may be helpful to have an understanding of ADF authentication. For more information, see Creating a Login Page.

You will need to complete this task:

Copy your login and logout image files (GIF, JPG, or PNG files) to the public_html directory of your project.

**Note:**
The images used should reference the appropriate skin image if your application uses skins. For more information about skins, see the "Customizing the Appearance Using Styles and Skins" chapter in Developing Web User Interfaces with Oracle ADF Faces.

To create the login link component and add it to a page:

1. In the Applications window, double-click the web page that will display the component.

2. In the ADF Faces page of the Components window, from the Common Components panel, drag a Link and drop it on the page.

3. In the Structure window, right-click af:link and choose Go to Properties.

4. In the Property window, to specify the label for the Link component, enter an Expression Language (EL) expression in the Text field.

   For example, you can enter an EL expression similar to this to conditionally render the link text:
   
   ```
   #{securityContext.authenticated ? "Click to log out" : "Click to log in"}
   ```

   The authenticated property of the securityContext bean will evaluate to true and render the log out option if the current user is authenticated. Otherwise, the link is rendered with the login option.

5. In the Property window, to specify the URL for the Link component, enter an EL expression in the Destination field.

   For example, this EL expression conditionally renders a URL to forward the user depending on whether or not they are authenticated:

   ```
   #{securityContext.authenticated ? "/Logout" : "/Login"} id="gl2"
   ```

   When the user clicks the link, the destination will be determined by the success_url and end_url settings on the ADF authentication servlet init-param. Note that these settings should specify the view activity name instead of the web page name to ensure control flow rules are enforced for page navigation after login. The authenticated property of the securityContext bean will evaluate to true and forward to the page defined by success_url if the current user is authenticated. When the user is not authenticated, there is no need to forward to the login page because the ADF authentication servlet triggers log in.
which is handled by the container-managed security configuration. Note that log
out is handled by the ADF authentication servlet which invalidates the session.

6. In the Property window, to specify the link component image for the Link
component, enter an EL expression in the Icon field.

For example, this EL expression conditionally renders the link component image as
the lock GIF if the user is not authenticated; otherwise, renders the image with the
key GIF:

#{securityContext.authenticated ? '/images/lock.gif' : '/images/key.gif'}

Figure 47-18 shows how the login link component appears when added to the
global menu facet of the page.

47.7.2 How to Create a Login Page Specifically for Explicit Authentication

The default login form that is generated for you when you run the Configure ADF
Security wizard is provided as a convenience for testing your application within
JDeveloper. The default form does not allow you to customize the page using ADF
Faces components to match the user interface of the application. You can replace the
default form with an ADF Faces-based login page that enables you to include
customizable components, as shown in Figure 47-19.

Figure 47-19   Login Page

However, if designing a login page with ADF Faces components is not a requirement,
then a simple JSP or HTML login page can be also used. For details about generating a
simple login page when running the Configure ADF Security wizard, see How to
Enable ADF Security.

47.7.2.1 Creating Login Code for the Backing Bean

Before you create the login page as an ADF Faces page, you need to create a managed
bean to handle login attempts. In this login bean sample, authentication is handled
programmatically using Servlet 3.0-specific API. The login bean handles the login
action initiated from a login link with the doLogin() method. Upon successful login,
this method invokes the servlet API to redirect to a landing page. You will add this
bean to the adfc-config.xml file and register it with request scope.

Note:
This backing bean example described in this section does not authenticate with Oracle Single Sign-On (Oracle SSO). The backing bean handles authentication using login and logout methods provided by Servlet 3.0, which provides generic support for programmatic login on application servers that support Java EE 6 or later.

Before you begin:

It may be helpful to have an understanding of the login page. For more information, see How to Create a Login Page Specifically for Explicit Authentication.

You will need to complete this task:

Run the Configure ADF Security wizard to enable ADF Authentication and Authorization.

To create and register a backing bean for login:

1. In the Applications window, right-click the project in which you want to create the backing bean and choose New and then From Gallery.

2. In the New Gallery, expand General, select Java and then Class, and click OK.

3. In the Create Java Class dialog, enter the name for the login page backing bean class file and disable the default options Constructors from Superclass and Implement Abstract Methods, and click OK.

For convenience, you might name the backing bean based on the name of your login page, for example, LoginPageName.java.

4. In the Applications window, expand Application Sources and double-click the new LoginPageName.java backing bean.

5. In the source editor, create two private fields by adding the following in the declaration section of the LoginPageName.java file:

```
private String _username;
private String _password;
```

6. Generate or create public accessors for both fields.

You can right-click in the source editor and choose Generate Accessors to add the following public accessors to the file:

```
public void setUsername(String _username) {
    this._username = _username;
}
public String getUsername() {
    return _username;
}
public void setPassword(String _password) {
    this._password = _password;
}
public String getPassword() {
    return _password;
}
```
7. Import the following classes:

```java
javax.faces.application.FacesMessage
javax.faces.context.ExternalContext
javax.faces.context.FacesContext
javax.servlet.ServletException
javax.servlet.http.HttpServletRequest
javax.servlet.http.HttpSession
```

8. Add a `doLogin()` method to this Java class to handle user attempts to log in:

```java
public String doLogin() {
    FacesContext ctx = FacesContext.getCurrentInstance();

    if (_username == null || _password == null) {
        showError("Invalid credentials",
                 "An incorrect username or password was specified.", null);
    } else {
        ExternalContext ectx = ctx.getExternalContext();
        HttpServletRequest request = (HttpServletRequest)
                                    ctx.getExternalContext().getRequest();
        try {
            request.login(_username, _password); // Servlet 3.0 login
            _username = null;
            _password = null;
            HttpSession session = request.getSession();
            session.setAttribute("success_url", "/faces" +
                                    ctx.getViewRoot().getViewId());
            redirect(ectx.getRequestContextPath() + "/adfAuthentication");
        } catch (ServletException fle) {
            showError("ServletException", "Login failed.
                                    Please verify the username and password and try again.", null);
        }
    }
    return null;
}
```

The `doLogin()` method performs the following tasks:

**Line 2 and Lines 6-9** get an object encapsulating the HTTP request from the `ExternalContext`.

**Lines 3-5** handle an error when credentials have not been provided. The `showError()` method is a method which you will implement to deal with miscellaneous problems with the login process.

**Lines 11-13** attempt to log in the user issuing the request using the Servlet 3.0 API `login()` method. In this programmatic login example, which relies on the Servlet API, Oracle Single Sign-On (Oracle SSO) is not supported.

**Lines 14-16** create an HTTP session and set the ADF authentication servlet parameters `success_url` as an attribute of the session. Setting `success_url` on the session ensures the destination page URL is not passed as a request parameter that would be subject to malicious redirects. In this example, the destination page is the current page obtained from the Faces context.

**Note:** If you run the ADF Security wizard and use the wizard to create a login form, upon successful login, you would want the session to redirect to the target protected page instead of returning to the login page. In this case, `session.setAttribute` in lines 15 and 16 should take `success_url` and the
full path of the destination page as attribute, for example: /faces/proTECTEDPage.

**Line 17** calls a method, `redirect()` which you will implement later in this section to forward the user to the URL that the ADF authentication servlet gets from the HTTP session, as set in Line 15.

**Lines 18-21** handle a ServletException, which can be thrown by many different problems with a login. For example, exceptions can result from incorrect credentials or attempts to log into a locked account or uses of an expired password. The `showError()` method is a method which you will implement to deal with miscellaneous problems with the login process.

**Line 23** returns null so that ADF Controller will not attempt to follow a control flow case.

9. Create stubs for the methods `redirect()` and `showError()`.

10. Add a `redirect()` method with its actions:

```java
private void redirect(String forwardUrl) {
    FacesContext ctx = FacesContext.getCurrentInstance();
    ExternalContext ectx = ctx.getExternalContext();
    try {
        ectx.redirect(forwardUrl);
    } catch (IOException ie) {
        showError("IOException", "An error occurred during redirecting. Please consult logs for more information.", ie);
    }
}
```

The `redirect()` method performs the following tasks:

**Line 2** gets the ADF Faces `ctx`, which forwards a response to a particular URI.

**Lines 3-5** use the `ctx` to redirect the current HTTP response to the URL.

**Lines 6-8** handle an IOException, which is thrown when the request cannot be read or the response cannot be written to.

11. Implement a `showError()` method:

```java
private void showError(String errType, String message, Exception e){
    FacesMessage msg =
        new FacesMessage(FacesMessage.SEVERITY_ERROR, errType, message);
    FacesContext.getCurrentInstance().addMessage("d2:it35", msg);
    if (e != null) {
        e.printStackTrace();
    }
}
```

This `showError()` method adds a summary error message to the FacesContext, and then prints the full stack trace of the exception to the console.

12. Optionally, when you want to trigger logout programmatically from a task flow method call activity, create a stub for a `logoff()` method and implement it as:

```java
public String logoff() {
    FacesContext ctx = FacesContext.getCurrentInstance();
    ExternalContext ectx = ctx.getExternalContext();
    HttpServletRequest httpRequest = (HttpServletRequest) ectx.getRequest();
    try {
```
httpRequest.logout(); // Servlet 3.0 logout
HttpSession session = httpRequest.getSession(false);
if (session != null) {
    session.invalidate();
}
String logoutUrl = ectx.getRequestContextPath() + "/faces" +
    ctx.getViewRoot().getViewId();
redirect(logoutUrl);
} catch (ServletException e) {
    showError("ServletException", "An error occurred during logout.
        Please consult logs for more information.", e);
}
return null;

This logoff() method uses the logout() method of Servlet 3.0 API to process a
logoff action.

13. Save the Java file.

15. In the editor window, click the Overview tab.

16. In the overview editor, click the Managed Beans navigation tab.

17. In the Managed Beans page, in the Managed Beans section, click the Add icon and
    enter a name for the bean, enter the fully qualified class name, and select scope
    request.

    For example, the class name might look like oracle.summit.bean.LoginBean, as shown in Figure 47-20.

    Figure 47-20 Login Bean Registered in adfc-config.xml File

18. Save all.

47.7.2.2 Creating an ADF Faces-Based Login Page Specifically for Explicit
    Authentication

A simple login page that utilizes ADF Faces layout components and ADF Faces user
interface components includes two input fields and a button. You must bind the
properties of these UI components to the login handler methods that you defined in
the managed bean for the login page.

Note that the page that you can create with this procedure does not support implicit
authentication. When you choose to implement implicit authentication, you can
customize the default, wizard-generated login form which supports container-
managed authentication. The Java EE container expects a form that relies on the
j_security_check mechanism to handle user-submitted j_username, and
j_password input. In the explicit authentication scenario documented here, Java EE
container-managed authentication is not used.

Before you begin:
It may be helpful to have an understanding of explicit authentication. For more information, see How to Create a Login Page Specifically for Explicit Authentication.

You will need to complete this task:

Create the managed bean to handle the user’s login attempts, as described in Creating Login Code for the Backing Bean.

To create the ADF Faces-based login page for explicit authentication:

1. In the Applications window, right-click the project in which you want to create the login page and choose New and then New Gallery.
2. In the New Gallery, expand Web Tier, select JSF and then Page, and click OK.
3. In the Create JSF Page dialog, select JSP XML.
4. In the File Name field, specify a name for your login page. For example, enter LoginPage.jspx. Select no other options and do not select the option to expose UI components in a managed bean. You will manually bind the components to the managed bean you created for the login page.
5. Click OK.
6. Save the page.
7. In the ADF Faces page of the Components window, from the Layout panel, drag a Panel Box and drop it on the Structure window below the af:form node.
8. In the Property window, enter values for the Text, Horizontal, Width, and Height fields. For example, to create a basic login page, you can enter:
   - Text set to Login Information
   - Icon set to /images/key_ena.png
   - Width/Height set to 300/200 pixels
9. From the Components window, drag a Panel Form Layout and drop it below the af:panelBox node in the Structure window, as shown in Figure 47-21.

   Figure 47-21   Login Page Structure with Panel Form Layout

10. From the Common Components panel, drag an Input Text and drop it on the Panel Form Layout node for the username field and another Input Text for the password field.
11. In the Property window for the input fields, enter Username and Password in the Label fields and expand the Behavior section and select true from both fields' Required dropdown list.
12. In the Property window, for the password field, expand the Appearance section and select true from the Secret dropdown list.

13. To handle processing of the values for the two input fields, perform these steps for each field:
   
a. In the Structure window, select one of the input fields (for example, select the af:inputText - Username node), and then in the Property window click the Property Menu dropdown menu next to the Value field and choose Expression Builder.

   b. In the Expression Builder, expand ADF Managed Beans and expand your login bean, and then select the expression value corresponding to your bean's handler method.

   For example, if you selected the username input field in the Structure window, then you would select username from the Expression Builder dialog, as shown in Figure 47-22.

   ![Figure 47-22 username Selection in Expression Builder Dialog](image)

   c. Click OK.

   The expression shown in the Property window binds the field to the managed bean you created for the login page. For example, for the username input field, the expression is similar to #{loginPageBean.username} as shown in Figure 47-23.

   ![Figure 47-23 username Value in Property Window](image)
14. From the Components window, from the Layout panel, drag a Panel Border Layout and drop it inside the footer node of the af:panelBox node, as shown in Figure 47-24.

![Figure 47-24 Login Page Structure with Panel Border Layout](image)

15. In the JSP/HTML visual editor, delete the panel border layout facets labeled End, Top, and Bottom. Leave only the Start facet.

16. In the Structure window, expand Panel Border Layout facets and select the start node, and then from the Components window drag and drop a Button.

17. In the Property window, enter Login in the button component's Text field.

18. To handle processing of the login button action, perform these steps.
   a. In the Structure window, select af:button under the start node, and then in the Property window, click the Property Menu dropdown menu next to the Action field and choose Expression Builder.
   b. In the Expression Builder, expand ADF Managed Beans and expand your login bean, and then select the expression value corresponding to your login method.
      
      For example, if you created a method in the login bean named doLogin(), then you would select doLogin in the Expression Builder dialog.
   c. Click OK.

      The expression shown in the Property window binds the button to the managed bean you created for the login page. For example, for the login button, the expression is similar to #{loginPageBean.doLogin} as shown in Figure 47-25.

![Figure 47-25 login Action in Property Window](image)

19. Save the page.
47.7.2.3 Ensuring That the Login Page Is Public

Because the application is secured by ADF Security, all web pages defined within bounded task flows and any web page defined by an ADF page definition will be inaccessible by default. Since all users must be allowed to log on, the login page should remain publicly accessible, and thus you should add no databound components to the page. As long as the login page uses no databound components, then it will be accessible by default.

No further steps are required to ensure that the container will always redirect to the defined authentication point before allowing access to the page (which in this case is the authentication page).

47.7.3 How to Ensure That the Custom Login Page's Resources Are Accessible for Explicit Authentication

When you run the ADF Security wizard and choose the ADF Authentication option (because you do not want to enable ADF authorization) and your application uses a custom login page or a custom error page, you may need to edit the default Java EE security constraint added to the web.xml file by ADF Security. As shown in the following example, the default URL pattern (/*) defined in the allPages security constraint covers everything under the Java EE application root, meaning that the resource files (such as images, style sheets, or JavaScript library) used by the login page are also included.

```xml
<security-constraint>
  <web-resource-collection>
    <web-resource-name>allPages</web-resource-name>
    <url-pattern>/*</url-pattern>
  </web-resource-collection>
  <auth-constraint>
    <role-name>valid-users</role-name>
  </auth-constraint>
</security-constraint>
```

If the pages you create use resources, such as images, CSS files, or JavaScript libraries, the default allPages security constraint in the web.xml file will prevent those resources from loading at runtime. To allow your application to display those resources, you should save the resources in a folder of their own and then edit the allPages security constraint so that the resources folder is not contained in the URL pattern.

Note that this resource issue does not apply when you run the ADF Security wizard and choose the ADF Authentication and Authorization option (the default). Specifically, in that case, the default generated constraint is on the ADF Authentication servlet and the constraint (/adfAuthentication) excludes any resource files.

47.7.4 How to Create a Public Welcome Page

Because web applications are generally secured, there is always a need for a starting point or home page for unauthenticated users. To create this public welcome page, you create an ADF Faces page to act as the entry point for the application, which contains links to other pages within the application. However, only links to public pages should be rendered to unauthenticated users and, conversely, links to secured pages should be rendered only after the user has logged in and has the appropriate privileges to view the target page.
47.7.4.1 Ensuring That the Welcome Page Is Public

After you have created a regular ADF Faces page, the page will, by default, be public and accessible by unauthenticated users. If, however, you have associated the welcome page with an ADF resource, for example, by dropping databound ADF Faces components into the welcome page using the Data Controls panel, then ADF Security will secure the page by default. You can make any ADF resource publicly accessible using the overview editor for security policies to grant a view privilege on the resource to the provided anonymous-role. For details about the anonymous-role, see, What Happens When You Make an ADF Resource Public.

47.7.4.2 Adding Login and Logout Links

You can add login and logout links to your public welcome page so that users can explicitly log in and out while they are in the application. While Java EE container-managed security supports the concept of authentication when accessing a secured resource, there is no standard way to log out and stay within a secured application. However, it is a common practice in web applications to allow the user to stay on the same page if that page is public or to return the user to the welcome page if that page is secured. While adding the login and logout links to each page would let the user end their login session anywhere within the application (and return to the welcome page), having these links on the welcome page enables users to explicitly authenticate on entering the application.

For example, you can create an ADF Faces panel group with three components, including an output text area, an image, and login/logout links. To render the appropriate login or logout link, you can use an EL expression that evaluates the user's authentication status. Specifically, you can use securityContext.authenticated to access the ADF security context, as shown in the following example. The expression evaluates to true or false and, in this example, the result determines which login/logout image and link to display. As the following example shows, the link triggers the logon and logoff methods of the security bean.

```
<af:panelGroupLayout inlineStyle="width:100%; height:15px;" id="ptpgl3">
    <af:spacer width="7" height="10" id="pts2"/>
    <af:outputText value="Welcome #{securityContext.userName}!" inlineStyle="font-weight:bold; width:100px" id="ptot2"
                rendered="#{securityContext.authenticated}"/>
    <af:image source="#{securityContext.authenticated ? '/images/lock.gif' : '/images/key.gif'}" id="pti2" inlineStyle="width:16px; height:16px;" shortDesc="switchable icon"/>
    <af:link text="Logon" id="l1" action="#{securityBean.logon}" rendered="#{!securityContext.authenticated}"/>
    <af:link text="Logoff" id="l2" action="#{securityBean.logoff}" rendered="#{securityContext.authenticated}"/>
    <f:facet name="separator">
```

Best Practice:

When the user presses Ctrl-N or Ctrl-T to open a new browser window or tab and no welcome page is defined in the application's web.xml file, the browser will display a 403 or 404 error. To prevent this error, you must specify a welcome page definition in the application's web.xml file. You can create this definition when you run the Configure ADF Security wizard. For details about running the wizard, see How to Enable ADF Security.
The security bean that implements the logon and logoff methods may use the ADF AuthenticationService API to protect the application from malicious redirects. This achieves the same level of protection as invoking the ADF authentication servlet with null success_url and end_url parameters that the web.xml file whitelists, but is considered a best practice alternative to handling navigation with task flows. For more details about redirects, see How to Redirect a User After Authentication.

As an alternative to rendering the link directly within a page, you can create a login link component with the login and logout links that you can add to a page template, as described in How to Create a Login Link Component and Add it to a Public Web Page for Explicit Authentication.

47.7.4.3 Hiding Links to Secured Pages

Since an anonymous user should not have access to any secured pages, any navigation component on the welcome page that points to a secured page should be hidden from view based on the following two criteria:

- Is the user authenticated with a known user identity?
- Does the specified user identity have permission to view the target?

If either of these criteria has not been met, the rendered attribute of any navigation component on a public page that points to a secured resource must have its rendered attribute set to false, thus hiding it from the anonymous user. To enforce these rules within your welcome page, see Using Expression Language (EL) with ADF Security.

47.7.5 How to Redirect a User After Authentication

When you have chosen to implement implicit authentication, after the user accesses a secured web page and logs in, the ADF authentication servlet will redirect back to the original page that initiated the login request. With ADF Security authentication enabled, the ADF automatically passes on the session map the original page as the ADF authentication success_url parameter. Typically, this is the desired behavior.

Additionally, when you have chosen to implement implicit authentication, you can protect the Fusion web application from malicious redirects by specifying the success_url parameter as an init-param element within the web.xml file. However, because the ADF authentication servlet automatically passes the original page as the success_url parameter, which supersedes any web.xml setting, in practice the only scenario in which an init-param setting in web.xml takes effect is when the user explicitly types the adfAuthentication URL into the browser.

However, when you choose to implement explicit authentication and display an explicit login link in your page, the ADF Security framework is not able to determine the originating page. In this case, your login link ensures the ADF Authentication servlet redirects to the desired page after authentication by passing the view activity name of the web page as the servlet success_url parameter, as shown in the following example.

```
<af:link text="Login" destination="/adfAuthentication?success_url=/faces/viewactivityname"/>
```

Best Practice:
For explicit authentication, to ensure that the Fusion web application handles the ADF authentication redirect as an ADF Controller navigation event, specify the redirect target by its view activity name. Specifically, without specifying a view activity as the redirect target, command components, such as the af:button component, will always return to the original page after login. Passing the view activity name as the redirect target of the ADF authentication servlet success_url and end_url parameters ensures the application handles navigation using control flow rules in all cases.

In the case of explicit authentication, following the best practice of defining the success_url with a task flow view activity name protects the Fusion web application from malicious redirects by ensuring the ADF authentication servlet ignores any adfAuthentication URL that a user may attempt to type into the browser. Alternatively, when a task flow activity is not convenient, your application can use the AuthenticationService API to implement login and logout methods that handle the redirect in a secure way. For more information about using the API in a security bean, see What You May Need to Know About Redirecting to a Different Host Server.

In cases where the user is authenticated but not authorized to view a web page, you can redirect the ADF authentication servlet to an error page in your application. Error handling in Fusion web applications is under the control of the ADF Controller exception handler unless you have created an application that does not use a task flow in its design. For example, in an unbounded task flow, where you have defined an unbounded task flow with a top-level welcome page and a browse page (secured through its ADF page definition), you would see an error page from the application, named authorizationErrorPage.jspx, specified in the adfc-config.xml file, as shown in the following example.

```xml
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <exception-handler>authorizationErrorPage</exception-handler>
  <view id="welcomePage">
    <page>/welcomePage.jspx</page>
  </view>
  <view id="browse">
    <page>/browse.jspx</page>
  </view>
  <view id="authorizationErrorPage">
    <page>/authorizationErrorPage.jspx</page>
  </view>
  <control-flow-rule>
    <from-activity-id>welcomePage</from-activity-id>
    <control-flow-case>
      <from-outcome>goToSecuredPage</from-outcome>
      <to-activity-id>browse</to-activity-id>
    </control-flow-case>
  </control-flow-rule>
</adfc-config>
```

For details about how to specify an error page as a view activity for the ADF Controller exception handler, see Handling Exceptions in Task Flows.

In cases where the user is not authenticated and an authorization failure occurs, the framework redirects to the ADF authentication servlet, which in turn triggers a Java EE constraint that prompts for login. In this case, container-managed security relies on the login page and error page that you specify in the login-config element of the web.xml file.
If you create a Fusion web application without utilizing task flows, then you can specify an <init-param> setting in web.xml for the ADF binding filter, as shown in the following example. In this case, when no task flow is present in the application, page authorization checking is handled by the ADF binding filter, and the unauthorizedErrorPage parameter will be passed to the ADF binding request handler.

Note:
The unauthorizedErrorPage parameter feature is provided for compatibility with previous releases where ADF Controller was not available. In Fusion web applications, when you need to redirect users to an error page, you use the task flow exception handler to specify the error page, as shown in the previous example.

```xml
<filter>
  <filter-name>adfBindings</filter-name>
  <filter-class>oracle.adf.model.servlet.ADFBindingFilter</filter-class>
  <init-param>
    <param-name>unauthorizedErrorPage</param-name>
    <param-value>faces/authorizationErrorPage.jspx</param-value>
  </init-param>
</filter>
```

47.7.6 How to Trigger a Custom Login Page Specifically for Implicit Authentication

When you have chosen to implement implicit authentication to allow users to access protected resources (which may be by direct URL access or by navigating to an ADF Security protected resource), the ADF Security authentication servlet initiates the Java EE container to display the login form configured in the web.xml file. For implicit authentication, when you have customized the default, wizard-generated login form to use ADF Faces components, you must modify the URL pattern for the servlet mapping to reference the ADF Faces servlet.

You can accomplish this in the Authentication Type page of the Configure ADF Security wizard when you configure ADF Security, or in the web.xml file directly. If you have already run the Configure ADF Security wizard, you can use the following procedure to confirm that the web.xml file has been updated as described.

When you have chosen to implement explicit authentication and have created a public page to allow users to login to access protected resources, the login form you create will not be triggered by ADF Security. In the explicit authentication scenario, you do need to configure the web.xml file.

Note:
Configuring the web.xml file with the login page application path when your application implements explicit authentication programmatically, as described in Creating an ADF Faces-Based Login Page Specifically for Explicit Authentication, may produce unpredictable results and login may fail. Only modify the web.xml file when you are implementing implicit authentication and you have created a form that relies on the j_security_check action, as does the default, wizard-generated login form.
Before you begin:

It may be helpful to have an understanding of the login page. For more information, see How to Create a Login Page Specifically for Explicit Authentication.

To reference an ADF Faces login page for implicit authentication:

1. In the Applications window, expand WEB-INF and double-click web.xml.

2. In the overview editor for the web.xml file, click the Security navigation tab.

3. In the Security page, expand the Login Authentication section, and set the login page to include a reference to the ADF Faces servlet such that the login page can be part of the ADF Faces lifecycle /faces/ADFlogin.jspx page.

   When you add a page using the file browser, the path entered in the web.xml file will not specify /faces. Modify the entry so that the path references the servlet mapping path for the ADF Faces servlet. For example, if the URL pattern specified by the mapping is /faces/*, then your path should look like /faces/yourpage.jspx, as shown in Figure 47-26.

   *Figure 47-26   Adding a Reference to the Faces Servlet in the Login Configuration*

47.7.7 How to Ensure That the Redirect Destination Page is Available

When the ADF authentication servlet directs the user to login, it puts the redirect destination defined by the success_url on the Session map. However, in the case where the session times out before the user has authenticated, the Session map looses the value of success_url and the application looses the ability to navigate to the destination page.

To ensure the login redirect destination is always available to the application, you can define the success_url parameter as a task flow navigation outcome rule or you can define it statically when you run the Configure ADF Security wizard as a single whitelisted page that will appear in the web.xml file.

Because the web.xml file must be defined prior to deployment, the Fusion web application supports an alternative, dynamic approach to configuring the redirect URL success_url parameter that involves defining connection reference values. These values may also be configured in connections.xml file directly.

To use the connections.xml file as a persistence store for the ADF authentication servlet redirect destination:

1. In the web.xml file, add the init-param named oracle.adf.share.security.authentication.connections to the ADF authentication servlet definition and specify the param_value as the connection reference name that appears in the connections.xml file, located in the adf/META-INF folder, as the following example shows.

   `<init-param>
     <param-name>oracle.adf.share.security.authentication.connections</param-name>
     <param-value>connection-reference-name</param-value>
   </init-param>`
2. In the connections.xml file, define the success_url and, optionally, end_url in the named connection reference, as the following example shows.

```xml
<References xmlns="http://xmlns.oracle.com/adf/jndi">
  <Reference name="my_connection_name"
    className="oracle.adf.share.security.authentication.AuthenticationConnection"
    xmlns="">
    <Factory className="oracle.adf.share.security.authentication.AuthenticationConnection"/>
    <RefAddresses>
      <StringRefAddr addrType="success_url">
        <Contents>
          http://localhost:port/context_root/faces/welcomePage</Contents>
      </StringRefAddr>
      <!-- end_url for logout -->
      <StringRefAddr addrType="end_url">
        <Contents>
      </StringRefAddr>
    </RefAddresses>
  </Reference>
</References>
```

Note that the destination URL may omit the host name, port number, and context root, when redirecting the application to the current request host, port, and context root. In this case, the URL is specified as /faces/pagename, where /faces loads the page in the context of ADF Faces and supports pages designed with ADF Faces components.

At runtime, if the redirect URL is not on Session map, the ADF authentication servlet gets the connection name from init-param named oracle.adf.share.security.authentication.connections to lookup the connection from connections.xml file. If no connection is named or if success_url (login) or end_url (logout) are not in connections.xml, then the ADF authentication servlet will check if success_url or end_url is defined in the web.xml.

**47.7.8 What You May Need to Know About Redirecting to a Different Host Server**

During logout it may be necessary to redirect the user to an arbitrary web page or host server that differs from the originating server of the Fusion web application. In this scenario, the application should be protected from a malicious redirect by ensuring the destination page URL is not placed by the application on the Request and will instead use the Session map. To accomplish this, a best practice is to block passing ADF redirect parameters on the browser URL by adding the servlet init-param element disable_url_param set to true to the ADF authentication servlet definition in the web.xml file as this example shows.

```xml
<servlet>
  <servlet-name>adfAuthentication</servlet-name>
  <servlet-class>
    oracle.adf.share.security.authentication.AuthenticationServlet
  </servlet-class>
  <init-param>
    <param-name>oracle.adf.share.security.authentication.connections</param-name>
    <param-value>my_connection_name</param-value>
  </init-param>
  ... 
</servlet>
```
Legacy applications that were built before ADF enforced passing the redirect parameters on the Session map that would otherwise expose the parameters on the browser URL Request should not set the `disable_url_param` to `true` and should instead consider implementing a security bean using the ADF interface `oracle.adf.share.security.AuthenticationService` to handles ADF-specific login and logout methods by placing the target destination on the Session map.

The following example illustrates how to use the `logout()` method of the `AuthenticationService` interface. This method will internally put the passed in URL on the Session map and will ignore the `end_url` parameter that might explicitly be set on the URL by a user. Similarly, the `login()` method places the login URL destination on the Session map. When you need logout to redirect to a web page on a different server, your method implementation may pass the URL of the desired web page and still be protected from a malicious redirect.

```java
import javax.faces.context.ExternalContext;
import javax.faces.context.FacesContext;
import javax.servlet.http.HttpServletRequest;
import javax.servlet.http.HttpServletResponse;
import oracle.adf.share.security.AuthenticationService;
import oracle.adf.share.security.authentication.AuthenticationServiceUtil;

public class SecurityBean {
    public SecurityBean() {
        super();
    }

    public boolean isAuthenticated() {
        ExternalContext ectx = FacesContext.getCurrentInstance().getExternalContext();
        return ectx.getUserPrincipal() != null;
    }

    public void logon() {
        if (!isAuthenticated()) {
            FacesContext ctx = FacesContext.getCurrentInstance();
            AuthenticationServiceUtil.getAuthenticationService().login("/faces" +
                      ctx.getRootView().getViewId(), null, null);
        }
    }
}
```
public void logoff() {
    if (isAuthenticated())
    {
        AuthenticationServiceUtil.getAuthenticationService().
        logout("/faces/index", null);
    }
}

An alternative to the programmatic approach handles placing the destination URL on
the Session map by invoking the ADF authentication servlet in an explicit link with
null value success_url and end_url parameters. In this case, the ADF
authentication servlet will try to obtain the redirect values from the web.xml file (or
the connections.xml file) and will ignore any values that a user might attempt to
enter on the URL. This approach requires configuring the ADF authentication servlet
definition in the web.xml by specifying an init-param element for the
success_url and end_url parameters. In effect, this is a declarative approach that
results in a whitelist with a single destination for login and logout redirects.

47.7.9 What You May Need to Know About Fusion Web Application Logout and Browser
Caching

When basic type authentication is in effect as specified in the Fusion web application's
web.xml file, the browser caches authentication credentials. This is a known issue
with basic authentication that re-authenticates users after the logout redirect is
performed by the ADF authentication servlet. In this scenario, in order to complete the
logout session and prevent users from accessing resources, it is necessary to close the
browser and restart a new browser session.

To ensure the ADF application completes logout and prevents a user from being able
to access resources after logout, use form-based authentication instead of basic
authentication. You can select form-based authentication when you run the Configure
ADF Security wizard, as described in How to Enable ADF Security.

47.7.10 What You May Need to Know About IBM WebSphere Application Server

When you deploy your application to IBM WebSphere application servers and use the
same machine to log into the WebSphere administrative console, your application may
display the name of the user logged into the administrative console, instead of the
name of the user who logs into the application. Normally, an expression that tests for
the authenticated user like #{securityContext.authenticated ?
securityContext.userName : ""} should display the name of the user who logs
into the application. However, the administration user's name is displayed on IBM
WebSphere application servers when the application is running in Mozilla Firefox,
where the session ID is shared across all browsers on the same machine. This behavior
is not observed when running on Oracle WebLogic Server or when running the
application in Microsoft Internet Explorer.

47.7.11 What You May Need to Know About Displaying Error Pages in Internet Explorer

When you enable ADF Security to display a custom error page, any HTTP errors that
the application generates in response to a request to view a page, should result in the
error page being displayed. However, in certain versions of Internet Explorer, the
browser will display either the custom error page or an error message built into
Internet Explorer. If Internet Explorer displays only an error message you can disable
the option to display error message numbers in the Advanced settings of the Internet Options dialog. In Internet Explorer 10, this option is enabled by default. You should disable **Show friendly HTTP error messages** when you want to display a custom error page that you enabled with the Configure ADF Security wizard.

To ensure custom error pages display in Internet Explorer 10:

1. In Internet Explorer toolbar, click the **Tools** button.
2. In the Internet Options dialog, click the **Advanced** tab.
3. In the Advanced tab, scroll and locate **Show friendly HTTP error messages**.
4. Click the option to disable it and click **OK**.

**47.8 Testing Security in JDeveloper**

Integrated WebLogic Server enables you to run the application directly within JDeveloper and determine whether or not to migrate security objects, including the application policies, users, and credentials that your application defines. By default, all security objects are migrated to Integrated WebLogic Server each time you run the application.

**47.8.1 How to Configure, Deploy, and Run a Secure Application in JDeveloper**

JDeveloper is configured by default to deploy the security objects from your application repositories to Integrated WebLogic Server each time you run the application. You can change this behavior by selecting security deployment options in the Application Properties dialog to:

- Decide whether to overwrite the domain-level policies with those from the application **jazn-data.xml** file
- Decide whether to overwrite the system credentials from the application's **cwallet.sso** file

The **cwallet.sso** file (located in JDeveloper in the Application Resources panel of the Applications window under the **Descriptors-META-INF** node) stores credentials as securely kept objects that are presented to the authentication provider to be matched against identities. The file is encrypted and cannot be browsed or edited within JDeveloper. At design-time, different components make use of the **cwallet.sso** file and are responsible for creating the necessary credentials in it.

- Decide whether to migrate the identity store portion of the **jazn-data.xml** file to the domain-level identity store

If you make no changes to the deployment settings, each time you run the application, JDeveloper will overwrite the domain-level security policies and system credentials. Additionally, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. However, if you prefer to run the application without updating the existing security objects in Integrated WebLogic Server, you have this option.

Before you begin:

It may be helpful to have an understanding of using Integrated WebLogic Server. For more information, see **Testing Security in JDeveloper**.
To configure security deployment and run the application in JDeveloper:

1. In the main menu, choose **Application** and then **Secure > Configure Security Deployment**.

2. In the Application Properties dialog, in the Deployment page, in the **Security Deployment Options** section, select the security objects that you want to deploy to Integrated WebLogic Server.

   By default, each time you run the application, JDeveloper will overwrite the application policies and system credentials at the domain level with those from the application. If you prefer not to overwrite either of these repositories, deselect **Application Policies** or **Credentials**. When deselected, JDeveloper will merge only new policies or credentials into the domain-level stores.

   By default, each time you run the application, JDeveloper will migrate new user identities you create for test purposes and update existing user passwords in the embedded LDAP server that Integrated WebLogic Server uses for its identity store. You can disable migration of the application identity store by deseleting **Users and Groups**.

3. Click **OK**.

4. In the Applications window, right-click the user interface project that contains the secured web pages and choose **Run**.

   When you choose **Run** on the user interface project, JDeveloper will run the application using the default run target you configured for the project. For example, you can configure a task flow activity as the run target to start your application. To configure the default run target, see **Testing Task Flows**.

   The Create Default Domain dialog appears the first time you run the application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

### 47.8.2 What Happens When You Configure Security Deployment Options

When you run the application using Integrated WebLogic Server, JDeveloper migrates the security policies and credentials to the domain level based on security deployment configuration settings specified in the Application Properties dialog. During the deployment process, JDeveloper updates the `weblogic-application.xml` file that it adds to the deployment archive file with the Application Properties settings, as shown in the following example. Note that these settings are not added to the `weblogic-application.xml` file in the application source directory and thus are not visible.

```xml
<application-param>
    <param-name>jps.credstore.migration</param-name>
    <param-value>OVERWRITE</param-value>
</application-param>
<application-param>
    <param-name>jps.policystore.migration</param-name>
    <param-value>OVERWRITE</param-value>
</application-param>
```

The **OVERWRITE** value allows you to modify the security policies and credentials in your application and redeploy either to Oracle WebLogic Server running in
development mode or to Integrated WebLogic Server (set up to run in development mode by default).

**Note:**

When you eventually deploy to a production environment, the migration settings in the `weblogic-application.xml` file are ignored; it would be considered a security vulnerability to allow existing policies and credentials to be overwritten. For information about deploying to a production environment, see Preparing the Secure Application for Deployment.

JDeveloper also updates the `weblogic-application.xml` file with OPSS lifecycle listeners, as shown in the following example. To initiate the migration process before the application runs, the lifecycle listeners observe the migration settings for policies and credentials and overwrite the security objects at the domain level.

```xml
<listener>
  <listener-class>
    oracle.security.jps.wls.listeners.JpsApplicationLifecycleListener
  </listener-class>
</listener>

<listener>
  <listener-class>
    oracle.security.jps.wls.listeners.JpsAppVersionLifecycleListener
  </listener-class>
</listener>
```

During the migration process, JDeveloper maps the Oracle Platform Security Services (OPSS) application role member classes to the Integrated WebLogic Server member classes and migrates the users to WebLogic Server identity store `users` and migrates the roles to WebLogic Server identity store groups. In Oracle WebLogic Server, `users` is an implicit group equivalent to OPSS `authenticated-role`.

Identity store migration is not controlled by the application lifecycle listener settings in the `weblogic-application.xml` file. Instead, an Oracle WebLogic Mbean handles migrating the identities when running in Integrated WebLogic Server or when deploying from JDeveloper. If the user already exists, the Mbean will not migrate the entire user definition. Only the user password will be updated.

### 47.8.3 How to Use the Built-In test-all Application Role

When you run the Configure ADF Security wizard, you can enable the option to add the `test-all` application role to the policy store in the `jazn-data.xml` file. When you enable this option, you also specify the scope of grants to the application role for your application:

- **Select Grant to Existing Objects Only** when you want JDeveloper to grant view rights to the `test-all` application role and you want this policy to apply to all the ADF task flows and web pages that appear in your user interface project at the time you run the wizard.

- **Select Grant to All Objects** when you want JDeveloper to grant view rights to the `test-all` application role and you want this policy to apply to all existing and future ADF task flows and web pages that developers will create in the user interface project. Note that the wizard displays the option **Grant to New Objects**
after you run the wizard the first time with the **Grant to All Objects** option selected.

After you run the wizard, the `test-all` role appears in the `jazn-data.xml` file and is visible in the overview editor for security policies. You will not need to populate the `test-all` role with test users since the wizard assigns the built-in application role `anonymous-role` to the `test-all` role. In this case, all users will automatically have the `anonymous-role` principal and will be permitted to access the application.

---

**Note:**

Before you deploy the application, you must remove all occurrences of the `test-all` role from the policy store, as described in *How to Remove the test-all Role from the Application Policy Store*. This will prevent unauthorized users from accessing the web pages of your application.

---

You can rerun the wizard and disable automatic grants at any time. Once disabled, new ADF task flows and web pages that you create will not utilize the `test-all` role and will therefore require that you define explicit grants, as described in *Defining ADF Security Policies*.

### 47.8.4 What Happens at Runtime: How ADF Security Handles Authentication

When you test the application in JDeveloper using Integrated WebLogic Server, the identity store is migrated to the embedded LDAP server, with information stored in Oracle Internet Directory.

**Figure 47-27** illustrates the authentication process when users attempt to access an ADF bounded task flow or any web page containing ADF bindings (such as `mypage.jspx`) without first logging in. Authentication is initiated implicitly because the user does not begin login by clicking a login link on a public page. In the case of the secured page, no grants have been made to the anonymous user.
In Figure 47-27, the implicit authentication process assumes that the resource does not have a grant to anonymous-role, that the user is not already authenticated, and that the authentication method is Form-based authentication. In this case, the process is as follows:

1. When the bounded task flow or web page (with ADF bindings) is requested, the ADF bindings servlet filter redirects the request to the ADF authentication servlet (in the figure, Step 1), storing the logical operation that triggered the login.

2. The ADF authentication servlet has a Java EE security constraint set on it, which results in the Java EE container invoking the configured login mechanism (in the figure, Step 2). Based on the container's login configuration, the user is prompted to authenticate:
   a. The appropriate login form is displayed for form-based authentication (in the figure, Step 2a).
   b. The user enters their credentials in the displayed login form (in the figure, Step 2b).
   c. The user posts the form back to the container's j_security_check() method (in the figure, Step 2c).
   d. The Java EE container authenticates the user, using the configured pluggable authentication module (in the figure, Step 2d).
3. Upon successful authentication, the container redirects the user back to the servlet that initiated the authentication challenge, in this case, the ADF authentication servlet (in the figure, Step 3).

4. On returning to the ADF authentication servlet, the servlet subsequently redirects to the originally requested resource (in the figure, Step 4).

Whether or not the resource is displayed will depend on the user’s access rights and on whether authorization for ADF Security is enforced, as explained in What Happens at Runtime: How ADF Security Handles Authorization.

Figure 47-28 illustrates the explicit authentication process when the user becomes authenticated starting with the login link on a public page.

Figure 47-28  ADF Security Explicit Authentication

In an explicit authentication scenario, an unauthenticated user (with only the anonymous user principal and anonymous-role principal) clicks the Login link on a public page (in the figure, Step 1). The login link is a direct request to the ADF authentication servlet, which is secured through a Java EE security constraint in the web.xml file.

In this scenario, the current page is passed as a parameter to the ADF authentication servlet. As with the implicit case, the security constraint redirects the user to the login page (in the figure, Step 2). After the container authenticates the user, as described in Step a through Step d in the implicit authentication case, the request is returned to the ADF authentication servlet (in the figure, Step 3), which subsequently returns the user to the public page, but now with new user and role principals in place.

47.8.5 What Happens at Runtime: How ADF Security Handles Authorization

When ADF authorization is enabled, the ADF bounded task flows and web pages outside of a task flow that have an ADF page definition will be secure by default. When a user attempts to access these web pages, ADF Security checks to determine whether the user has been granted access in the policy store. If the user is not yet authenticated, and the page is not granted to the anonymous-role, then the
application displays the login page or form. If the user has been authenticated, but
does not have permission, a security error is displayed. If you do not configure the
policy store with appropriate grants, the pages will remain protected and therefore
stay unavailable to the authenticated user.

Figure 47-29 illustrates the authorization process.

Figure 47-29  ADF Security Authorization

The user is a member of the application role staff defined in the policy store. Because
the user has not yet logged in, the security context does not have a subject (a container
object that represents the user). Instead, Oracle Platform Security Services provides
ADF Security with a subject with the anonymous user principal (a unique definition
of the user) and the anonymous-role principal.

With the anonymous-role principal, typically the user would be able to access only
pages not defined by ADF resources, such as the public.jsp page, whereas all pages
that are defined either by an ADF task flow or outside of a task flow using an ADF
page definition file are secure by default and unavailable to the user. An exception to
this security policy would be if you were to grant anonymous-role access to ADF
resources in the policy store. In this case, the user would not be allowed immediate
access to the page defined by an ADF resource.

When the user tries to access a web page defined by an ADF resource, such as
mypage.jsp (which is specified by an ADF page definition, for example), the ADF
Security enforcement logic intercepts the request and because all ADF resources are
secured by default, the user is automatically challenged to authenticate (assuming that
the anonymous-role is not granted access to the ADF resource).

After successful authentication, the user will have a specific subject. The security
enforcement logic now checks the policy store to determine which role is allowed to
view mypage.jsp and whether the user is a member of that role. In this example for
mypage.jsp, the view privilege has been granted to the staff role and because the
user is a member of this role, they are allowed to navigate to mypage.jsp.

Similarly, when the user tries to access secpage.jsp, another page defined by ADF
resources, for which the user does not have the necessary view privilege, access is
denied.
Users and roles are those already defined in the identity store of the resource provider. Application roles are defined in the policy store of the jazn-data.xml file.

47.9 Preparing the Secure Application for Deployment

After testing in JDeveloper using Integrated WebLogic Server, you will eventually want to deploy the application to a standalone server. Initially, the server you target will be your staging environment where you can continue development testing using that server’s identity store before deploying to the production environment. Thus, you will typically not migrate the test users you created to run with Integrated WebLogic Server. The steps you perform to migrate credentials (in the cwallet.sso file) and security policies (in the jazn-data.xml file) to standalone Oracle WebLogic Server will depend on the configured mode of the target server and whether you deploy using JDeveloper or a tool outside of JDeveloper.

Note:
For details about deploying from JDeveloper to a development environment, see Deploying Fusion Web Applications.

When the target server is configured for development mode, you can deploy directly from JDeveloper. In this case, JDeveloper automatically handles the migration of the policy store, system credentials, and identity store (users and groups) as part of the deployment process. Application security deployment properties are configured by default to allow the deployment process to overwrite the domain-level policy store and the system credentials. Additionally, the identity store deployment property is configured by default to migrate the identity store consisting of your test users. You can change this default deployment behavior in the Application Properties dialog, as described in How to Configure, Deploy, and Run a Secure Application in JDeveloper.

Note:
Note that migration of system credentials to Oracle WebLogic Server running in development mode will be performed only if the target server is configured to permit credential overwrite. For details about configuring Oracle WebLogic Server to support overwriting of system credentials, see the "Configuring the OPSS Security Store" chapter in Securing Applications with Oracle Platform Security Services.

When the target server is configured for production mode, you typically handle the migration task outside of JDeveloper using tools like Oracle Enterprise Manager. For details about using tools outside of JDeveloper to migrate the policy store to the domain-level in a production environment, see the "Configuring the OPSS Security Store" chapter in Securing Applications with Oracle Platform Security Services. Note that Oracle WebLogic Server running in production mode does not support the overwriting of system credentials under any circumstances.

Before you deploy the application, you will want to remove the test-all application role if you enabled the automatic grants feature in the Configure ADF Security wizard. Because the test-all role makes all ADF resources public, its presence increases the risk that your application may leave some resources unprotected. You must therefore remove the role before you migrate application-level policy store.
Additionally, when you prepare to deploy the application to Oracle WebLogic Server, you will want to remove the test identities that you created in the jazn-data.xml file. This will ensure that users you created to test security policies are not migrated to the domain-level identity store.

**Best Practice:**
If you deploy your application to the standalone environment, you must not migrate users and enterprise roles in your local identity store that are already configured for Oracle WebLogic Server. For example, if you were to deploy the identity store with the user weblogic and enterprise role Administrators, you would overwrite the default administration configuration on the target server. To ensure you avoid all possible conflicts, you can disable migration of the identity store, as described in How to Remove Test Users from the Application Identity Store.

### 47.9.1 How to Remove the test-all Role from the Application Policy Store

The overview editor for security policies provides the facility to display all resources with view grants made to ADF Security's built-in test-all role. You can use this feature in the overview editor to delete the test-all role grant and replace it with a grant to the roles that your application defines.

Alternatively, you could delete the test-all role using the overview editor for the jazn-data.xml file, by selecting the test-all role in the Application Roles page of the editor and clicking the **Delete Application Role** button. However, when you remove the test-all role this way, you will still need to create a grant to replace the ones that you delete. Because the overview editor lets you combine both of these tasks, the following procedure describes its usage.

**Before you begin:**

It may be helpful to have an understanding of the Oracle WebLogic Server. For more information, see Preparing the Secure Application for Deployment.

To remove the test-all application role and substitute custom application roles:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.

2. In the Resource Grants page of the overview editor for security policies, select **Task Flow** from the **Resource Type** dropdown list and then select the **Show task flows with test-all grants only** checkbox to view the list of task flows with grants to this built-in role.

   If no grant exists for the test-all role, then the **Resources** list in the overview editor will appear empty. The test-all role is defined only when enabled in the Configure ADF Security wizard. If it is enabled, you will see those task flows with test-all grants listed, as shown in Figure 47-30.
3. In the Resources column, select the first task flow in the list.

4. In the Granted to column, select test-all and click the Remove Grantee icon.

5. In the Granted to column, click the Add Grantee icon and choose Add Application Role and then use the Select Application Roles dialog to add the desired role.

6. Repeat these steps to remove the test-all role and substitute your own application role for all remaining task flows.

7. In the Resource Grants page of the overview editor, select Web Page from the Resource Type dropdown list and repeat these steps to remove the test-all role for all web pages and their ADF page definitions.

8. With the Show task flows/web pages with test-all grants only checkbox selected, verify that the overview editor displays no resources with test-all grants.

### 47.9.2 How to Remove Test Users from the Application Identity Store

The standalone Oracle WebLogic Server that you will deploy to will have its own identity stored already configured. To ensure that you do not migrate test users and enterprise role groups you created in JDeveloper to the domain level, you should remove the test user realm from the jazn-data.xml file.

Alternatively, if you are deploying from JDeveloper, you can disable the migration of users and groups by deselecting the Users and Groups option in the Application Properties dialog, as described in How to Configure, Deploy, and Run a Secure Application in JDeveloper.

**Before you begin:**

It may be helpful to have an understanding of the Oracle WebLogic Server. For more information, see Preparing the Secure Application for Deployment.

To remove test users and enterprise role groups from the identity store:

1. In the main menu, choose Application and then Secure > Users.

2. In the editor window for the jazn-data.xml file, click the Source tab.

3. In the source for the jazn-data.xml file, click the - icon next to the `<jazn-realm>` element so the entire element appears collapsed as shown in Figure 47-31.
4. With the element selected, press **Delete** and save the file.

### 47.9.3 How to Secure Resource Files Using a URL Constraint

Resource files, including images, style sheets, and JavaScript libraries are files that the Fusion web application loads to support the individual pages of the application. ADF Security does not secure these files. Although securing such files is not a requirement for securing the web pages of the application, in some cases it may be desirable to protect resource files to fully harden your application. Please note that JavaScript files are downloaded to the browser and, as such, can be read at that time.

To serve up resource files, the ADF Faces framework relies on `org.apache.myfaces.trinidad.webapp.ResourceServlet`, which delegates to a resource loader. The Fusion web application's `web.xml` file contains a servlet mapping that maps the resource servlet to URL patterns. By default, JDeveloper uses the patterns `/adf/*` for MyFaces Trinidad Core, and `/afr/*` for ADF Faces.

Because ADF Security does not protect the resource servlet, you can protect the Java EE access paths for the resource servlet with a security constraint. To implement your own security for the resource files in the `web.xml` file, define a security constraint for the `/adflib/*`, `/adf/*` and `/afr/*` paths and assign a specific security role to them. This security constraint will require all users to be authenticated before they can access the first page of the Fusion web application.

The following example shows the security role `resource_role` and the constraint with the URL patterns mapped to this role. After you define the security role, the administrator for the target server must map this role to an Oracle WebLogic Server enterprise role (user group) or create an enterprise role with the same name (in which case no mapping is required).

```xml
<security-role>
    <description>Java EE role to map to an enterprise role. All users who will be allowed to run Fusion web app must be members of that role.</description>
    <role-name>resource_role</role-name>
</security-role>

<security-constraint>
    <web-resource-collection>
        <web-resource-name>resources</web-resource-name>
    </web-resource-collection>
    <url-pattern>/adf/*</url-pattern>
</security-constraint>
```

```xml
<security-constraint>
    <web-resource-collection>
        <web-resource-name>adflib</web-resource-name>
    </web-resource-collection>
    <url-pattern>/adflib/*</url-pattern>
</security-constraint>
```

```xml
<security-constraint>
    <web-resource-collection>
        <web-resource-name>adf</web-resource-name>
    </web-resource-collection>
    <url-pattern>/adf/*</url-pattern>
</security-constraint>
```

```xml
<security-constraint>
    <web-resource-collection>
        <web-resource-name>afr</web-resource-name>
    </web-resource-collection>
    <url-pattern>/afr/*</url-pattern>
</security-constraint>
```
47.10 Disabling ADF Security

JDeveloper allows you to disable ADF Security when you want to temporarily run the application without enforcing authorization checks against the application policy store. This will allow you to run the application and access all resources without the protection provided by existing security policies.

47.10.1 How to Disable ADF Security

To disable ADF Security at the level of your application, run the wizard and choose one of these options:

- **ADF Authentication** disables ADF authorization but leaves the ADF authentication servlet enabled. For example, you may want to run your application in JDeveloper with authorization checking against security policies temporarily disabled. This option will require the user to log in the first time a page in the application is accessed by mapping the Java EE application root "/" to the allPages Java EE security constraint that will trigger user authentication. ADF resources will not be security-aware because authorization checking is not enforced. Thus, once the user is logged in, all web pages containing ADF resources will be available to the user.

- **Remove ADF Security Configuration** disables the ADF authentication servlet and disables authorization checking on ADF resources. In this case, you can run the application with no user authentication and no security for ADF resources in place.

You may select either option with the intention of reenabling ADF Security at any time. The wizard specifically does not alter the application policy store that contains the security policies that application developers defined for ADF resources. This means that you can return to the wizard at any time, select the **ADF Authentication and Authorization** option, and reenable ADF Security against your application’s existing policy store and identity store.

Before you begin:

It may be helpful to have an understanding of disabling ADF Security. For more information, see Disabling ADF Security.

To disable ADF authorization checking:

1. In the main menu, choose Application and then Secure > Configure ADF Security.

2. In the ADF Security page, select either the ADF Authentication option or the Disable ADF Security Configuration option. Click Next.

   After you run the wizard with either of these options, the ADF resources of your user interface projects will no longer be security-aware.

3. Click Finish.
47.10.2 What Happens When You Disable ADF Security

If you run the Configure ADF Security wizard with the Remove ADF Security Configuration option selected, it removes the ADF-specific metadata in the web.xml file and adf-config.xml file, as described in Table 47-2.

Similarly, running the wizard with the ADF Authentication option selected to disable only authorization checking performs the following updates:

- Leaves the ADF-specific metadata in the web.xml file unchanged and adds the allPages security constraint.
  
  With the allPages security constraint present, users will be expected to authenticate when they first access the application.

- Sets the authorizationEnforce parameter in the <JaasSecurityContext> element of the adf-config.xml file to false, as shown in the following example.

```xml
<JaasSecurityContext
  initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
  jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext"
  authorizationEnforce="false"
  authenticationRequire="true"/>
```

The adf-config.xml file is located in the /.adf/META_INF folder of your workspace. In JDeveloper, you can locate the file in the Application Resources panel of the Applications window by expanding the Descriptors-ADF META-INF node. Note that if you view the adf-config.xml file in an editor outside of JDeveloper, you must save the workspace to see the wizard-applied changes in the file.

47.11 Advanced Topics and Best Practices

After you have completed the process of enabling ADF Security, you may want to customize your application to work with ADF Security in the user interface. For example, you can use Expression Language (EL) to render UI components in the web page based on evaluation of custom permissions that you define just for a group of UI components. Additionally, you can define methods within a managed bean to expose information, such as the user name and role membership, in your application.

47.11.1 Using Expression Language (EL) with ADF Security

You can use Expression Language (EL) to evaluate the policy directly in the UI, while the use of Java enables you to evaluate the policy from within a managed bean. ADF Security implements several convenience methods for use in EL expressions to access ADF resources in the security context. For example, you can use the EL expression and ADF Security Context API methods to determine whether the user is allowed to access a particular task flow. Good security practice dictates that your application should hide resources and capabilities for which the user does not have access. And for this reason, if the user is not allowed access to a particular task flow, you would evaluate the user's permission grant to determine whether or not to render the navigation components that initiate the task flow.

Note:
The ability to evaluate a policy is limited to the current request. For this reason, it is important to understand where the policy evaluation occurs, because evaluating the policy at anything other than the request scope can lead to unexpected results.

### 47.11.1.1 How to Evaluate Policies Using EL

The use of EL within a UI component allows for the component's attribute values to be defined dynamically, resulting in modification of the UI component at runtime. In the case of securing resources, the UI component attribute of interest is the rendered attribute, which allows you to show and hide components based on available permissions. By default, the rendered attribute is set to `true`. By dynamically changing this value based on the permission, you can set the UI component to be shown or hidden. For example, if the user has the appropriate permission, the rendered attribute should be set to `true` so that the UI component is shown. If they do not have permission, the attribute should be set to `false` and the UI component hidden from view.

To evaluate a policy using EL, you must use the ADF Security methods in the `securityContext` EL namespace. These methods let you access information in the ADF security context for a particular user or ADF resource.

Table 47-11 shows the EL expression that is required to determine whether a user has the associated permission. If the user has the appropriate permission, the EL expression evaluates to `true`; otherwise, it returns `false`.

<table>
<thead>
<tr>
<th>Expression</th>
<th>Expression action</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>{securityContext.taskflowViewable['MyTaskFlow']}</code></td>
<td>Where <code>MyTaskFlow</code> is the WEB-INF node-qualified name of the task flow being accessed. Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.</td>
</tr>
<tr>
<td><code>{securityContext.taskflowViewable ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}</code></td>
<td>Where <code>MyPagePageDef</code> is the qualified name of the page definition file associated with the web page being accessed. Returns <code>true</code> if the user has access rights. Returns <code>false</code> if the user does not have sufficient access rights.</td>
</tr>
<tr>
<td><code>{securityContext.regionViewable['MyPagePageDef']}</code></td>
<td></td>
</tr>
</tbody>
</table>

**Note:**

In the case of page permission, the value of the page definition can be specified dynamically by using late-binding EL within a managed bean, as described in What You May Need to Know About the valid-users Role.

Table 47-12 shows the EL expression that lets you get general information from the ADF security context not related to a particular ADF resource. For example, you can access the current user name when you want to display the user’s name in the user interface. You can also check whether the current user is a member of certain roles or permissions.
granted certain privileges. Your application may use this result to dynamically hide or show menus.

### Table 47-12  EL Expression to Determine User Information in the ADF Security Context

<table>
<thead>
<tr>
<th>Expression</th>
<th>Expression Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>#{securityContext.userName}</td>
<td>Returns the user name of the authenticated user.</td>
</tr>
<tr>
<td>#{securityContext.authenticated}</td>
<td>Returns true if the user is logged in. Returns false if the user is not logged in. This is useful for rendering a dynamic link for login/logout, or for rendering a &quot;Welcome, username&quot; message when the user has been authenticated. For an example that uses this expression, see Adding Login and Logout Links.</td>
</tr>
<tr>
<td>#{securityContext.userInRole['roleList']}}</td>
<td>Where roleList is a comma-separated list of role names. Returns true if the user is in at least one of the roles. Returns false if the user is in none of the roles, or if the user is not currently authenticated.</td>
</tr>
<tr>
<td>#{securityContext.userInAllRoles['roleList']}}</td>
<td>Where roleList is a comma-separated list of role names. Returns true if the user is in all of the roles. Returns false if the user is not in all of the roles, or if the user is not currently authenticated.</td>
</tr>
<tr>
<td>#{securityContext.userGrantedPermission['permission']}}</td>
<td>Where permission is a string containing a semicolon-separated concatenation of permissionClass=&lt;class&gt;;target=&lt;artifact_name&gt;;action=&lt;action&gt;. Returns true if the user has access rights. Returns false if the user does not have sufficient access rights. Note that the convenience methods taskflowViewable and regionViewable shown in Table 47-11 provide the same functionality.</td>
</tr>
</tbody>
</table>
Table 47-12  (Cont.) EL Expression to Determine User Information in the ADF Security Context

<table>
<thead>
<tr>
<th>Expression</th>
<th>Expression Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>#{securityContext.userGrantedResource['resource']}</td>
<td>Where resource is a string containing a semicolon-separated concatenation of resourceName=&lt;name&gt;;resourceType=&lt;type&gt;;action=&lt;action&gt;. Returns true if the user has access rights. Returns false if the user does not have sufficient access rights. You can use this expression to test the permission grant in the display property of a resource that is not contained in a task flow (like an ADF Faces panel or a menu item). You first create a custom resource type for the UI component that you want to protect. For more details, see How to Protect UI Components Using OPSS Resource Permissions and EL.</td>
</tr>
</tbody>
</table>
For example, as shown in Figure 47-33, to limit access to a task flow that your application displays, you would create an expression like:

```java
#{securityContext.taskflowViewable
    ['/WEB-INF/audit-expense-report.xml#audit-expense-report']}
```

In this example, the expression determines the user's access rights to view the target task flow `audit-expense-report`. If the user has the access rights, then the expression evaluates to `true` and the `rendered` attribute receives the value `true`.

**Figure 47-33  Defining EL in the Expression Builder Dialog**

![Expression Builder Dialog](image)

*Tip:* In the Expression Builder dialog, expand `Description` for additional information about any security EL method you select.

5. Click OK.

When you run the application, the component will be rendered or hidden based on the user's ability to view the target page.

### 47.11.1.2 What Happens When You Use the Expression Builder Dialog

When you use the Expression Builder to define an expression for the `rendered` attribute, JDeveloper updates the component definition in the open `.jspx` file. The component's `rendered` attribute appears with an expression that should evaluate to either `true` or `false`, as shown in the following example. In this example, the component is a navigation link with the link text `Checkout` defined by another expression. The page that contains the navigation link renders the component only when the user has sufficient rights to access the checkout task flow.
47.11.3 What You May Need to Know About Delayed Evaluation of EL

The ability to evaluate a security permission is scoped to the request. If you want to evaluate permissions to access a target page from a managed bean that is scoped to a higher level than request (for example, a global menu that is backed by a managed bean), you must implement delayed EL evaluation (late-binding). By passing in the target page as a managed property of the bean, you ensure that the EL expression is evaluated only after the required binding information is available to the managed bean. Because EL is evaluated immediately when the page is executed, placing the EL expression directly in the properties of a UI component, backed by a managed bean, would result in an out-of-scope error.

The following example shows a property (authorized) of a managed bean that returns true or false based on a user's ability to view a named target page. In this case, the _targetPageDef variable is a managed property containing the name of the target page. Within the UI, the EL expression would reference the authorized property.

```java
public boolean isAuthorized()
{
    if (_targetPageDef != null) {
        FacesContext fctx = FacesContext.getCurrentInstance();
        ADFContext adfCtx = ADFContext.getCurrent();
        SecurityContext secCtx = adfCtx.getSecurityContext();
        boolean hasPermission = secCtx.hasPermission(new RegionPermission
                                             (_targetPageDef, RegionPermission.VIEW_ACTION));
        if (hasPermission) {
            return hasPermission;
        }
        else {
            fctx.addMessage(null, new FacesMessage (
                FacesMessage.SEVERITY_WARN, "Access Permission not defined! ", null));
            return false;
        }
    }
}
```

47.11.2 How to Protect UI Components Using OPSS Resource Permissions and EL

Security expressions in the ADF Security EL namespace described in Table 47-12 let you check the user permission, authentication and role membership status before displaying UI components in your page. When you need fine-grained protection over UI components to secure functional parts of the application that are not part of task flow security or web page security, you use the EL value userGrantedResource and a resource grant that you define for a custom resource type. For instance, through a resource grant that you create for a menu item, the application may either enable or disable a Cancel Shipment menu item to limit who may perform customer order updates.

Resource grants for custom resources types rely on the ResourcePermission class, which is provided by Oracle Platform Security Services (OPSS) and packaged with the application.
You use the overview editor for security policies to create a security policy for the custom resource type. And, in your web page, you use the security expression to evaluate the user’s access rights to the UI component projected by the resource grant.

**Best Practice:**

Custom resource types in combination with the `ResourcePermission` matcher class let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user’s ability to view UI components without having to overload the built-in actions defined by the ADF resources’ permission classes. Be aware that you do not need to create custom resource types to manage access to web pages. This level of access is provided by the default ADF Security view permission that you work with in the overview editor for security policies.

To grant resource policies for a custom resource type:

1. Create the custom resource type for the UI component you want to protect.
2. Create the resource grant for the custom resource.
3. Associate the rendering of a UI component with a role’s granted resource permission.

**47.11.2.1 Creating the Custom Resource Type**

You use the Create Resource Type dialog to create a resource type for the UI component that you want to protect. JDeveloper will match your resource type definition to the OPSS permission class `oracle.security.jps.ResourcePermission`. This class allows you to specify custom actions that you can grant to functional parts of your application that are not protected by task flow security or web page security. For example, you might want to create a resource type to protect sensitive parts of the application accessed by the user through a menu UI component.

The Create Resource Type dialog lets you identify the type of resource you wish to protect (for example, the name `MenuProtection` would identify the menu UI component), a display name visible in the security policy store (for example, `Menu Protection`), and a description of how the resource type will be used in the resource grant (for example, `Resource permission to grant menu item permissions`). The dialog also lets you enter one or more custom action names that you will use to grant permission. For example, you might name the action `process` for use in a security policy that grants access to a protected menu item.

Before you begin:

It may be helpful to have an understanding of the ADF Permission class. For more information, see [How to Protect UI Components Using OPSS Resource Permissions and EL](#).

To create the custom resource type:

1. In the main menu, choose **Application** and then **Secure > Resource Grants**.
2. In the Resource Grants page of the overview editor for security policies, click **New Resource Type**.
3. In the Create Resource Type dialog, enter the name and display name that describes the UI component.

For example, to protect menu items, you might enter MenuProtection for the name and Menu Protection for the display name.

4. In the Actions list, click Add and enter the name of the actions that your permission will grant and click OK.

For example, when protecting a menu item, you might enter process to signify that permission to process the menu selection is being granted. You can enter multiple action names when you intent to grant specific actions to individual users or roles. The overview editor displays the custom permission grant, as shown in Figure 47-34.

![Figure 47-34 Creating a Custom Resource Type](image)

**47.11.2.2 Creating a Resource Grant for a Custom Resource Type**

You use the overview editor for the jazn-data.xml file to create the ADF Security policy for a custom resource. The finished source should look similar to the permission grant defined in the policy store, as shown in the following example.

```xml
<grant>
  <grantee>
    <principals>
      <principal>
        <name>AccountManagersadmin</name>
        <class>oracle.security.jps.service.policystore.ApplicationRole</class>
      </principal>
    </principals>
  </grantee>
  <permissions>
    <permission>
      <class>oracle.security.jps.ResourcePermission</class>
    </permission>
  </permissions>
</grant>
```
The <permission> target name identifies the custom resource type and name that you assigned the resource. For example, a resource name that lets users cancel shipments from a menu selection in their account might be named CancelShipment.

The actions are those that your custom resource type defines. For example, in the Menu Protection resource type defines the single action process to grant permission to process the menu selection.

Before you begin:

It may be helpful to have an understanding of the ResourcePermission class. For more information, see How to Protect UI Components Using OPSS Resource Permissions and EL.

You will need to complete this task:

Create the custom resource type, as described in Creating the Custom Resource Type.

To create the resource grant for a custom resource type:

1. In the main menu, choose Application and then Secure > Resource Grants.

2. In the Resource Grants page of the overview editor for security policies, select the custom resource from the Resource Type dropdown list.

3. In the Resources column, click the Add Resource icon.

4. In the Create Resource dialog, enter the name, display name, and description for the resource that the security policy will specifically protect and then click OK.

5. In Resource Grants page of the overview editor, in the Granted to column, click the Add Grantee icon and choose Add Application Role.

6. In the Actions column, select action that you defined for the custom resource type.

The overview editor displays the resource grant, as shown in Figure 47-35.

Figure 47-35 Creating a Grant for a Custom Resource in the Overview Editor

47.11.2.3 Associating the Rendering of a UI Component with a Resource Grant

You use the Expression Builder dialog for the UI component display property to define an EL expression that controls rendering the component. For example, to protect a menu item in an application that allows authorized users to cancel shipments, the application specifies a userGrantedResource expression on the disabled property of the menu item defined by af:commandMenuItem. As the
following example shows, the expression tests whether the user has been granted the resource type and then either displays the menu item or, when the user has not been granted the resource, disables the menu item.

```java
#{!securityContext.userGrantedResource
    ['resourceName=CancelShipment;resourceType=MenuProtection;action=process']}
```

Figure 47-36 shows how the expression appears in the Expression Builder dialog.

**Figure 47-36   Defining EL in the Expression Builder Dialog**

Before you begin:

It may be helpful to have an understanding of the ResourcePermission class. For more information, see How to Protect UI Components Using OPSS Resource Permissions and EL.

You will need to complete these tasks:

1. Create the custom resource type, as described in Creating the Custom Resource Type.
2. Create the ADF security policy using the custom permission, as described in Creating a Resource Grant for a Custom Resource Type.

To associate the rendering of a UI component with a user’s granted resource:

1. In the Applications window, double-click the page that contains the UI component that you wish to conditionally render.
2. In the visual editor for the page, select the component that is used to navigate to the secured page.
3. In the Property window, click the Property Menu dropdown menu displayed menu next to the Rendered field and choose Expression Builder.
4. In the Expression Builder, expand the **ADF Bindings - securityContext** node and select **userGrantedResource**, and then, in the **Expression** field, enter a concatenated string that defines the permission.

Enter the permission string as a semicolon-separated concatenation of resourceName=theResourceInstanceName;resourceType=customResou rceTypeName;action=actionName. For example, to protect a menu item in an application that allows authorized users to cancel shipments, you would enter an expression similar to the one shown in the following example, where the resource type for userGrantedResource identifies the resource type used in the custom resource grant.

```java
#{!securityContext.userGrantedResource
   ['resourceName=CancelShipment;resourceType=MenuProtection;action=process']}
```

In this example, the expression evaluates the permission based on the custom resource type named MenuProtection that you added to the application policy store.

5. Click OK.

### 47.11.3 How to Perform Authorization Checks for Entity Object Operations

In the Fusion web application, you can enable security for the data collection when you secure the operations of the entity object. The user must have sufficient privileges to view, update, or delete the data for the entire row set.

The `oracle.jbo.ViewCriteriaRow` API allows you to perform authorization checks for the standard operations (read, update, removeCurrentRow) at the level of entity rows. The following example shows how to use the authorization checking API, `getSecurityHints()` and `allowsOperation()`, on the entity row, to test whether the user has permission to delete data.

```java
if(row.getSecurityHints().allowsOperation("removeCurrentRow").hasPermission())
   // code for the data
else
   // display error message
```

Note that the `allowsOperation()` method expects as input the secured operation name rather than the name of the action that secures it. The operation name for deleting an entity row is `removeCurrentRow` (where delete is the action name).

When you want to perform authorization checks for the entity object that underlies data bound components in a JSF page of the Fusion web application, you can use EL expressions. For example, the following EL expression returns true if the user has been granted the permission to perform the operation specified. The `<operationName>` used in the expression must be the read, update, or removeCurrentRow operation that you enabled for the entity object.

```java
#{row.hints.allows.<operationName>}
```

Authorization checking expressions are evaluated in the context of a row collection. When you want to check entity permissions outside of the context of the row collection, you must use the `userGrantedResource` method as shown in Table 47-12.
47.11.4 Getting Information from the ADF Security Context

The implementation of security in a Fusion web application is by definition an implementation of the security infrastructure of the ADF Security framework. As such, the security context of the framework allows access to information that is required as you define the policies and the overall security for your application.

47.11.4.1 How to Determine Whether Security Is Enabled

Because the enforcement of ADF Security can be turned on and off at the container level independent of the application, you should determine whether ADF Security is enabled prior to making authorization checks. You can achieve this by calling the isAuthorizationEnabled() method of the ADF Security Context, as shown in the following example.

```java
if (ADFContext.getCurrent().getSecurityContext().isAuthorizationEnabled()) {
    //Authorization checks are performed here.
}
```

47.11.4.2 How to Determine Whether the User Is Authenticated

As the user principal in a Fusion web application is never null (that is, it is either anonymous for unauthenticated users or the actual user name for authenticated users), it is not possible to simply check whether the user principal is null to determine if the user has logged on or not. As such, you must use a method to take into account that a user principal of anonymous indicates that the user has not authenticated. You can achieve this by calling the isAuthenticated() method of the ADF Security Context, as shown in the following example.

```java
// ============ User's Authenticated Status ============
private boolean _authenticated;
public boolean isAuthenticated() {
    _authenticated = ADFContext.getCurrent().getSecurityContext().isAuthenticated();
    return _authenticated;
}
```

47.11.4.3 How to Determine the Current User Name

Fusion web applications support the concept of public pages that, while secured, are available to all users. Furthermore, components on the web pages, such as portlets, require knowledge of the current user identity. As such, the user name in a Fusion web application will never be null. If an unauthenticated user accesses the page, the user name anonymous will be passed to page components.

You can determine the current user's name by evaluating the getUserName() method of the ADF security context, as shown in the following example. This method returns the string anonymous for all unauthenticated users and the actual authenticated user's name for authenticated users.

```java
// ============ Current User's Name/PrincipalName ============
public String getCurrentUser() {
    _currentUser = ADFContext.getCurrent().getSecurityContext().getUserName();
    return _currentUser;
}
```

Because the traditional method for determining a user name in a Faces-based application

(FacesContext.getCurrentInstance().getExternalContext().getRemot...
eUser() returns null for unauthenticated users, you need to use additional logic to handle the public user case if you use that method.

47.11.4.4 How to Determine Membership of a Java EE Security Role

As Fusion web applications are JavaServer Faces-based applications, you can use the isUserInRole(roleName) method of the Faces external context, as shown in the following example, to determine whether a user is in a specified role. Because ADF Security is based around JAAS policies, you should not need to use Java EE security roles to secure pages associated with ADF security-aware resources based on role membership. However, you might use the method to check the role for a page that is not associated with an ADF security-aware resource.

In this example, a convenience method (checkIsUserInRole) is defined. The use of this method within a managed bean enables you to expose membership of a named role as an attribute, which can then be used in EL.

```java
class UserBean {
    public boolean checkIsUserInRole(String roleName){
        return (FacesContext.getCurrentInstance().getExternalContext().isUserInRole(roleName));
    }

    public boolean isCustomer() {
        return (checkIsUserInRole("Application Customer Role"));
    }
}
```

47.11.4.5 How to Determine Permission Using Java

To evaluate the security policies from within Java, you can use the hasPermission method of the ADF security context. This method takes a permission object (defined by the resource and action combination) and returns true if the user has the corresponding permission.

In the following example, a convenience function is defined to enable you to pass in the name of the page and the desired action, returning true or false based on the user's permissions. Because this convenience function is checking page permissions, the RegionPermission class is used to define the permission object that is passed to the hasPermission method.

```java
private boolean TestPermission (String PageName, String Action)  {
    Permission p = new RegionPermission("view.pageDefs." + PageName + "PageDef", Action);
    if (p != null) {
        return ADFContext.getCurrent().getSecurityContext().hasPermission(p);
    } else {
        return (true);
    }
}
```

As it is possible to determine the user's permission for a target page from within a backing bean, you can use this convenience method to dynamically alter the result of a Faces navigation action. In the following example, you can see that a single command button can point to different target pages depending on the user's permission. By checking the view permission from the most secured page (the manager page) to the least secured page (the public welcome page), the command button's backing bean will apply the appropriate action to direct the user to the page that corresponds to their permission level. The backing bean that returns the appropriate action uses a convenience method defined in the following example.
47.11.5 Best Practices for Working with ADF Security

These best practices summarize the rules that govern enforcement of security by the ADF Security framework. Understanding these best practices will help you to secure the application to allow users to access the web pages you intend.

**Do build your application with ADF Security enabled from the start.**

When you enable security, you essentially lock down the application and you will be required to make explicit permission grants to specific ADF security-aware resources you create. Knowing about these resources and making grants on them as you build the application will enable you to iteratively test security to ensure that you structure your application in a way that achieves the desired result.

**Do define permission grants for bounded task flows.**

Pages that the user accesses within the process of executing a bounded task flow will not be individually permission-checked and will run under the permission grants of the task flow. This means that any page that you add to the task flow should not have its own page definition-level security defined. Upon requesting a flow, the user will be allowed either to view all the pages of the task flow or to view none of the pages, depending on their level of access.

**Do not define permission grants for individual pages of a bounded task flow.**

It is important to realize that task flows do not prevent users from accessing pages directly. Any web page that is located in a directory that is publicly accessible can be reached from a browser using a URL. To ensure that pages referenced by a bounded task flow cannot be accessed directly, remove all permission grants that exist for their associated page definition file. When pages require additional security within the context of a bounded task flow, wrap those pages in a sub-task flow with additional grants defined on the nested task flow.

**Do use task flows to reduce the number of access points exposed to end users.**

When you use task flows you can reduce the number of access points that you expose to end users. For example, configure an unbounded task flow to display one page that provides navigation to the remaining pages in your application. Use bounded task flows for the remaining pages in the application. By setting the URL Invoke property of these bounded task flows to url-invoke-disallowed, your application has one access point (the page on the unbounded task flow). For more information about the URL Invoke property, see [How to Call a Bounded Task Flow Using a URL](#).
Do specify an alternative task flow for unauthorized users.

End users who attempt to invoke a bounded task flow in a region for which they do not have the necessary permission will see a region that renders as blank in place of the requested task flow. The region when left blank may confuse end users as it does not provide feedback as to why the requested task flow does not appear. Consider configuring an alternative task flow that does not require authorization when this scenario occurs. For more information configuring an alternative task flow, see Handling Access to Secured Task Flows by Unauthorized Users.

Do define permission grants for individual pages outside of a bounded task flow.

Page-level security is checked for pages that have an associated page definition binding file only if the page is directly accessed or if the page is accessed in an unbounded task flow. There is a one-to-one relationship between the page definition file and the web page it secures.

If you want to secure a page that uses no ADF bindings, you can create an empty page definition binding file for the page.

Do define custom permissions to render UI component based on the user's access rights.

Custom ADF permission classes let you extend ADF Security to define custom actions for use in grants. This gives you the flexibility to define security policies to manage the user's ability to view UI components without having to overload the built-in actions defined by the ADF resources' permission classes.

Do define entity object attribute permissions to manage the user's access rights to row-level data displayed by UI components.

Entity objects and entity object attributes both define permission classes that let you define permissions for the read, update, and delete operations that the entity object initiates on its data source. In the case of these data model project components, you must explicitly grant permissions to an application role in order to opt into ADF Security authorization. However, once you enable authorization for an entity object, all rows of data defined by the entity object will be protected by the grant. At this level of granularity, your table component would render in the web page either with all data visible or with no data visible—depending on the user's access rights. As an alternative to securing the entire collection, you can secure individual columns of data. This level of granularity is supported by permissions you set on the individual attributes of entity objects. When entity objects are secured, users may see only portions of the data that the table component displays.

Do use task flow or page-level permission grants to avoid exposing row-level create/insert operations to users with view-only permission.

The correct way to control access to a page that should allow only certain users to update new rows in a table is to use task flow or page-level permission grants. However, as an alternative, it is possible to secure table buttons corresponding to particular operations by specifying an EL expression to test the user's access rights to view the button. When the custom permission is defined and the userGrantedPermission expression is set on the Rendered property of the button, only users with sufficient privileges will see the button. This may be useful in a case where the user interface displays a page that is not restricted and view-only permission for row-level data is defined for the entity object. In this case, when viewed by the user, the Delete button for the editable table associated with the entity object will appear disabled. However, in the case of an input table, the user interface does not disable the button for the CreateInsert operation even though the user may not have update permission.
Do not use JDeveloper as a user identity provisioning tool.

JDeveloper must not be used as an identity store provisioning tool, and you must be careful not to deploy the application with user identities that you create for testing purposes. Deploying user identities with the application introduces the risk that malicious users may gain unintended access. Instead, always rely on the system administrator to configure user identities through the tools provided by the domain-level identity management system. You should delete all users and groups that you create in the jazn-data.xml file before deploying the application.

Do not allow users to access a web page by its file name.

When you deploy the Fusion web application, you should always permit users to access the web page from a view activity defined in the ADF Controller configuration file. Do not allow users to access the JSPX file directly by its physical name (for example, similar to the file name AllDepartments.jspx).

Assuming the view activity is named AllDepartments, then there are two ways to call the page:

1. localhost:7101/myapp/faces/AllDepartments
2. localhost:7101/myapp/faces/AllDepartments.jspx

The difference is that the call 1) is in the context of the ADF Controller task flow, which means that navigation on the page will work and any managed beans that are referenced by the page will be properly instantiated. The call in 2) also serves the page, however, the page may not function fully. This may be considered a security breach.

To prevent direct JSPX file access, move the JSPX file under the /public_html/WEB-INF directory so that direct file access is no longer possible. To access a document, users will have to call its view activity name.

Note that this suggestion does not protect documents that are unprotected in ADF Security. It only helps to lock down access to the physical file itself.

Thus, the following security guidelines still apply:

1. Apply ADF Security permissions to all JSPX documents associated with view activities defined in the adfc-config.xml file.
2. Move all JSPX documents in the user interface project under the /public_html/WEB-INF directory to prevent direct file access.
3. Limit the pages in the adfc-config.xml to the absolute minimum and place all other pages into bounded task flows.
4. Make bounded task flows inaccessible from direct URL access (which is the default configuration setting for new task flows).
5. Apply ADF Security permissions to bounded task flows.
This chapter describes the tools for logging and testing an application that uses Oracle ADF. It contains debugging procedures for setting breakpoints using the ADF Declarative Debugger. Finally, it explains how to write and run regression tests for your ADF Business Components-based business services.

This chapter includes the following sections:

- About ADF Debugging
- Correcting Simple Oracle ADF Compilation Errors
- Correcting Simple Oracle ADF Runtime Errors
- Reloading Oracle ADF Metadata in Integrated WebLogic Server
- Validating ADF Controller Metadata
- Using the ADF Logger
- Using the Oracle ADF Model Tester for Testing and Debugging
- Using the ADF Declarative Debugger
- Setting ADF Declarative Breakpoints
- Setting Breakpoints in Java Code and Groovy Script
- Regression Testing with JUnit

## 48.1 About ADF Debugging

Like any debugging task, debugging the web application’s interaction with Oracle Application Development Framework (Oracle ADF) is a process of isolating specific contributing factors. However, in the case of web applications, generally this process does not involve compiling Java source code. Your web pages contain no Java source code, as such, to compile. In fact, you may not realize that a problem exists until you run and attempt to use the application. For example, these failures are only visible at runtime:

- A page not found servlet error
- The page is found, but the components display without data
- The page fails to display data after executing a method call or built-in operation (like Next or Previous)
- The page displays, but a method call or built-in operation fails to execute at all
- The page displays, but unexpected validation errors occur
The failure to display data or to execute a method call arises from the interaction between the web page's components and the ADF Model layer. When a runtime failure is observed during ADF lifecycle processing, the sequence of preparing the model, updating the values, invoking the actions, and, finally, rendering the data failed to complete.

Fortunately, most failures in the web application's interaction with Oracle ADF result from simple and easy-to-fix errors in the declarative information that the application defines or in the EL expressions that access the runtime objects of the page's ADF binding container.

In your databound Fusion web application, you should examine the declarative information and EL expressions as likely contributing factors when runtime failures are observed. To understand editing the declarative files, see Correcting Simple Oracle ADF Compilation Errors, and Correcting Simple Oracle ADF Runtime Errors.

One of the most useful diagnostic tools is the ADF Logger. You use this logging mechanism in JDeveloper to capture runtime traces messages. With ADF logging enabled, JDeveloper displays the application trace in the Message Log window. The trace includes runtime messages that may help you to quickly identify the origin of an application error. Read Using the ADF Logger, to configure the ADF Logger to display detailed trace messages.

Supported Oracle ADF customers can request Oracle ADF source code from Oracle Worldwide Support. This can make debugging ADF Business Components framework code a lot easier. Read Using ADF Source Code with the Debugger, to understand how to configure JDeveloper to use the Oracle ADF source code.

If the error cannot be easily identified, you can utilize the ADF Declarative Debugger in JDeveloper to set breakpoints. When a breakpoint is reached, the execution of the application is paused and you can examine the data that the ADF binding container has to work with, and compare it to what you expect the data to be. Depending on the types of breakpoints, you may be able to use the step functions to move from one breakpoint to another. For more information about the debugger, read Using the ADF Declarative Debugger.

JDeveloper provides integration with JUnit for your Fusion web application through a wizard that generates regression test cases. Read Regression Testing with JUnit, to understand how to write test suites for your application.

### 48.2 Correcting Simple Oracle ADF Compilation Errors

When you create web pages and work with the ADF data controls to create the ADF binding definitions in JDeveloper, the Oracle ADF declarative files you edit must conform to the XML schema defined by Oracle ADF. When an XML syntax error occurs, the JDeveloper XML compiler immediately displays the error in the Structure window.

Although there is some syntax checking during design time, the JDeveloper compiler is currently limited by an inability to resolve EL expressions. EL expressions in your web pages interact directly with various runtime objects in the web environment, including the web page's ADF binding container. At present, errors in EL expressions can be observed only at runtime. Thus, the presence of a single typing error in an object-access expression will not be detected by the compiler, but will manifest at runtime as a failure to interact with the binding container and a failure to display data in the page. For information about debugging runtime errors, see Correcting Simple Oracle ADF Runtime Errors.

**Tip:**

---

48-2 Developing Fusion Web Applications with Oracle Application Development Framework
The Expression Builder is a dialog that helps you build EL expressions by providing lists of objects, managed beans, and properties. It is particularly useful when creating or editing ADF databound EL expressions because it provides a hierarchical list of ADF binding objects and their valid properties from which you can select. You should use the Expression Builder to avoid introducing typing errors. For details, see Creating ADF Data Binding EL Expressions.

The following example illustrates two simple compilation errors contained in a page definition file: `false` instead of `false` and `ChangeEventPolicy="ppr"`/ instead of `ChangeEventPolicy="ppr"/>` (that is, the attribute is missing a closing angle bracket).

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
Package="oracle.summit.view.pageDefs"
SkipValidation="false">
<parameters/>
<executables>
<iterator Binds="InventoryForOrderItem" RangeSize="-1"
DataControl="BackOfficeAppModuleDataControl" id="InventoryForOrderItemIterator"
  ChangeEventPolicy="ppr"/>
...
</pageDefinition>
```

During compilation, the Structure window displays the XML errors in the page, as shown in Figure 48-1.

**Figure 48-1   The Structure Window Displays XML Errors**

The Compiler-Log window also displays the compilation errors in the page, as shown in Figure 48-2.

**Figure 48-2   The Compiler Window Displays XML Compile Errors**

To view and correct schema validation errors:

1. In the main menu, choose View and then Structure to open the Structure window or choose View and then Log to open the Log Window.
2. In either window, double-click the error message.

3. In the XML editor, locate the highlighted lines.
   The highlighted lines will be lines with errors.

4. Correct any errors.
   After an error has been corrected, the corresponding error message will be
   automatically removed from the Structure window.

5. Optionally, you can recompile the project by choosing Run > Make and checking
to see whether the compiler still produces the error message.

### 48.3 Correcting Simple Oracle ADF Runtime Errors

Failures of the ADF Model layer cannot be detected by the JDeveloper compiler, in
part because the page's data-display and method-execution behavior relies on the
declarative ADF page definition files. The ADF Model layer utilizes those declarative
files at runtime to create the objects of the ADF binding container.

To go beyond simple schema validation, you will want to routinely run and test your
web pages to ensure that none of the following conditions exists:

- The project dependency between the data model project and the user interface
  project is disabled.
  By default, the dependency between projects is enabled whenever you create a web
  page that accesses a data control in the data model project. However, if the
dependency is disabled and remains disabled when you attempt to run the
application, an internal servlet error will be generated at runtime:

  `oracle.jbo.NoDefException: JBO-25002: Definition
model.DataControls.dcx of type null not found`

  To correct the error, double-click the user interface project, and select the
  Dependencies node in the dialog. Make sure that the `ModelProjectName.jpr`
option appears selected in the panel.

- Page definition files have been renamed, but the `DataBindings.cpx` file still
  references the original page definition file names.
  While JDeveloper does not permit these files to be renamed within the IDE, if a
  page definition file is renamed outside of JDeveloper and the references in the
  `DataBindings.cpx` file are not also updated, an internal servlet error will be
  generated at runtime:

  `oracle.jbo.NoDefException: JBO-25002: Definition
oracle.<path>.pageDefs.<pagedefinitionName> of type Form
Binding Definition not found`

  To correct the error, open the `DataBindings.cpx` file and use the source editor to
  edit the page definition file names that appear in the `<pageMap>` and
  `<pageDefinitionUsages>` elements.

- The web page file (.jsp or .jspx) has been renamed, but the
  `DataBindings.cpx` file still references the original file name of the same web
  page.
  The page controller uses the page's URL to determine the correct page definition to
  use to create the ADF binding container for the web page. If the page's name from
the URL does not match the `<pageMap>` element of the `DataBindings.cpx` file, an internal servlet error will be generated at runtime:

`javax.faces.el.PropertyNotFoundException: Error testing property <propertynname>`

To correct the error, open the `DataBindings.cpx` file and use the source editor to edit the web page file names that appear in the `<pageMap>` element.

- Bindings have been renamed in the web page EL expressions, but the page definition file still references the original binding object names.

The web page may fail to display information that you expect to see. To correct the error, compare the binding names in the page definition file and the EL expression responsible for displaying the missing part of the page. Most likely the mismatch will occur on a `value binding`, with the consequence that the component will appear but without data. Should the mismatch occur on an `iterator binding` name, the error may be more subtle and may require deep debugging to isolate the source of the mismatch.

- Bindings in the page definition file have been renamed or deleted, and the EL expressions still reference the original binding object names.

Because the default error-handling mechanism will catch some runtime errors from the ADF binding container, this type of error can be very easy to find. For example, if an iterator binding named `findUsersByNameIter` was renamed in the page definition file, yet the page still refers to the original name, this error will display in the web page:

`JBO-25005: Object name <iterator> for type Iterator Binding Definition is invalid`

To correct the error, right-click the name in the web page and choose **Go to Page Definition** to locate the correct binding name to use in the EL expression.

- EL expressions were written manually instead of using the expression picker dialog and invalid object names or property names were introduced.

This error may not be easy to find. Depending on which EL expression contains the error, you may or may not see a servlet error message. For example, if the error occurs in a binding property with no runtime consequence, such as displaying a label name, the page will function normally but the label will not be displayed. However, if the error occurs in a binding that executes a method, an internal servlet error `javax.faces.el.MethodNotFoundException: methodname` will display. Or, in the case of an incorrectly typed property name on the method expression, the servlet error `javax.faces.el.PropertyNotFoundException: propertyname` will display.

If this list of typical errors does not help you to find and fix a runtime error, you can initiate debugging within JDeveloper to find the contributing factor. For an Oracle ADF application, start setting ADF declarative breakpoints to find the problem. Using the ADF Declarative Debugger to set ADF declarative breakpoints is described in **Using the ADF Declarative Debugger** and **Setting ADF Declarative Breakpoints**. This process involves pausing the execution of the application as it proceeds through the application and examining data. You can also use the ADF Declarative Debugger to set Java code breakpoints, as described in **Setting Breakpoints in Java Code and Groovy Script**.
48.4 Reloading Oracle ADF Metadata in Integrated WebLogic Server

JDeveloper support for hot reloading of Oracle ADF metadata is an alternative to quitting the running application, editing your project’s XML definition files, redeploying, and rerunning the application in Integrated WebLogic Server to view the latest changes.

Changes that you make to the Fusion web application projects will not be picked up automatically by an application that you have deployed to Integrated WebLogic Server. You can, however, reload metadata from the data model project and user interface project any time you want to synchronize the running application with changes you have made to your application’s XML definition files.

To reload metadata so your changes are reflected in the deployed Fusion web application, you must recompile the project and refresh the web browser.

Metadata that JDeveloper will hot reload in Integrated WebLogic Server, include:

- In the data model project, changes to the definition files of business components.
- In the user interface project, changes to the binding definitions in the page definition files and changes to task flows in the task flow definition files.

This support makes it possible to make incremental changes and test them.

48.5 Validating ADF Controller Metadata

Basic validation is performed when ADF Controller retrieves metadata. The most serious errors, for example, a task flow that is missing a default activity, result in parsing exceptions.

The enable-grammar-validation setting in adf-config.xml allows you to validate the grammar in ADF Controller metadata before deploying an application. When enable-grammar-validation is set to true, ADF Controller metadata is validated against ADF Controller XSDs. For example, invalid characters in ADF Controller metadata, such as a slash (/) in a view activity ID, are flagged as exceptions.

By default, enable-grammar-validation is set to false. For performance reasons, it should be set to true only during application development or when troubleshooting an application.

48.6 Using the ADF Logger

If you are not able to easily find the error in either your web page or its corresponding page definition file, you can use the JDeveloper debugging tools to investigate where your application failure occurs.

You configure the logging session by editing the logging.xml configuration file using the editor for Oracle Diagnostic Logging Configuration. Logging configuration can be set at any time, even while the application is running in JDeveloper.

Unlike many files in JDeveloper, you cannot directly open the logging.xml file. Instead you use menu commands at these locations to open the Oracle Diagnostic Logging Configuration editor:

- Right-click an active server instance in the Application Servers window.
• Click the Actions dropdown menu displayed in the Log window’s debugger process panel, after you have started the application in debug mode.

You use the Oracle Diagnostic Logging Configuration editor to set the desired logging level to control the level and number of messages that are displayed. You can set the logging level for both persistent and transient loggers and declare handlers for each logger.

JDeveloper creates diagnostic log files in the Oracle Diagnostic Logging (ODL) format, used by Oracle Fusion Middleware components. Log file naming and the format of the contents of log files conform to an Oracle standard. By default, the diagnostic messages are in text format. For more information about the ODL format, see Administering Oracle Fusion Middleware.

In the editor, as an alternative to the default ODL format, you can configure the Java Logger to display Java diagnostic messages.

After you have created a log, you can view and filter the log messages with Oracle Diagnostic Log Analyzer. This tool allows you to set filters for different log levels, define message time frames, and search on message text.

You can then use the ADF Declarative Debugger to set breakpoints and examine the application. For more information, see Setting ADF Declarative Breakpoints, and Setting Breakpoints in Java Code and Groovy Script.

48.6.1 How to Set ADF Logging Levels

You can use the Oracle Diagnostic Logging Configuration editor to configure the logging levels specified in the logging.xml configuration file. The file can be configured before and while the application is running in Integrated WebLogic Server. The changes will apply without the need to restart the server.

When Integrated WebLogic Server is running, you can define both persistent and transient loggers. When Integrated WebLogic Server is not running, you can only define persistent loggers. The transient loggers will last only for the session and will not be entered in the logging.xml configuration file. If the server is not running, you must explicitly save the configuration changes to the logging.xml file for the updates to take effect in the next server run.

You can access the Oracle Diagnostic Logging Configuration editor from the Application Servers window or from the Log window, which is shown in Figure 48-3.

Figure 48-3    Log Window with Toolbar

However, while the server is running, when you access the editor via the Log window menu, then the editor has the ability to add transient loggers.

Figure 48-4 shows the Oracle Diagnostic Logging Configuration while the server is running.
You can only use JDeveloper menu commands to open the logging.xml configuration file and launch the editor for Oracle Diagnostic Logging Configuration. However, you may find the following information about the location of the configuration file useful.

**Note:**

You can declare and add log handler definitions by clicking the **Source** tab and entering them in the XML editor.

If you are using Integrated WebLogic Server in JDeveloper on the Windows platform, you can find the logging.xml configuration file in a location similar to:

C:\Users\username\AppData\Roaming\JDeveloper\<your_JDev_system_folder>\DefaultDomain\config\fmwconfig\servers\DefaultServer

The log files for Integrated WebLogic Server are in a location similar to:

C:\Users\username\AppData\Roaming\JDeveloper\<your_JDev_system_folder>\DefaultDomain\servers\DefaultServer\logs

The log files for a standalone WebLogic Server instance are in a location similar to:
You can configure logging levels before a test run from the Application Servers window, or, while the application is running, from the Log window’s run panel toolbar, or, during a debug session, from the Log window’s debug process toolbar.

To configure the log levels:

1. In the main menu, choose Window and then Application Servers.

2. In the Application Servers window, expand Application Servers, and right-click IntegratedWebLogicServer and choose Configure Oracle Diagnostic Logging for "IntegratedWebLogicServer".

   Or, after you start the application, from the Log window’s Running: IntegratedWebLogicServer panel, choose Actions - Configure Oracle Diagnostic Logging. The Running Log window is only visible while you run the application.

   Or, while you debug the application, from the Log window’s debug process panel, choose Actions - Configure Oracle Diagnostic Logging. The debug process panel is only visible in the Log window after you have started the application in debug mode.

3. In the editor for Oracle Diagnostics Logging Configuration, select ODL Log Levels or Java Log Levels for the logger type you want to view.

4. If you want to see persistent loggers only, select Hide Transient Loggers.

5. To add a logger:
   a. If the server is running, click the Add icon dropdown menu and choose Add Persistent Logger or Add Transient Logger. If the server is not running, click Add to add a persistent logger. You cannot add a transient logger.
   b. In the Add Logger dialog, enter a logger name.
   c. Select the logging level.
   d. Click OK.

6. For any logger, including a newly created logger, you can specify its handlers by selecting from a list of available handlers by clicking the Add icon for the Handler Declarations section.

   Or, you can select Use Parent Handlers to assign its parent’s handler to the logger. By default, a logger uses its parent’s handler.

---

**Note:**

You can declare and add log handler definitions by clicking the Source tab and entering them in the XML editor.

---

### 48.6.2 How to Create an Oracle ADF Debugging Configuration

Oracle ADF leverages the Java Logging API (java.util.logging.Logger) to provide logging functionality when you run a debugging session. Java Logging is a standard API that is available in the Java platform at [http://docs.oracle.com/javase/7/docs/api/java/util/logging/package-summary.html](http://docs.oracle.com/javase/7/docs/api/java/util/logging/package-summary.html).
To log a complete hierarchy tree of ADF event messages, you must configure a Java log level that is not more restrictive than CONFIG (or an ODL log level that is not more restrictive than Notification:16) for the single package:

- oracle.adfdiagnostics will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, ADF Desktop Integration, and Oracle ADF internal classes.

Figure 48-5 shows specific the logger configured to enable the most detailed Oracle ADF log messages. Note that the oracle.adfdiagnostics package is set to CONFIG and not to a higher, more restrictive log level (where SEVERE, WARNING, and INFO are Java log levels higher than CONFIG and FINE, FINER, and FINEST are lower levels than CONFIG). Enabling a logger for the oracle.adfdiagnostics package ensures that the logger records a complete hierarchy of ADF events.

For backward compatibility, the Java system property jbo.debugoutput set to the value console or ADFLogger (to route diagnostics through the standard Logger implementation, which can be controlled in a standard way through the logging.xml file) is supported. The easiest way to set this system property while running your application inside JDeveloper is to edit your project properties and in the Run/Debug page, select a run configuration and click Edit. Then add the string -Djbo.debugoutput=console to the Java Options field.

To create an ADF Model debugging configuration:

1. In the main menu, choose Window and then Application Servers.
2. In the Application Servers window, expand Application Servers, and right-click IntegratedWebLogicServer and choose Configure Oracle Diagnostic Logging.

Or, after you start the application, from the Log window’s Running: IntegratedWebLogicServer panel, choose Actions - Configure Oracle Diagnostic Logging. The Running Log window is only visible while you run the application.

Or, while you debug the application, from the Log window’s debug process panel, choose Actions - Configure Oracle Diagnostic Logging. The debug process panel is only visible in the Log window after you have started the application in debug mode.
3. In the editor for Oracle Diagnostics Logging Configuration, select ODL Log Levels or Java Log Levels for the logger type you want to view.

4. Expand the oracle node and select a log level that are not more restrictive than CONFIG (for Java Log) or that are not more restrictive than Notification (for ODL Log) for the following package:

   - oracle.adfdiagnostics will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.
     Enabling a logger for this package ensures that the logger records a complete hierarchy of ADF events.

5. Select the Java log level FINEST for other desired Oracle ADF loggers.

To create an ADF view Javascript logging configuration:

1. In the Applications window, double-click the application or project web.xml file.

2. In the source editor, add the following elements to the file:

   ```xml
   <context-param>
   <param-name>oracle.adf.view.rich.LOGGER_LEVEL</param-name>
   <param-value>FINE</param-value>
   </context-param>
   ```

48.6.3 How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers

For non-Oracle ADF loggers, before you use the actual debugger, running the application with Java log level set to FINE, FINER, or FINEST will enable framework diagnostics logging. The debug diagnostic messages can be helpful to see what happens when the problem occurs. To enable debug diagnostic messages, use the Oracle Diagnostics Logging Configuration Editor to configure the desired loggers with a Java log level set to FINEST. If you have configured diagnostic logging for the supported loggers, JDeveloper will direct debug diagnostics messages to the JDeveloper Log window.

Currently, Oracle ADF does not support logging with Java log level FINE, FINER, or FINEST. For more details about Oracle ADF loggers, see How to Create an Oracle ADF Debugging Configuration.

48.6.4 How to Use the Log Analyzer to View Log Messages

You can use Oracle Diagnostic Log Analyzer to view the log entries of a log file. The log analyzer allows you to filter the entries by log level, entry type, log time, and entry content (using one or more search criteria). You can also order the messages and show and hide columns for better viewing.

Figure 48-6 shows Oracle Diagnostic Log Analyzer set to view Java Log levels.
You can also use the log analyzer on log files created in other test runs. For instance, you can analyze the log sent to you by another developer for another application.

### 48.6.4.1 Viewing Diagnostic Messages in the Log Analyzer

You can configure logging levels before a test run from the Application Servers window or during a debug session from the Log window toolbar. The level you specify will determine the type and quantity of log messages.

In the case of ADF events, all messages are generated for the ODL log at the level Notification or for the Java log at the level Info. Fewer ADF messages will be generated at the Incident Error/Severe and Error/Warning levels.

After you select the log level for the messages you wish to view, you can use the Search panel of the By Log Message page to filter the messages to display from the log file.

---

**Note:**

For further details about search criteria that you can specify to search on ADF-specific messages, see [Sorting Diagnostic Messages By ADF Events](#).

---

You can start the log analyzer before a test run from the **Tools** menu or during a debug session from the log window toolbar.

Before you begin:

It may be helpful to have an understanding of logging. For more information, see [Using the ADF Logger](#).

You will need to complete these tasks:

1. Set logging levels, as described in [How to Set ADF Logging Levels](#).
2. Enable logging, as described in How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers.

3. Create a log file, either from your test run or from another source.

To start the log analyzer:

1. In the main menu, choose Tools and then Oracle Diagnostic Log Analyzer.

   Or, from the Log window Action menu, choose Analyze Log and then either Current in Console or Open Selected (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, select By Log Message.

3. In the By Log Message page, in the Log field, enter the path and name of the log file or click Browse Log Files to navigate to the log file.

   **Tip:**
   The Choose Log File dialog helps you to navigate to the directory that contains the log files generated by JDeveloper. Click the Browse Log Files icon next to the Log text field, and then click the Server Logs icon from the scroll list. From the list of log files, you can select more than one log file to analyze at a time.

4. From the dropdown list, select either ODL Log Level or Java Log Level.

5. Select the corresponding checkbox for each type of log entry you want to view. You must select at least one type.

   The available ODL log level types are:
   - INCIDENT ERROR
   - ERROR
   - WARNING
   - NOTIFICATION - corresponds to ADF event messages
   - TRACE
   - UNKNOWN.

   The available Java log level types are:
   - SEVERE
   - WARNING
   - INFO
   - CONFIG - corresponds to ADF event messages
   - FINE
   - FINER
   - FINEST
6. Specify a time period for the entries you want to view. You can select the most recent period or a range.

7. To filter the results, use the Search panel to query the log for a text pattern. For additional search criteria, click Add. The supported search criteria include:

- **Enterprise Name**: Filters the log by the name of the enterprise.
- **Detail**: Filters text in statements from the stack where the method was invoked.
- **EnterpriseID**: Filters the log by the ID of the enterprise.
- **Message**: Filters text in the logged messages.
- **ADF Message Data**: Filters the log for data related to ADF lifecycle phase names, view object names, view object query statements, data control names, binding container names, and iterator binding names logged during the execution of ADF events.
- **Source Method**: Filters the log by the method where the message is logged. For example, you can filter on the method execute to view all messages logged for view object query execution or ADF lifecycle phase execution.
- **Application**: Filters the log by the application name where the message is logged. This is useful when the application is running in a composite application and you want to view messages for a specific application.
- **Source Class**: Filters the log by the fully qualified class name of the method where the message is logged. To see more messages, enter a partial package name. For example, you can enter the partial package name oracle.adf or the full package name oracle.jbo to filter for all classes related to Oracle ADF.
- **Module**: Filters the log by the fully qualified package name of the class where the message is logged. This is same package as the source class.
- **Message Id**: Filters the log by the ID of the logged messages. Many messages share the same ID. For example, message ID ADFC-52008 might have four INFO messages and one Warning message. You can select Group by Id in the log analyzer Results panel to group messages by their common ID.

8. To initiate the filters and display the log messages, click **Search**.

9. To order the results by the message ID, select the **Group by Id** checkbox.

10. To group the messages by time period or by request, in the Related column, select either Related by Time or Related by Request.

    When you select Related by option, the log analyzer groups the messages in the Results Messages panel according to the selected criteria (time, HTTP request, or enterprise name).

11. To open the ADF request (if any) that the message is a part of, in the Related column, select Related by ADF Request.

    When you select Related by ADF Request, the log analyzer displays the related request in the By ADF Request page.
12. To show or hide columns in the Results section, click the dropdown list to the right of the column headers and select among the list of displayed columns to change the visibility of a column.

48.6.4.2 Using the Log Analyzer to Analyze the ADF Request

Because Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases, you can use the log analyzer to investigate the details of the active (or previous) page request in your running application. Specifically, the By ADF Request page of the log analyzer lets you view ADF event messages in a hierarchical list, organized by the sequence of their execution. It also provides a graphical representation of the duration of each event. When you run your application and start the log analyzer with ADF logging configured, you can use this page to quickly identify whether a component of your application is contributing to a performance bottleneck due to unusually long execution times.

Note:

In contrast to the By Log Message page, the By ADF Request page of the log analyzer displays a hierarchical view of ADF event messages. The difference between these two pages is that the By ADF Request page focuses only on ADF page requests made when a page or region is submitted. For details about the ADF page lifecycle, see Understanding the Fusion Page Lifecycle.

You can enter search criteria in the By ADF Request page to display one or more specific requests from the log file. You can combine any of the following search criteria to filter the log file:

- The number of requests to display
- The timestamp for the request recorded in the log
- The logged-in user name, enterprise name, request header (to specify a search based on the page or region name), message, source class, module, server, detail, enterprise ID, ADF message data, application name in a composite application, source method, message ID, or ECID (a globally unique ID associate with every top-level task; sub-tasks invoked by that top-level task operate with an execution context that shares the same ECID)

After the request is completed, the log analyzer displays a summary of the ADF requests in a single table. Figure 48-7 shows the summary table that displays the list of ADF web requests.
For each ADF request displayed in the summary table, you can click the request link to view details about the request event hierarchy. Figure 48-8 shows the ADF Requests panel with the JSF lifecycle Restore View and Render Response phases displayed and their duration in milliseconds. The bar graph for the root node of the request event hierarchy (ADF web request) displays the total execution time.

**Note:**

The **Percentage Request Time** bar graphs (black and gray) indicate which portion of the request’s execution time resulted from ADF source code that was instrumented to generate ADF event messages (shown in black) and which portion resulted from ADF source code that is uninstrumented and therefore cannot generate ADF event messages (shown in gray). Additionally, note that the individual phases of the request do not sum to equal the total request time. This is due to the fact that only those phases of the lifecycle that are useful are represented in the log analyzer.
To examine the request in more detail, you can expand the tree for any ADF lifecycle node to further investigate where in the application the performance bottleneck occurred. Drilling down and then selecting the ADF event node in the request message panel gives you details about the component associated with each ADF event. For instance, expanding the JSF Phase RENDER_RESPONSE node displays all ADF events generated during that phase. Figure 48-9 shows the JSF Phase RENDER_RESPONSE node expanded with a long request duration bar graph for the Get LOV list node and the Execute query node. The Execute query node has been selected to reveal detailed ADF data in the ADF Message Data Details panel, including the view object's name and query statement. By drilling down and selecting the ADF event with the long execution time as indicated by the bar graph, you can obtain, for example, the name of the view object in the data model project that should be tuned for improved performance.

**Figure 48-9  Oracle Diagnostic Log Analyzer Displays ADF Event Messages with ADF Data**

Before you begin:

It may be helpful to have an understanding of logging. For more information, see Using the ADF Logger.

You will need to complete these tasks:

1. Set logging levels, as described in How to Set ADF Logging Levels.

   To log a complete hierarchy tree of ADF event messages, you must configure an ODL log level that is not more restrictive than NOTIFICATION:16 or a Java log level that is not more restrictive than CONFIG for the following single package:

   - oracle.adfdiagnostics will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

   **Tip:**

   The default log level for the Root Logger displayed by the editor for Oracle Diagnostics Logging Configuration ensures that ADF event messages are logged.
2. Enable logging, as described in How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers.

3. Create a log file, either from your test run or from another source.

To display ADF request messages in the log analyzer:

1. In the main menu, choose Tools and then Oracle Diagnostic Log Analyzer.

   Or, from the Log window Action menu, choose Analyze Log and then either Current in Console or Open Selected (to browse log files in the server log directory).

2. In the editor for Oracle Diagnostic Log Analyzer, click the By ADF Request tab.

3. In the By ADF Request page, specify how many of the most recent request you want to display.

   The default displays only the most recent request.

4. Specify a time period for the entries you want to view. You can select the most recent period or a range.

5. To filter the request to display, use the search fields to query the log for a text pattern. For additional search fields, click the Add Row icon.

6. To initiate the filters and display matching ADF requests, click Search.

7. In the ADF Requests panel, click the desired request link to view the event hierarchy and look for ADF events that display long execution times as indicated by the Time (ms) bar graphs.

8. Select the desired ADF event and examine the ADF Message Data Details panel for details about the ADF component associated with the ADF event.

9. Examine the component in your application and determine whether optimization is possible.

**48.6.4.3 Sorting Diagnostic Messages By ADF Events**

Oracle instrumented the Oracle ADF source code to generate log messages during the execution of the ADF lifecycle phases and during operations executed in the ADF Model data binding layer, ADF Controller source, and ADF Business Components source. Combined, the log analyzer refers to these messages as ADF events. You can use the log analyzer to investigate ADF events in your running application. The By Log Message page of the log analyzer lets you view ADF event messages in a flat list, organized by time of execution, with the option to switch to the By ADF Request page to view the ADF events in a hierarchical list, organized by the sequence of their execution.

ADF event messages contain useful information that helps you identify which ADF components in your application generated the event. For example, you can search the log for ADF event messages to identify the components related to displaying data in the page, executing queries, or initiating actions:

- Executing iterator binding: Displays the names of the iterators executed to manage displaying data in the page. This can be useful for diagnosing slow query updates.
• Execute query: Displays the name of the view object associated with the executed query. This can be useful when you want to view the query statement, bind parameters, and name of the view object.

• Executing method binding: Displays the names of the Java methods executed on the bound data source. This can be useful for diagnosing slow method execution.

After you display an ADF event message in the log analyzer, you can organize the event in the context of other logged messages. You can select options from the Related column to display:

- All messages leading up to the ADF event (related by time)
- All messages in the same web request as the ADF event (related by request)
- Only ADF event messages in the same web request (related by ADF request)

Tip:
The **Related by ADF Request** option displays detailed ADF data for the ADF event messages. This is the view to use, for example, when you want to display the query statement associated with the **Execute query** message.

Figure 48-10 shows the log analyzer search result for the ADF event message **Create Application Module**. The Results panel displays all messages that match the search criteria and the bottom panel displays detailed information about the component.

**Figure 48-10    Oracle Diagnostic Log Analyzer Displays ADF Event Messages**

When you select **Related by ADF Request** in the Related column of the Results panel, the log analyzer switches to display the By ADF Request page with the ADF event messages arranged hierarchically to show their execution dependencies. The By ADF Request page of the log analyzer is the preferred way to diagnose performance issues. For details about the By ADF Request page, see Using the Log Analyzer to Analyze the ADF Request. In the By Log Message page, the elapsed time is information that you can leave visible or hide from the Results panel.

Before you begin:
It may be helpful to have an understanding of logging. For more information, see Using the ADF Logger.

You will need to complete these tasks:

1. Set logging levels, as described in How to Set ADF Logging Levels.
   To log ADF event messages, do not configure an ODL log level that is more restrictive than `NOTIFICATION:16` or a Java log level that is more restrictive than `CONFIG` for the following package:
   - `oracle.adfdiagnostics` will log events generated by source code for the ADF Model data binding layer, ADF Controller source code, ADF Business Components, and Oracle ADF internal classes.

   **Tip:**
   The default log level for the Root Logger displayed by the editor for Oracle Diagnostics Logging Configuration ensures ADF event messages are logged.

2. Enable logging, as described in How to Turn On Diagnostic Logging for Non-Oracle ADF Loggers.

3. Create a log file, either from your test run or from another source.
   To display messages related by ADF events:
   1. In the main menu, choose **Tools** and then **Oracle Diagnostic Log Analyzer**.
      Or, from the Log window **Action** menu, choose **Analyze Log** and then either **Current in Console** or **Open Selected** (to browse log files in the server log directory).
   2. In the editor for Oracle Diagnostic Log Analyzer, click the **By Log Message** tab.
   3. In the By Log Message page, select the desired logger type, log levels, and log time.
      To search the log for ADF event messages, you must minimally select log level `Notification` (for ODL log level) or `Info` (for Java log level).
   4. In the search dropdowns, choose the search criteria **Message** and **Contains**, and then enter any of the following ADF event messages and click **Search**.
      - Executing iterator binding - this can be useful for diagnosing slow query updates.
      - Executing method binding - this can be useful for diagnosing slow method execution.
      - Execute query - this can be useful when you want to view the query statement, bind parameters, and name of the view object.
      You can also filter the log on these additional ADF event messages:
      - Refreshing binding container
      - Attaching an iterator binding to a datasource
      - Converting rows into hierarchical nodes
      - Estimated row count
• Get LOV list
• Filter LOV list
• Validate Entity
• Lock Entity's Parent
• Lock Entity
• Before posting the entity's changes
• Posting the entity's changes
• Posting in batches
• Before committing the entity's changes
• After committing the entity's changes
• Before rolling back the entity's changes
• After rolling back the entity's changes
• Entity notifying an event
• Entity notification name
• Removing Entity
• Updating audit columns
• Applying Effective Date change
• Entity DML
• Entity read all attributes
• Create Application Module
• Create nested Application Module
• Passivating Application Module
• Activating Application Module
• Establish database connection
• Commit transaction
• Rollback transaction
• Validate transaction
• Validate value

Examine the data portion of the Results panel for the ADF event information.

5. To view a hierarchical sequence of ADF events, with the desired ADF event message selected in the Results panel, in the Related column, click the icon for the desired event row and choose Related By ADF Request from the dropdown menu.
The editor for Oracle Diagnostic Log Analyzer displays the By ADF Request page for the selected ADF event. Examine the bottom portion of the Results panel for additional ADF data for the ADF event. For example, you can see the query statement associated with the Execute query message in the ADF Data area of the Results panel.

48.6.5 What You May Need to Know About ADF Loggers and Log Levels

By default, the level is set to WARNING for all Oracle loggers. For Oracle ADF packages set level="FINE" for detailed logging diagnostics.

For the ADF view layer packages oracle.adf.view.faces and oracle.adfinternal.view.faces, edit these elements:

<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.adfinternal" level="FINE"/>

For the ADF Model layer packages, edit these elements:

<logger name="oracle.adf" level="FINE"/>
<logger name="oracle.jbo" level="FINE"/>

For the ADF Controller layer packages, edit these elements:

<logger name="oracle.adf.controller" level="FINE"/>
<logger name="oracle.adfinternal.controller" level="FINE"/>

Alternatively, you can create a debug configuration in JDeveloper that you can choose when you start a debugging session.

The following example shows the portion of the logging.xml file where you can change the granularity of the log messages. Note in the example that the log for oracle.adf.faces has been changed to FINE to display more messages.

</logging_configuration>

... 
<loggers>
  <logger name="oracle.adf" level="INFO"/>
  <logger name="oracle.adf.faces" level="FINE"/>
  <logger name="oracle.adf.controller" level="INFO"/>
  <logger name="oracle.bc4j" level="INFO"/>
  <logger name="oracle.adf.portal" level="INFO"/>
  <logger name="oracle.vcr" level="INFO"/>
  <logger name="oracle.portlet" level="INFO"/>
  <logger name="oracle.adfinternal" level="INFO"/>
  <logger name="oracle.adfdt" level="INFO"/>
  <logger name="oracle.adfdtinternal" level="INFO"/>
</loggers>
</logging_configuration>

For the latest information about the different levels of the Java Logging system, go to http://www.oracle.com/technetwork/java/index.html. Normally, the Java logging system supports the following log levels:

- SEVERE (most restrictive, highest log level)
- WARNING
- INFO
- CONFIG (the highest low level supported for Oracle ADF)
48.6.6 What You May Need to Know About ADF Logging and Log Output

By default, loggers are hierarchical, so a logger that is a child of another logger will inherit the log level of its parent and may generate an unexpectedly large log output. As a result, when you enable loggers in the editor for Oracle Diagnostic Logging Configuration, you may want to set one log level for the parent logger and another log level for child loggers. This is especially important when you use settings FINE, FINER, FINEST that can be useful to diagnosis certain conditions like memory leaks, where detailed log messages are beneficial.

For example, when debugging memory leaks, you might set the oracle.adf.share.ADFContext logger to FINEST. This setting will automatically trigger the child oracle.adf.share.ADFContext.allocationLogger logger and may result in an allocation buffer exceeded condition for the log output file. Therefore, the solution to enable the messages needed to fix memory leaks is to make the parent level FINEST, while turning down the child logger to INFO.

```xml
<logger name="oracle.adf.share.ADFContext" level="FINE"/>
<logger name="oracle.adf.share.ADFContext.allocationLogger" level="INFO"/>
```

48.6.7 What You May Need to Know About ADF Logging and Oracle WebLogic Server

After you have deployed the Fusion web application to Oracle WebLogic Server, the operations performed by the application are logged directly to the Managed Server where the application is running:

```
DOMAIN_HOME/servers/server_name/logs/server_name-diagnostic.log
```

The log files for the different Managed Servers are also available from the Oracle WebLogic Server Administration Console. To verify the logs, access the Oracle WebLogic Server Administration Console at http://<admin_server_host>:<port>/console and click Diagnostics-Log Files.

This log’s granularity and logging properties can be changed using Oracle Enterprise Manager Fusion Middleware Control (Fusion Middleware Control). Fusion Middleware Control is a web browser-based, graphical user interface that you can use to monitor and administer a farm.

When the Fusion web application is deployed to a high availability environment, you can receive warning diagnostic messages specific to high availability by setting the level to FINE.

For details about using Fusion Middleware Control to change the log settings of Managed Servers and Oracle ADF, see Administering Oracle Fusion Middleware.

48.7 Using the Oracle ADF Model Tester for Testing and Debugging

The Oracle ADF Model Tester (also referred to as the tester) is a Java application that you launch from JDeveloper when you want to interact with the business objects of the ADF Business Components data model project. The Oracle ADF Model Tester runs outside of JDeveloper and provides a full UI for testing and examining the data model project. You can run the tester to examine the view instances of the ADF application module, navigate the hierarchical relationship of view links, and execute custom...
methods from the application module’s client interface, view object interface, and view row interface. The tester also interacts with the ADF Declarative Debugger to allow you to set breakpoints on the custom methods of these interfaces.

Additionally, the tester simulates many features that the user interface might expose by allowing you to view, insert, and update the contents of business objects in the database specified by the application module's configuration file (bc4j.xcfg).

Specifically, you can use the tester to verify many aspects of the data model design, including a master-detail relationship between view instances, view instances and their attributes, view instance query result sets, search forms using view criteria, validation rules defined for attribute values, and dropdown lists on LOV-defined attributes (list of values). For more information about ways to interact with the tester to test your business objects, see Testing View Object Instances Using the Oracle ADF Model Tester. Additional information about testing with the Oracle ADF Model Tester also appears in sections specific to each business object throughout the chapters in the “Building Your Business Services” part of this book.

48.7.1 How to Run in Debug Mode and Test with the Oracle ADF Model Tester

Often you will find it useful to analyze and debug custom code in the service methods of your client interface implementation classes. When you use the Oracle ADF Model Tester, you can do this without needing to run the application with the user interface. You can use the Oracle ADF Model Tester as a testing tool to complement your debugging process.

---

Note:

The Oracle ADF Model Tester that you run in debug mode will not inherit your JDeveloper IDE Java options. To ensure that specific run/debug Java options are used with the tester, you must edit the run configuration for the data model project. You can modify the default run confirmation in the Run/Debug page of the Project Properties dialog.

---

Before you begin:

It may be helpful to have an understanding of the using the runtime testing tools. For more information, see Using the Oracle ADF Model Tester for Testing and Debugging.

You will need to complete these tasks:

1. Set the desired Java options for your preferred run configuration, as described in the “Running and Debugging Java Projects” chapter in Developing Web User Interfaces with Oracle ADF Faces.

2. Set breakpoints in the custom methods of your client interface, as described in Setting ADF Declarative Breakpoints.

To launch the Oracle ADF Model Tester and go into debug mode:

1. In the Applications window, right-click the desired application module and choose Debug.

2. In the Oracle ADF Model Tester, open the method testing panel for the desired client interface, as described in How to Test Custom Service Methods Using the Oracle ADF Model Tester.
3. In the method panel, select the desired method from the dropdown list, enter values to pass as method parameters, and click **Execute**.

Return to JDeveloper to step through your code using the ADF Declarative Debugger. When you complete method execution, the method panel displays the return value (if any) and test result. The result displayed in the Oracle ADF Model Tester will indicate whether or not the method executed successfully.

### 48.7.2 How to Run the Oracle ADF Model Tester and Test with a Specific Application Module Configuration

When you right-click the application module in the Applications window and choose **Run** or **Debug**, JDeveloper will run the Oracle ADF Model Tester using the default configuration defined for the application module. If you want to test your business components with a different application module configuration (which can specify a different data source and its own set of runtime parameters), you can do so from the overview editor for the `bc4j.xcfg` file. The file is not visible in the Applications window and is only accessible from the Configurations page of the overview editor for the application module.

To run the Oracle ADF Model Tester with a specific application module configuration:

1. In the Applications window, double-click the application module that you want to test.

2. In the overview editor, click the **Configurations** navigation tab and then click the `bc4j.xcfg` configuration file link.

3. In the overview editor, select the configuration from the **Configurations** list.

4. Right-click the selected configuration and choose **Run** or **Debug** to launch the Oracle ADF Model Tester.

### 48.7.3 What Happens When You Run the Oracle ADF Model Tester in Debug Mode

The Oracle ADF Model Tester behaves as any other Java program. Specifically, it does not inherit Java options that you may have specified for the JDeveloper IDE. The tester instead uses the run configuration that you have specified for the data model project and any Java options that you may have set in that configuration.

JDeveloper lets you run the Oracle ADF Model Tester in two modes: either in debug mode or non-debug mode. When run in debug mode, the tester interacts with the ADF Declarative Debugger so that you execute custom methods using breakpoints you insert in custom Java code and Groovy script of the client interfaces. For instance, if you set a breakpoint on a method in the client interface and execute that method in the tester, then in debug mode, you can step through the code before the tester returns a success/fail result. In non-debug mode, the tester will immediately return a result to indicate whether the method executed successfully. Additionally, in either debug or non-debug mode, the tester can display runtime artifacts from the system catalog created at runtime for the application module.

### 48.7.4 How to Verify Runtime Artifacts in the Oracle ADF Model Tester

When you want to run the Oracle ADF Model Tester, but do not require the use of the ADF Declarative Debugger you can display information about the runtime artifacts from the application module's system catalog. The system catalog displays business object metadata and other information that you may find useful when you need to compare business objects.
To launch the Oracle ADF Model Tester without debugging:

1. In the Applications window, right-click the desired application module and choose Run.

2. In the Oracle ADF Model Tester, choose Create - Create SysCat AM.

3. In the data model tree, expand the SysCatAMDefs, right-click ViewDefs, and choose Show Table.

4. In the data viewer, scroll vertically to locate the desired view instance in the SCName (system catalog name) field.

   Exposing the system catalog in the tester allows access to metadata and other information specific to the runtime objects without running the debugger. For example, you can check whether a view instance has a custom Java implementation class or not.

### 48.7.5 How to Refresh the Oracle ADF Model Tester with Application Changes

The Oracle ADF Model Tester is a highly interactive tool. When you run the tester and determine a change is needed in the data model project, you can return to JDeveloper to edit the desired application module instance and refresh the Oracle ADF Model Tester data model to display the changes. This way you can verify your changes without needing to rerun the tester.

To reload application metadata in the Oracle ADF Model Tester:

1. In the data model project, edit your business objects and save the changes in the JDeveloper.

2. Recompile the data model project.

   For example, you can right-click the data model project in the Applications window and choose Make to complete the recompile step.

   Although the metadata changes that you make are not involved in compiling the project, the compile step is necessary to copy the metadata to the class path and to allow the Oracle ADF Model Tester to reload it.

3. In the Oracle ADF Model Tester, in the toolbar, click Reload application metadata.

   Alternatively, you can choose Reload Application from the File menu of the Oracle ADF Model Tester.

### 48.8 Using the ADF Declarative Debugger

The ADF Declarative Debugger provides declarative breakpoints that you can set at the ADF object level (such as task flows, page definition executables, method and action bindings, ADF lifecycle phases), as well as standard breakpoints in custom Java code and Groovy script. ADF declarative breakpoints provide a high-level object view for debugging ADF applications. For example, you can break before a task flow activity to see what parameters would be passed to the task flow, as shown in Figure 48-11. To perform the same function using only Java breakpoints would require you to know which class or method to place the breakpoint in. ADF declarative breakpoints should be the first choice for ADF applications.
The ADF Declarative Debugger also supports standard Java code breakpoints. You can set Java code breakpoints in any ADF application. You may be able to use Java code breakpoints when an ADF declarative breakpoint does not break in the place you want.

The ADF Declarative Debugger is built on top of the Java debugger, so it has the features and behaviors of the Java debugger. But instead of needing to know the Java class or method, you can set ADF declarative breakpoints in visual editors.

The ADF Declarative Debugger provides standard debugging features such as the ability to examine variable and stack data. When an application pauses at any breakpoint (ADF Declarative or Java code breakpoint), you can examine the application status using a variety of windows. You can check where the break occurs in the Breakpoints window. You can check the call stack for the current thread using the Stack window. When you select a line in the Stack window, information in the Data window, Watches window, and all Inspector windows is updated to show relevant data. You can use the Data window to display information about arguments, local variables, and static fields in your application.

The ADF Structure window displays the runtime structure of the project. The ADF Data window automatically changes its display information based on the selection in the ADF Structure window. For example, if a task flow node is selected, the ADF Data window displays the relevant debugging information for task flows, as shown in Figure 48-12.

You can mix ADF declarative breakpoints with standard Java and Groovy breakpoints as needed in your debugging session. Although you can use step functions to advance the application from Java code breakpoint to Java code breakpoint, the step functions for ADF declarative breakpoints have more constraints and limitations. For more
information about using step functions on ADF declarative breakpoints, see Table 48-3.

For information on how to use ADF declarative breakpoints, see Setting ADF Declarative Breakpoints.

For information on how to use Java breakpoints on classes and methods, see Setting Breakpoints in Java Code and Groovy Script.

In a JSF application (including Fusion web applications), when a breakpoint breaks, you can use the EL Evaluator to examine the value of an EL expression. The EL Evaluator has the browse function that helps you select the correct expression to evaluate. For more information, see How to Use the EL Expression Evaluator.

Whether you plan to use ADF declarative breakpoints or standard Java and Groovy breakpoints, you can use the ADF Declarative Debugger with Oracle ADF source code. You can obtain Oracle ADF source code with Debug libraries. For more information about loading source code, see Using ADF Source Code with the Debugger.

48.8.1 Using ADF Source Code with the Debugger

If you have valid Oracle ADF support, you can obtain complete source code for Oracle ADF by opening a service request with Oracle Worldwide Support. You can request a specific version of the Oracle ADF source code. You may be given download and password information to decrypt the source code ZIP file. Contact Oracle Worldwide Support for more information.

Adding Oracle ADF source code access to your application debugging session will:

• Provide access to the JDeveloper Quick Javadoc feature in the source editor. Without the source code, you will have only standard Javadoc.

• Enhance the use of Java code breakpoints by displaying the Oracle source code that's being executed when the breakpoint is encountered. You can also set breakpoints easier by clicking on the margin in the source code line you want to break on. Without the source code, you will have to know the class, method, or line number in order to set a breakpoint within Oracle code.

• For Java code breakpoints set within the source code, you will be able to see the values of all local variables and member fields in the debugger.

The ADF source code ZIP file may be delivered within an encrypted "outer" ZIP file to protect its contents during delivery. The "outer" ZIP name is sometimes a variant of the service request number.

After you have received or downloaded the "outer" ZIP archive file, unzip it with the provided password to access the actual source code ZIP file. The ADF source code ZIP name should be a variant of the Oracle ADF version number and build number. For example, the Oracle ADF source ZIP file may have a format similar to adf_vvvv_nnnn_source.zip, where vvvv is the version number and nnnn is the build number.

After you have access to the Oracle ADF source code ZIP file, extract its contents to a working directory.

48.8.2 How to Set Up the ADF Source User Library

You create a name for the source user library and then associate that name with the source ZIP file.
To add the ADF source zip file to the user library

1. In the main menu, choose Tools and then Manage Libraries.
2. In the Manage Libraries dialog, with the Libraries tab selected, click New.
3. In the Create Library window, enter a library name for the source that identifies the type of library.
4. Select the Source Path node in the tree structure. Click Add Entry.

---

**Note:**
Do not enter a value for the class path. You need to provide a value only for the source path.

---

5. In the Select Path Entry window, browse to the directory where the file was extracted and select the source ZIP file. Click Select.
6. In the Create Library window, verify that the source path entry has the correct path to the source ZIP file, and deselect Deployed by Default. Click OK.
7. Click OK.

### 48.8.3 How to Add the ADF Source Library to a Project

After the source library has been added to the list of available user libraries, add it to the project you want to debug.

To add the ADF source zip file to the project:

1. In the Applications window, double-click the project to which you want to add the ADF library or right-click the project and choose Project Properties.
2. In the Project Properties dialog, select Libraries and Classpaths.
3. Click Add Library.
4. In the Add Library dialog, under the Users node, select the source library you want to add and click OK.
   
   The source library should appear in the Classpath Entries section in the Project Properties dialog.
5. Click OK.

### 48.8.4 How to Use the EL Expression Evaluator

When the application is paused at a breakpoint, you can use the EL expression evaluator to enter an EL expression for evaluation. You can enter arbitrary EL expressions for evaluation within the current context. If the EL expression no longer applies within the current context, the value will be evaluated to `null`.

The EL Evaluator is different from the Watches window in that EL evaluation occurs only when stopped at a breakpoint, not when stopped at subsequent debugging steps.

The EL Evaluator is available for debugging any JSF application.

---

**Caution:**
Be wary when you are evaluating EL expressions that you do not indirectly change application data and therefore the behavior of the application. For example, if you evaluate #{foo.bar}, the corresponding getBar() method modifies application data.

Before you begin:

It may be helpful to have an understanding of the ADF Declarative Debugger. For more information, see Using the ADF Declarative Debugger.

You will need to complete this task:

Set the desired breakpoints in the application, as described in Setting ADF Declarative Breakpoints. The application must be a JSF application. It does not need to be an ADF application.

To use the EL Evaluator:

1. Start the debugging process by using any of the following techniques.
   - In the main menu, choose Run and then Debug <project_name>.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose Debug.
   - From the task flow diagrammer, right-click an activity and choose Debug. Only task flows that do not use page fragments can be run.

2. When the breakpoint is reached, the EL Evaluator should appear as a tab in the debugger window area. Click the EL Evaluator tab to bring it forward. If it does not appear, in the main menu, choose Window and then Debugger > EL Evaluator.

   Note:

   Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an Execution Point icon (red right arrow) next to the object breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

3. Enter an EL expression in the Expression input field.

   When you click in the field after entering #( or after a period, a discovery function provides a selectable list of expression items, as shown in Figure 48-13. Auto-completion will be provided for easy entry. You can evaluate several EL expressions at the same time by separating them with semicolons.
4. When you finish entering the EL expression, click **Evaluate** and the expression is evaluated, as shown in Figure 48-14.

**Figure 48-14 EL Expression Evaluated**

![Figure 48-14 EL Expression Evaluated](image)

48.8.5 How to View and Export Stack Trace Information

If you are unable to determine what the problem is and you cannot resolve it yourself, typically your next step is to ask someone else for assistance. Whether you post a question in the OTN JDeveloper Discussion Forum or open a service request on Metalink, including the stack trace information in your posting is extremely useful to anyone who will need to assist you further to understand exactly where the problem is occurring.

JDeveloper’s Stack window makes communicating this information easy. Whenever the debugger is paused, you can view the Stack window to see the program flow as a stack of method calls that got you to the current line. You can use the Preferences dialog to set the Stack window preference to include the line number information, as well as the class and method name that will be there by default. Finally, the Stack window context menu option **Export** lets you save the current stack information to an external text file whose contents you can then post or send to whomever might need to help you diagnose the problem.

Before you begin:

It may be helpful to have an understanding of the ADF Declarative Debugger. For more information, see Using the ADF Declarative Debugger.

You will need to complete this task:

- Set the desired breakpoints in the application, as described in Setting ADF Declarative Breakpoints. The application must be a JSF application. It does not need to be an ADF application.

To save stack information to a text file:
1. Start the debugging process by using any of the following techniques.

   - In the main menu, choose Run and then Debug <project_name>.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose Debug.
   - From the task flow diagrammer, right-click an activity and choose Debug. Only task flows that do not use page fragments can be run.

2. When the breakpoint is reached and the debugger is paused, the Stack window should appear as a window to the side of the debugger window area. Click the Stack tab to bring it forward. If the Stack window does not appear, in the main menu, choose Window and then Debugger > Stack.

3. When you want to change the Stack window preference for example to include the line number information in the export file, right-click the Stack window background and choose Preferences, as shown in Figure 48-15.

4. Right-click the Stack window background and choose Export.

5. In the Export Stack dialog, name the file and choose the location where you want to save the file. Click OK.

### 48.9 Setting ADF Declarative Breakpoints

You use the ADF Declarative Debugger features in JDeveloper to declaratively set breakpoints on ADF task flow activities, page definition executables, method, action, and value bindings, ADF Lifecycle phases, and contextual events. Instead of needing to know all the internal constructs of the ADF code, such as method names and class names, you can set breakpoints at the highest level of object abstraction.

You can add breakpoints to task flow activities in the task flow diagrammer or you can launch the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window. In the task flow diagrammer, you can select a task flow activity and use the context menu to toggle or disable breakpoints on that activity, or press the F5 button. After the application pauses at the breakpoint, you can view the runtime structure of the objects in the ADF Structure window as a tree structure. The ADF Data window displays a list of data for a given object selected in the ADF Structure window.

For example, when you set a breakpoint on a task flow call activity in the Browse Orders task flow, a red dot icon appears in the call activity, as shown in Figure 48-16.
When the breakpoint is reached, the application is paused and the icon changes, as shown in Figure 48-17.

Similarly, you can set Before and After breakpoints in the page definition file. You set breakpoints for supported value bindings (see Table 48-1 for the list of supported value binding) and for executables by clicking on the left or right margin next to the item or by selecting from the context menu. Clicking on the left margin adds a Before page definition breakpoint, and clicking on the right margin adds an After page definition breakpoint. Again, a red dot icon that indicates the breakpoint is set, as shown in Figure 48-18.

The page definition file also lets you set breakpoints on contextual events that your page or region within a page raises at runtime, as shown in Figure 48-19.
You can also set Before and After breakpoints on all the ADF lifecycle phases. You can launch the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window, as shown in Figure 48-20.

The Create ADF Lifecycle Phase Breakpoint dialog allows you to select different lifecycle breakpoint options, as shown in Figure 48-21.

Alternatively, you can use the ADF Lifecycle Breakpoints dialog from the ADF Structure window or the task flow diagrammer to set ADF lifecycle phase breakpoints. For more information about ADF lifecycle phases, see Understanding the Fusion Page Lifecycle.

You can define both ADF declarative breakpoints and standard Java code breakpoints when using the ADF Declarative Debugger. Depending on your debugging scenario,
you may only need to use the declarative breakpoints to debug the application. Or you may find it necessary to add additional breakpoints in Java code that are not available declaratively. For information on Java code breakpoints, see How to Set Java Breakpoints on Classes and Methods. Table 48-1 lists the available ADF Declarative Debugger breakpoint locations.

### Table 48-1  ADF Declarative Debugger Breakpoints

<table>

</tr>
<tr>
<td>ADF task flow</td>
<td>Break before activity</td>
<td>Task flow diagrammer</td>
<td>Toggle Breakpoint or F5</td>
<td>Pauses debugging before the activity executes within the JSF Invoke Application phase. The activity where the declarative breakpoint is defined has not yet been executed. An exception are view activities; they pause within the JSF Render Response phase after the view activity is executed, but before the new page is rendered. By pausing at that point, the view activity values can be inspected using the ADF Structure and ADF Data windows.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Breakpoints window Add button</td>
<td>Disable Breakpoint</td>
<td></td>
</tr>
</tbody>
</table>

The ADF Declarative Debugger uses the standard debugger icons and notations for setting, toggling, and indicating the status of ADF declarative breakpoints.

When an ADF declarative breakpoint is set, it appears as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window, as shown in Figure 48-22, Figure 48-23, Figure 48-24, and Figure 48-25.

Figure 48-22  ADF Declarative Breakpoint Enabled on a Task Flow Activity

Figure 48-23  ADF Declarative Breakpoints Enabled in the Page Definition Executables
Setting ADF Declarative Breakpoints

Figure 48-24  ADF Declarative Breakpoint Enabled on a Contextual Event in the Page Definition File

Figure 48-25  ADF Lifecycle Phase Breakpoints Enabled in the ADF Lifecycle Breakpoints Window

When an ADF task flow or page definition declarative breakpoint is disabled, the red icon becomes a gray icon, as shown in Figure 48-26.

Figure 48-26  ADF Declarative Breakpoint Disabled

When an ADF task flow declarative breakpoint is active, the red dot icon has a green checkmark, as shown in Figure 48-27.

Figure 48-27  ADF Declarative Breakpoint Active

When the application is paused at an ADF declarative breakpoint, an Execution Point icon appears, as shown in Figure 48-28.

Figure 48-28  Application Paused at an Execution Point on a Task Flow

When the application is paused at an ADF lifecycle declarative breakpoint, an Execution Point icon appears next to the lifecycle phase in the ADF Lifecycle Breakpoints window, as shown in Figure 48-29. The name of the current ADF lifecycle phase is also displayed in the ADF Structure window.
The Breakpoints window list all breakpoints, including ADF declarative breakpoints, as shown in Figure 48-30.

You can use the Breakpoints window to view the location of the ADF declarative breakpoint in its corresponding source file:

- Double-click a contextual event breakpoint to open the overview editor for the corresponding page definition file. You can then click the Contextual Events tab to view the location of the breakpoint.
- Double-click an ADF lifecycle phase breakpoint to open the ADF Lifecycle Breakpoints window which displays all ADF lifecycle execution points.
- Double-click a task flow activity breakpoint to open the task flow diagrammer for the corresponding task flow.
- Double-click an ADF binding breakpoint to open the overview editor for the corresponding page definition file.

To manage how the debugger handles a breakpoint, you can open the Edit ADF Breakpoint dialog for individual breakpoints that appear in the Breakpoints window. Or, you can select multiple ADF declarative breakpoints and customize the behavior of their common fields.

Table 48-2 lists how an ADF declarative breakpoint will appear in the Breakpoints window under the Description and Type columns.
Table 48-2  Breakpoints Window Display of ADF Declarative Breakpoints

<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Find Execution Point</td>
<td>Supported for declarative breakpoints to display the current execution point open and active within the corresponding editor.</td>
</tr>
<tr>
<td>Step Over (F8)</td>
<td>Supported for task flow activity declarative breakpoints to step from activity to activity within a task flow. If user interaction is required (for example, page displayed), once it is received (for example, button selected), processing will resume and then will pause before the next task flow activity. Supported for page definition executable breakpoints. The application will step to the next page definition executable breakpoint. Supported for ADF lifecycle phase declarative breakpoints to step to the next Before or After ADF lifecycle phase location.</td>
</tr>
</tbody>
</table>
Table 48-3  (Cont.) ADF Declarative Debugger Step Commands

<table>
<thead>
<tr>
<th>ADF Debugger Step Commands</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Step Into (F7)</td>
<td>Supported only for task flow activity declarative breakpoints defined on task flow call activities. Task flow activity declarative breakpoints pause the application just before the activity is executed. The Step Into function provides the ability to pause debugging just prior to executing the called task flow default activity. This action would be the same as placing a task flow activity declarative breakpoint on the called task flow default activity.</td>
</tr>
<tr>
<td>Step Out (Shift F7)</td>
<td>Supported for task flow activity declarative breakpoints to step out of the current called task flow and back into the caller (if any). If user interaction is required (for example, page displayed) once user interaction received (for example, button selected), processing will resume and will pause before the next user interaction or activity within the calling task flow.</td>
</tr>
<tr>
<td>Continue Step (Shift F8)</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Step to End of Method</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Run to Cursor</td>
<td>Not supported for declarative breakpoints.</td>
</tr>
<tr>
<td>Pop Frame</td>
<td>Not supported for declarative breakpoints, as it is for Java code, to return to a previous point of execution.</td>
</tr>
</tbody>
</table>

48.9.1 How to Set and Use Task Flow Activity Breakpoints

After you have created a task flow diagram, you can set ADF declarative breakpoints on task flow activities.

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on a task flow activity:

1. Open the task flow in the task flow diagrammer, or from the Breakpoints window, click the Add icon and select ADF Task Flow Activity Breakpoint.

   If the Breakpoints window is not already displayed, in the main menu, choose Window and then Breakpoints.

2. Set the task flow activity breakpoint.

   • If you use the task flow diagrammer, right-click and choose Toggle Breakpoint from the context menu, or press F5.
     A breakpoint icon appears on the task flow activity.
   
   • If you launched the Create ADF Task Flow Activity Breakpoint dialog from the Breakpoints window, click Browse to select a task flow definition, select the task flow from the Task Flow dropdown list, select the task flow activity from the Activity dropdown list, and click OK.
3. Optionally, configure a breakpoint’s settings to manage the debugger:
   a. In the main menu, choose Window and then Breakpoints.
   b. In the Breakpoints window, select the task flow activity breakpoint you want to configure and click the Edit icon.
   c. In the Edit ADF Task Flow Activity Breakpoint dialog, click the Conditions tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the Actions tab, specify the actions that you want the debugger to take when the breakpoint occurs and click OK.

   For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.
   • In the main menu, choose Run and then Debug <project_name>.
   • From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose Debug.
   • From the task flow diagrammer, right-click an activity and choose Debug. Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an Execution Point icon (red right arrow) appears next to the breakpoint icon on the task flow activity. You can examine the application using various debugger windows.

   **Note:**

   Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an Execution Point icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

   Task flow activity declarative breakpoints pause the application just before the task flow activity is executed (except for view activities).

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See How to Use the ADF Structure Window, and How to Use the ADF Data Window.

7. In the ADF Structure window, select a node and view pertinent information in the ADF Data window.

   Task flow activity declarative breakpoints pause the application just before the task flow activity is executed. You can use the Step Into (F7) function to pause the application just prior to executing the called task flow default activity.

8. Continue debugging the application as required, using the step functions as described in Table 48-3. The key step function is Step Into (F7).
When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 48.9.2 How to Set and Use Page Definition Executable Breakpoints

If your page definition has executables, you can set breakpoints to pause the application before or after these executables. For example, you can set breakpoints to pause the application when iterators are refreshed.

**Note:**

If you are setting an After iterator breakpoint to pause the application after a view object query has been executed, be aware that the application may pause at this breakpoint multiple times. Also be aware that it may pause at this breakpoint even when the query has not been executed. If you need to know whether the query has been executed, select the relevant ADF Business Components in the ADF Structure window and view their corresponding data in the ADF Data window. For more information on how to use these windows, see How to Use the ADF Structure Window, and How to Use the ADF Data Window.

For more information about using Java code breakpoints on view object query execution, see What You May Need to Know About Oracle ADF Breakpoints.

---

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on an executable in the page definition file:

1. In the Applications window, double-click the page definition file that contains the executable in which you want to set a breakpoint.

2. In the overview editor, click the **Bindings and Executables** tab, select an executable from the **Executables** list, and click in the breakpoint margin to the left of the item.

   A breakpoint icon appears in the margin next to the item.

3. Optionally, configure a breakpoint's settings to manage the debugger:

   a. In the main menu, choose **Window** and then **Breakpoints**.

   b. In the Breakpoints window, select the executable breakpoint you want to configure and click the **Edit** icon.

   c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.

   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.
4. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug <project_name>**.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose **Debug**.
   - From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears in the margin next to the breakpoint icon of the executable item. You can examine the application using several debugger windows. The application pauses when the executable binding is refreshed. If this is a taskFlow executable, the pause occurs in the `prepareModel` and the `prepareRender` lifecycles.

   **Note:**
   Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Executable Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See **How to Use the ADF Structure Window**, and **How to Use the ADF Data Window**.

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 48.9.3 How to Set and Use Page Definition Action Binding Breakpoints

You can set breakpoints in the page definition file on action bindings and `methodAction` bindings. The application pauses when the binding is executed.

**Before you begin:**
It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see **Setting ADF Declarative Breakpoints**.

**To set a breakpoint on an action binding in the page definition file:**

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.

2. In the overview editor, click the **Bindings and Executables** tab, select a `methodAction` binding or built-in operation item from the **Bindings** list, and click in the breakpoint margin to the left of the item.

   A breakpoint icon appears next to the item.

3. Optionally, configure a breakpoint's settings to manage the debugger:
a. In the main menu, choose **Window** and then **Breakpoints**.

b. In the Breakpoints window, select the action binding breakpoint you want to configure and click the **Edit** icon.

c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.

d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.

   • In the main menu, choose **Run** and then **Debug <project_name>**.

   • From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose **Debug**.

   • From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the action binding item. You can examine the application using several debugger windows.

The application is paused when the binding is executed.

---

**Note:**

Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See **How to Use the ADF Structure Window**, and **How to Use the ADF Data Window**.

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

8. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

---

**48.9.4 How to Set and Use Page Definition Value Binding Breakpoints**

If the page definition has one of these values bindings, you can set breakpoints to pause the application:

   • Attribute value binding
• Tree value binding
• Table value binding

Before you begin:
It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on a value binding in the page definition file:

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.

2. In the overview editor, click the **Bindings and Executables** tab, select an attribute, tree, or table binding from the **Bindings** list, and click in the breakpoint margin to the left of the item. A breakpoint icon appears next to the value binding.

3. Optionally, configure a breakpoint’s settings to manage the debugger:
   a. In the main menu, choose **Window** and then **Breakpoints**.
   b. In the Breakpoints window, select the binding breakpoint you want to configure and click the **Edit** icon.
   c. In the Edit ADF Page Definition Binding Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

   For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.
   a. In the main menu, choose **Run** and then **Debug <project_name>**.
   b. From the Applications window, right-click the project, `adfc-config.xml`, task flow, or page and choose **Debug**.
   c. From the task flow diagrammer, right-click an activity and choose **Debug**.

5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the attribute value binding. You can examine the application using several debugger windows.

The application pauses before an appropriate method of the ADF source code executes, as described in Table 48-1. New values will be the parameters that go into the method.

---

**Note:**

Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the
breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See How to Use the ADF Structure Window, and How to Use the ADF Data Window.

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

8. Continue debugging the application as required, using the step functions as described in Table 48-3. The key step function is Step Over (F8).

When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

48.9.5 How to Set and Use Page Definition Contextual Event Breakpoints

If the page definition defines contextual events, you can set breakpoints on the contextual events to pause the application.

Before you begin:

It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set a breakpoint on a contextual event in the page definition file:

1. In the Applications window, double-click the page definition file that contains the binding in which you want to set a breakpoint.

2. In the overview editor, click the **Contextual Events** tab, select a contextual event from the **Events** list, and click in the breakpoint margin to the left of the item. A breakpoint icon appears next to the contextual event.

3. Optionally, configure a breakpoint's settings to manage the debugger:
   a. In the main menu, choose **Window** and then **Breakpoints**.
   b. In the Breakpoints window, select the contextual event breakpoint you want to configure and click the **Edit** icon.
   c. In the Edit ADF Contextual Events Breakpoint dialog, click the **Conditions** tab, specify the conditions which apply to the breakpoint. The conditions must be valid for the breakpoint to occur.
   d. Click the **Actions** tab, specify the actions that you want the debugger to take when the breakpoint occurs and click **OK**.

   For example, the usual action for a breakpoint is to halt the program you are debugging, but you may want the debugger to beep and log information to the Log window without halting the program.

4. Start the debugging process by using any of the following techniques.
   - In the main menu, choose **Run** and then **Debug <project_name>**.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose **Debug**.
• From the task flow diagrammer, right-click an activity and choose **Debug**. Only task flows that do not use page fragments can be run.

5. When the application is paused at a breakpoint, an **Execution Point** icon (red right arrow) appears next to the breakpoint icon on the contextual event. You can examine the application using several debugger windows. The application pauses before the contextual event is raised.

```
Note:

Be sure that the application has actually hit a breakpoint by checking the Breakpoints window or checking that there is an **Execution Point** icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.
```

6. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. See **How to Use the ADF Structure Window**, and **How to Use the ADF Data Window**.

7. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

8. Continue debugging the application as required, using the step functions as described in **Table 48-3**. The key step function is **Step Over (F8)**. When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.

### 48.9.6 How to Set and Use ADF Lifecycle Phase Breakpoints

You can set both Before and After ADF lifecycle phase breakpoints on any of the ADF lifecycle phases. For each phase, you can set Before only, After only, or both. You can set breakpoints on as many phases as you want.

You can create the breakpoint and customize the options using the Create ADF Lifecycle Phase Breakpoint dialog from the Breakpoints window menu. Or You can create breakpoints with the default options using the ADF Lifecycle Breakpoints window. After a lifecycle breakpoint has been set, you can edit the options using the Edit ADF Lifecycle Phase Breakpoint dialog, which is also launched from the Breakpoints window.

You can set ADF lifecycle breakpoints on any of the ADF lifecycle phases:

- JSF Restore View
- Initialize Content
- Prepare Model
- JSF Apply Request Values
- JSF Process Validations
- JSF Update Model Values
- Validate Model Updates
• JSF Invoke Application
• Metadata Commit
• Prepare Render
• JSF Render Response

Before you begin:
It may be helpful to have an understanding of when to use ADF declarative breakpoints. For more information, see Setting ADF Declarative Breakpoints.

To set or manage an ADF lifecycle phase breakpoint from the Breakpoints window:

1. In the main menu, choose **Window** and then **Breakpoints**.
2. In the Breakpoints window, click **Add** and choose **ADF Lifecycle Phase Breakpoint**.
3. In the Create ADF Lifecycle Phase Breakpoint dialog **Definition** tab:
   • Select the ADF lifecycle phase where you want to set a breakpoint
   • Select **Before Phase** or **After Phase** breakpoint
4. In the **Conditions** tab, select the options you want and click **OK**.
5. In the **Actions** tab, select the options you want and click **OK**.

To set an ADF Lifecycle Phase Breakpoint using the breakpoint icon:

1. In the Applications window, double-click any task flow configuration file and in the overview editor click the **Diagram** tab.
2. In the toolbar of the task flow diagrammer or in the title bar of ADF Structure window, click the **ADF Lifecycle Breakpoints** icon, as shown in **Figure 48-31**.

**Figure 48-31**  ADF Lifecycle Breakpoints Icon

3. In the ADF Lifecycle Breakpoints window, click in the left margin next to the ADF lifecycle phase to set a Before breakpoint, and on the right margin to set an After breakpoint. A red dot icon appears to indicate the breakpoint is set, as shown in **Figure 48-32**. The breakpoint will be set with the default breakpoint options. To remove the breakpoint, click the red dot icon.

**Figure 48-32**  Setting Breakpoints in the ADF Lifecycle Breakpoints Window
4. If you want to edit breakpoint options, select the breakpoint in the Breakpoints window and click the Edit icon.

To debug an application using ADF Lifecycle Phase Breakpoints:

1. Start the debugging process by using any of the following techniques.
   - In the main menu, choose Run and then Debug <project_name>.
   - From the Applications window, right-click the project, adfc-config.xml, task flow, or page and choose Debug.
   - From the task flow diagrammer, right-click an activity and choose Debug. Only task flows that do not use page fragments can be run.

2. When the application is paused at an ADF lifecycle phase breakpoint, an Execution Point icon (red right arrow) appears next to the breakpoint icon and the ADF lifecycle phase is in bold in the ADF Lifecycle Breakpoints window, as shown in Figure 48-33. You can examine the application using several debugger windows.

   **Figure 48-33  Execution Point Displayed in the ADF Lifecycle Breakpoints Window**

   ![Execution Point Displayed in the ADF Lifecycle Breakpoints Window](image)

   **Note:**

   Be sure that the application has actually hit a breakpoint by checking the Breakpoints window for an breakpoint encounter or checking that there is an Execution Point icon (red right arrow) next to the breakpoint. Depending on where you set the breakpoint, an application may appear to be stopped when in fact it is waiting for user input at the page.

3. The ADF Structure window and the ADF Data window appear by default, as well as several debugger windows. You can examine the runtime structure in the ADF Structure window and its corresponding data in the ADF Data window. The current ADF lifecycle phase is displayed at the top of the ADF Structure window. For more information, see How to Use the ADF Structure Window, and How to Use the ADF Data Window.

4. Select a node in the ADF Structure window and view pertinent information in the ADF Data window.

5. Continue debugging the application as required, using the step functions as described in Table 48-3. The key step function is Step Over (F8).

   When the application is paused, you can remove or disable existing breakpoints and set new breakpoints.
48.9.7 How to Use the ADF Structure Window

When the application is paused at a breakpoint, the ADF Structure window displays a tree structure of the ADF runtime objects and their relationships within the application. In particular, it shows the hierarchy of view ports, which represent either the main browser window or contained regions and portlets. When you select different items in the ADF Structure window, the data display in the accompanying ADF Data window changes. For more information about the ADF Data window, see How to Use the ADF Data Window.

The ADF Structure window and the ADF Data window are shown by default during a debugging session when either of the following is true:

- The project being debugged contains a WEB-INF/adfc-config.xml file.
- The project being debugged contains any ADF Faces tag libraries.

You can launch the ADF Structure window by choosing **Window > Debugger > ADF Structure** in the main menu. From the ADF Structure window, you can launch the ADF Lifecycle Breakpoints window using the **ADF Lifecycle Breakpoints** icon.

When a breakpoint is encountered, the ADF Structure window displays the ADF lifecycle phase and a tree structure of the runtime objects, as shown in Figure 48-34.

![Figure 48-34  ADF Structure Window Showing the Runtime Objects](image)

When you select an item in the ADF Structure window, the data and values associated with that item are displayed in the ADF Data window. Figure 48-35 shows a task flow selected in the ADF Structure window, with its corresponding information displayed in the ADF Data window.
The roots of the hierarchy are the sibling nodes **Scopes** and **ADF Context**. The current view port where processing has stopped appears in bold. Default selections within the tree will be retained from the previous breakpoint, so you can monitor any changes between breakpoints. The ADF object where the ADF declarative breakpoint was defined will be opened in the corresponding JDeveloper editor, either the task flow diagrammer or the overview editor for page definition files.

The ADF Structure tree will be rebuilt each time the application breaks and at subsequent steps to reflect the changed state of the objects. Although the entire tree hierarchy will be displayed, only items within the current view port and its parent view port(s) will be available for selection and further inspection. All other items in the tree hierarchy not in the current context will be dimmed and disabled. You can still use the hierarchy to identify runtime object relationships within the application, but it will be limited to the current context (and its parent view ports).

Table 48-4 lists the different types of items that can be displayed in the ADF Structure window hierarchy tree.

**Table 48-4 ADF Structure Window Items**

<table>
<thead>
<tr>
<th>ADF Structure Tree Item</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Scopes</td>
<td>Displayed at the top of the ADF Structure hierarchy above its sibling <strong>ADF Context</strong> node. There is only one <strong>Scopes</strong> node in the ADF Structure hierarchy. You can expand the <strong>Scopes</strong> node to show a list of child scope nodes (such as <strong>viewScope</strong> and <strong>pageFlowScope</strong>). If you select a child scope node, the ADF Data window displays the variables and values for that scope.</td>
</tr>
<tr>
<td>ADF context</td>
<td>Displayed as the root node of the ADF Structure hierarchy below its sibling <strong>Scopes</strong> node. There will only be one <strong>ADF Context</strong> within the ADF Structure hierarchy.</td>
</tr>
</tbody>
</table>
### Table 48-4  (Cont.) ADF Structure Window Items

<table>
<thead>
<tr>
<th>ADF Structure Tree Item</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>View port</td>
<td>View ports are an ADF Controller concept. For this reason, view ports appear within the ADF Structure hierarchy only when the application being debugged utilizes ADF Controller. View ports can represent one of the following:</td>
</tr>
<tr>
<td></td>
<td>• Browser: Main browser view ports, also known as root view ports, appear as children of the root ADF Context. If multiple browser windows are open during the debugging runtime session, multiple browser view ports are presented within the hierarchy. The label of each browser view port displays the text &quot;Browser&quot;. The view port also provides a tooltip for the view port ID similar to the following example: &quot;Root View Port: 999999&quot;.</td>
</tr>
<tr>
<td></td>
<td>• Region: Region view ports appear as the children of page or page fragments. They are also known as child view ports. The label of each region view port displays the text &quot;Region&quot;. The region also provides a tooltip for the view port ID similar to the following example: &quot;Child View Port: 999999&quot;.</td>
</tr>
<tr>
<td>ADF task flows</td>
<td>The page flow stack corresponding to each view port appears as a hierarchy of ADF task flows. The initial ADF task flow called for the stack is a direct child of its corresponding view port. The label of each ADF task flow reflects the corresponding ADF task flow display name (if any) or its task flow ID. Region view ports will not display the item in their page flow stack hierarchy for their implied unbounded task flow. The task flow also provides a tooltip displaying the ADF task flow path, and a context menu item to open to the corresponding ADF task flow within the editor workspace.</td>
</tr>
<tr>
<td></td>
<td>If ADF Controller is not utilized in the application (or if the page is run outside the context of an ADF task flow), ADF task flows will not appear within the hierarchy.</td>
</tr>
<tr>
<td>Page</td>
<td>Represents the page (view) currently displayed within a browser view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, pages will be children of each browser view port. The label of each page reflects its corresponding runtime view ID. The page also provides a tooltip displaying the page path, and a context menu item to open to the corresponding page within the editor workspace. If a visual user interface in not implemented for the application, the page will not appear within the hierarchy.</td>
</tr>
<tr>
<td>Page fragment</td>
<td>Represents the page fragment currently displayed within a region view port. Presented along with its associated binding container (if any) as a child. If the application being debugged utilizes ADF Controller, page fragments will be children of each region view port. The label of each page fragment node reflects its corresponding runtime view ID. The page fragment also provides a tooltip displaying the source file page definition path, and a context menu item to open to the corresponding page fragment within the editor workspace.</td>
</tr>
<tr>
<td>Binding container</td>
<td>Represents the binding container for the corresponding page or page fragment. The label of each binding container reflects its corresponding file name (page definition file) without the extension. The binding container node will also provide a tooltip displaying the page fragment path. The binding container also appears under current task flows when used to represent task flow activity bindings (for example, method call activity bindings).</td>
</tr>
<tr>
<td></td>
<td>If ADF Model is not utilized for the application, binding containers will not appear.</td>
</tr>
</tbody>
</table>
Table 48-4  (Cont.) ADF Structure Window Items

<table>
<thead>
<tr>
<th>ADF Structure Tree Item</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Application data</td>
<td>Represents the application data objects (for example, ADF Business Components objects or ADF Business Components business service objects) instantiated within the data control frame for the corresponding view port (or binding container if ADF Controller is not used). Application data objects don't need to be currently instantiated for the Application Data node to appear.</td>
</tr>
</tbody>
</table>

48.9.8 How to Use the ADF Data Window

When an application is paused at an ADF declarative breakpoint, the ADF Data window displays relevant data based on the selection in the ADF Structure window. You can launch the ADF Data window by choosing Window > Debugger > ADF Data in the main menu. The content of the ADF Data window based on the selection in the ADF Structure window is summarized in Table 48-5.

Table 48-5  ADF Data Window Content for an ADF Structure Window Selection

<table>
<thead>
<tr>
<th>ADF Structure Window</th>
<th>ADF Data Content</th>
</tr>
</thead>
<tbody>
<tr>
<td>Scopes</td>
<td>Displays memory scope values based on the current context. pageFlowScope will also appear within ADF task flow content for the pageFlowScope values specific to a selected ADF task flow (not necessarily the current context). viewScope will also appear within the view port content for the viewScope values specific to a selected view port (not necessarily the current context).</td>
</tr>
<tr>
<td>ADF context</td>
<td>Displays the ADF context variables and values hierarchy. ADF context variables and values can be inspected by evaluating the #((data.adfContext) EL expression in the EL Evaluator.</td>
</tr>
<tr>
<td>View port</td>
<td>Displays view port details, including the viewScope contents.</td>
</tr>
<tr>
<td>Page flow stack entry</td>
<td>Displays information for the selected page flow stack entry, including current transaction status and ADF Model save point status.</td>
</tr>
<tr>
<td>Page/page fragment</td>
<td>Displays the page or page fragment UI component tree hierarchy for the selected page or page fragment if the page or page fragment has been rendered.</td>
</tr>
<tr>
<td>Binding container</td>
<td>Displays the binding container runtime values, including parameters, bindings, and executables.</td>
</tr>
</tbody>
</table>
Table 48-5  (Cont.) ADF Data Window Content for an ADF Structure Window Selection

<table>
<thead>
<tr>
<th>ADF Structure Window</th>
<th>ADF Data Content</th>
</tr>
</thead>
<tbody>
<tr>
<td>Application data</td>
<td>Displays application data objects (for example, ADF Business Components objects) instantiated within the current binding context. If the business service layer is implemented with a technology other than ADF Business Components objects (for example, EJB) the application data objects will be displayed in a more generic form.</td>
</tr>
</tbody>
</table>

The Scopes node in the ADF Structure window can be expanded to show a list of child scope nodes. When a child scope node is selected in the ADF Structure window, the ADF Data window displays the current context values for the selected memory scope, as shown in Figure 48-36.

Figure 48-36  Child Scope Selected in the ADF Structure Window

If the Scopes node itself is selected, then the full list of memory scopes appears also in the ADF Data windows, which can also be expanded for inspection. Figure 48-37 shows the Scopes node selected in the ADF Structure window, and the viewScope child node being selected with its values displayed in the ADF Data window. You can inspect the values of requestScope, viewScope, pageFlowScope, applicationScope, and sessionScope by expanding each corresponding node. pageFlowScope will also appear within the ADF Task Flow content to reflect the values of the specific ADF task flow currently selected in the ADF Structure window. viewScope will also appear within the view port content to reflect the values of the specific view port currently selected in the ADF Structure window.
When the ADF context is selected in the ADF Structure window, as shown in Figure 48-38, the current value of the ADF context variables will be displayed in the ADF Data window. You can also inspect ADF context variables and values by evaluating the `#(data.adfContext)` EL expression in the EL Evaluator. For more information, see How to Use the EL Expression Evaluator.

Selecting a view port within the ADF Structure hierarchy will display the view port's current view port details in the ADF Data window, as shown in Figure 48-39. Values displayed for each view port are summarized in Table 48-6.
Table 48-6  ADF Data Window Content for View Port

<table>
<thead>
<tr>
<th>View Port</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>View port ID</td>
<td>It is displayed</td>
</tr>
<tr>
<td>Client ID</td>
<td>It is displayed</td>
</tr>
<tr>
<td>Initial task flow ID</td>
<td>Initial ADF task flow on the view ports page flow stack. Not displayed for unbounded task flows. Appears as a link to open the corresponding task flow definition in the editor workspace.</td>
</tr>
<tr>
<td>Current task flow ID</td>
<td>Displayed for bounded task flows and not displayed for unbounded task flows. Current ADF task flow on the view port's page flow stack. Appears as a link to open the corresponding task flow definition in the editor workspace.</td>
</tr>
<tr>
<td>View activity ID</td>
<td>Current ADF task flow view activity ID. Applicable only if the current ADF task flow activity is a view activity.</td>
</tr>
<tr>
<td>Submitted activity ID</td>
<td>ADF task flow activity submitting the current request.</td>
</tr>
<tr>
<td>Final activity ID</td>
<td>ADF task flow activity receiving the current request.</td>
</tr>
<tr>
<td>Bookmark redirect outstanding</td>
<td>(Boolean)</td>
</tr>
<tr>
<td>Exception</td>
<td>(If any)</td>
</tr>
<tr>
<td>View memory scope</td>
<td>View memory scope variables and values for the selected view port.</td>
</tr>
</tbody>
</table>

In the ADF Structure window, each individual ADF task flow within a page flow stack hierarchy is selectable. An ADF task flow selected in the ADF Structure window will display the current task flow information in the ADF Data window, as shown in Figure 48-40. Task flow templates utilized by the selected ADF task flow will be determined by manually navigating to the ADF task flow source file. This is the same way similar functionalities are handled for Java source files. Current information for a selected ADF task flow is summarized in Table 48-7.

Figure 48-40  Task Flow Selected for the ADF Data Window
### Table 48-7  ADF Data Window Content for Task Flow

<table>
<thead>
<tr>
<th>Task Flow</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ADF task flow reference</td>
<td>ADF task flow reference</td>
</tr>
<tr>
<td>Task flow call activity ID</td>
<td>Task flow activity ID for the calling task flow. Will be <code>null</code> for the first ADF task flow within each view port task flow Calls window.</td>
</tr>
<tr>
<td>Calling view activity ID</td>
<td>The calling view activity of the current view activity displayed by the ADF task flow, if any.</td>
</tr>
<tr>
<td>View reached</td>
<td>(Boolean)</td>
</tr>
<tr>
<td>Train model</td>
<td>Only applicable if the ADF task flow is created as a train.</td>
</tr>
<tr>
<td>Transaction started</td>
<td>(Boolean) Identifies the current status of the ADF task flow transactional state. For example, did the ADF task flow begin a new transaction?</td>
</tr>
<tr>
<td>Transaction shared</td>
<td>(Boolean) Identifies the current status of the ADF task flow transactional state. For example, did the ADF task flow join an existing transaction?</td>
</tr>
<tr>
<td>Save point</td>
<td>Identifies the current status of the ADF task flow’s ADF Model save point creation state. For example, was a model save point created upon ADF task flow entry?.</td>
</tr>
<tr>
<td>Remote task flow called</td>
<td>(Boolean)</td>
</tr>
<tr>
<td>Remote task flow return URL</td>
<td>Applies only when calling an ADF task flow remotely. Identifies the URL for return once the task flow called remotely completes.</td>
</tr>
<tr>
<td>Data control frame created</td>
<td>(Boolean)</td>
</tr>
<tr>
<td>Data control frame</td>
<td>Name of data control frame associated with the ADF task flow.</td>
</tr>
<tr>
<td>Page flow memory scopes</td>
<td>Appears as an expandable node to allow inspection of the values of the page flow memory scopes for the task flow selected in the ADF Structure window. The page flow memory scopes will also be displayed within the ADF Structure window’s Scopes node. However, the page flow memory scope for the Scopes node will always be based on the application’s current context, not the selected task flow.</td>
</tr>
</tbody>
</table>

When you select a page or page fragment node in the ADF Structure hierarchy, the corresponding UI component tree is displayed within the ADF Data window, as shown in Figure 48-41. If a page or page fragment is based on a page template, you can include the content coming from the page template outside any facet reference elements by selecting the Include Page Template Content checkbox at the top of the ADF Data window. If the page template content is not included, the page or page fragment UI component tree will appear structurally similar to its source file.
When you select a binding container in the ADF Structure hierarchy, it displays within the ADF Data window the node selection listed in Table 48-8.

### Table 48-8  ADF Data Window Content for Binding Container

<table>
<thead>
<tr>
<th>Binding Container</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Page definition link</td>
<td>Navigates to the corresponding page definition source file and opens it within the editor workspace.</td>
</tr>
</tbody>
</table>

#### Data Controls

Displays the binding container's data controls.

Data controls implemented by ADF Business Components objects and non-ADF Business Components objects will be presented slightly different. ADF Business Components-based data controls will appear similar to the actual business service implementation using row collections. Non-ADF Business Components-based data controls will typically appear as raw member variables similar to what is displayed in the ADF Declarative Debugger Data window. The ADF Data window shows only cached information such as member variables and arrays. Standard debugger functionality can also be used to customize each element.

Each ADF Business Components data control will display the following information:

- Row collections
- Query string for each row collection
- Query string with variable substitution for each row collection
- Application data rows
- Current row indicator
- Change indicator
- Current and original values (if changed within the same request)

#### Parameters

Current values of all binding container parameters.
Table 48-8  (Cont.) ADF Data Window Content for Binding Container

<table>
<thead>
<tr>
<th>Binding Container</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Executables</td>
<td>Displays executables showing current row indicators, and current and original values (if changed within the same request). This includes the following types of executables:</td>
</tr>
<tr>
<td></td>
<td>• Iterator - presents corresponding attribute bindings along with their Refresh and RefreshCondition properties.</td>
</tr>
<tr>
<td></td>
<td>• task flow - current value of the task flow ID assigned to the task flow binding and all of its associated parameter values. Task flow IDs will appear as links navigating to open the corresponding task flow definition source file within the editor workspace. Link text consists of <code>&lt;task flow source document&gt;#{task flow id}</code>.</td>
</tr>
<tr>
<td></td>
<td>• Search region - presented similar to iterators, but also displays criteria and criteria with substitution information.</td>
</tr>
<tr>
<td>Bindings</td>
<td>Displays value, table, tree, and method bindings. Each binding will display the following information:</td>
</tr>
<tr>
<td></td>
<td>• Associated executables</td>
</tr>
<tr>
<td></td>
<td>• Change indicator</td>
</tr>
<tr>
<td></td>
<td>• Current and original values (if changed within the same request)</td>
</tr>
<tr>
<td>Binding container of page template</td>
<td>If the corresponding page or page fragment utilized a page template, the binding container of the page template will appear as a child of page or page fragment binding container content.</td>
</tr>
</tbody>
</table>

When you select a binding container for an application based on non-ADF Business Components objects, the ADF Data window displays the binding container content, as shown in Figure 48-1.

Figure 48-42  Binding Container (Non-Business Components) Selected for the ADF Data Window

![Binding Container (Non-Business Components) Selected for the ADF Data Window](image)

When you select a binding container for an application based on ADF Business Components objects, the ADF Data window displays standard row collection icons, as shown in Figure 48-2.

![Binding Container (Business Components) Selected for the ADF Data Window](image)
Expanding the Parameters node in the ADF Data window displays information similar to that shown in Figure 48-44.

Expanding the Executables node in the ADF Data window displays information similar to that shown in Figure 48-45.
If a value has changed, the changed item will be marked with a blue dot to its left and the previous value is displayed in parenthesis. For instance, suppose the `OrderTotal` value has changed from 7895.81 to 7670.11. The ADF Data window places a blue dot next to `OrderTotal` and its parent `OrdersView1Iterator` and displays the current and previous values in the `Value` column, as shown in Figure 48-46.

**Figure 48-46  A Value Change Is Indicated by a Blue Dot in the ADF Data Window**

Method binding information is displayed in the ADF Data window similar to what is shown in Figure 48-47.

**Figure 48-47  Method Bindings Selected for the ADF Data Window**

When you select an Application Data node from the ADF Structure window, the ADF Data window displays the application objects, such as ADF Business Components objects, instantiated within the current data control frame for the corresponding view port (or binding context if ADF Controller is not used).

Business services implemented by ADF Business Components objects display the application data content, as shown in Figure 48-48 and described in Table 48-9.
Table 48-9  ADF Data Window Content for Application Data

<table>
<thead>
<tr>
<th>Binding Container</th>
<th>Description</th>
</tr>
</thead>
</table>
| Application module | The application module(s) of the corresponding view port data control frame will appear within the application data hierarchy as the root node(s). An application module design time icon will be used to identify the node(s). The application module node(s) will provide the following information:  
  - Application module link - link to open the corresponding application module source file within the editor workspace.  
  - Transaction - the application module current transaction status, if applicable.  
  - View objects  
  - Entity objects |

<td>• Entity object rows - each row displayed will be identified by its concatenated key values. The current entity-state and post-state of the row (e.g., STATUS_MODIFIED) will also be presented.</td>
</tr>
<tr>
<td></td>
<td>• Attributes - attributes contained on each row will display their current values.</td>
</tr>
<tr>
<td></td>
<td>• Modifications - changes made within the same request will be identified by a blue dot to left of attribute, row, and entity objects node labels. Both the old and new value of the modification will be displayed.</td>
</tr>
</tbody>
</table>

Business services implemented by non-ADF Business Components objects display application data content using raw member variables. The format is similar to the
display of non-ADF Business Components content for the binding container, as shown in Figure 48-42.

**48.9.9 What Happens When You Set an ADF Declarative Breakpoint**

When you set an ADF declarative breakpoint, JDeveloper adds the breakpoint to the appropriate class, method, or other construct in the ADF source Java code that corresponds to the breakpoint. Once the breakpoint is set in the code, the standard Java debugger mechanism pauses application execution when the breakpoint is reached. When the breakpoint is reached, it will be identified by a red dot icon in the Breakpoints window. Depending on the type of declarative breakpoint that was reached, it will also appear as a red dot icon in the task flow activity, in the page definition breakpoint margins, or in the ADF Lifecycle Breakpoints window.

For task flow activity breakpoints, the debugger pauses the application within the JSF Invoke Application phase before the activity where the breakpoint is set. In other words, the activity where the breakpoint is set is not executed.

For task flow view activities, however, the application is paused within the JSF Render Response phase after the view activity is executed, but before the new page is rendered.

For a page definition Before executable breakpoint, the debugger pauses the application when the executable is refreshed. For a page definition Before action binding breakpoint, the debugger pauses the application when the binding is executed. For a page definition Before attribute value binding breakpoint, the debugger pauses the application before the attribute's `setInputValue()` method in the ADF source code is executed.

For a Before lifecycle breakpoint, the debugger pauses the application before it enters the next lifecycle phase. For an After lifecycle breakpoint, the debugger pauses the application after the lifecycle phase and before the next phase.

**48.10 Setting Breakpoints in Java Code and Groovy Script**

You can use the ADF Declarative Debugger to set breakpoints on Java classes and methods, as in any standard Java code debugger. You can use Java code breakpoints and Groovy snippet breakpoints in combination with ADF declarative breakpoints. For most ADF applications, ADF declarative breakpoints will provide enough debugging information to troubleshoot the application. For information about using ADF declarative breakpoints, see Setting ADF Declarative Breakpoints. However, you may need to set breakpoints on specific classes or methods for further inspection. Or, you may be debugging a non-ADF application, in which case, you can use Java code breakpoints.

JDeveloper provides a class locator feature that assists you in finding the class you want to break on. If you can obtain Oracle ADF source code, you can enhance your debugging by having access to various ADF classes and methods. For more information about getting ADF source code, see Using ADF Source Code with the Debugger. If you obtained the ADF source, you can further enhance the debugging experience by using the debug library version of the ADF source, as described in How to Use Debug Libraries for Symbolic Debugging.

**48.10.1 How to Set Breakpoints in Groovy Script**

When you define validation rules or attribute default values using Groovy script, you can set breakpoints on these Groovy snippets.
Before you begin:

It may be helpful to have an understanding of when to use code breakpoints instead of ADF declarative breakpoints. For more information, see Setting Breakpoints in Java Code and Groovy Script.

To set Groovy snippet breakpoints to debug an application:

1. In the Applications window, expand the entity object or view object that contains the Groovy script where you want to set a breakpoint, and then double-click the object’s .bcs file.
2. In the source editor, click in the margin next to the appropriate line to set a breakpoint, and then run the debugger.
3. When the application stops on the breakpoint, you can use the Data window to examine the local variables and arguments of the current context.

48.10.2 How to Set Java Breakpoints on Classes and Methods

You can set Java breakpoints on your classes and methods. If you have ADF source code, you can set Java breakpoints in the source as well. If you are debugging an ADF application, you should check to see whether ADF declarative breakpoints can be used instead of Java code breakpoints. For more information, see Setting ADF Declarative Breakpoints.

Before you begin:

It may be helpful to have an understanding of when to use Java code breakpoints instead of ADF declarative breakpoints. For more information, see Setting Breakpoints in Java Code and Groovy Script.

You will need to complete this task:

Before you attempt to use breakpoints, you should try to run the application and look for missing or incomplete data, actions and methods that are ignored or incorrectly executed, or other unexpected results. If you did not find the problem, create a debugging configuration that will enable the ADF Log and send Oracle ADF messages to the Log window. For more information, see How to Create an Oracle ADF Debugging Configuration.

To set Java breakpoints to debug an application:

1. In the main menu, choose Navigate and then Go To Java Type (or press Ctrl +Minus) and use the dialog to locate the Oracle ADF class that represents the entry point for the processing failure.

Note:

JDeveloper will locate the class from the user interface project with current focus in the Applications window. If your workspace contains more than one user interface project, be sure that the one with the current focus is the one you want to debug.

2. Open the class file in the source editor and find the Oracle ADF method call that will enable you to step into the statements of the method.
3. Set a breakpoint on the desired method and run the debugger.
4. When the application stops on the breakpoint, use the Data window to examine the local variables and arguments of the current context.

**Tip:**

If you are using the **Go to source** context menu command in the Data, Watches, or Smart Data window, you can go back to the execution point by using the back button. You can also access the back button through the **Navigate** menu.

Once you have set breakpoints to pause the application at key points, you can proceed to view data in the Data window. To effectively debug your web page's interaction with the ADF Model layer, you need to understand:

- The ADF page lifecycle and the method calls that get invoked
- The local variables and arguments that the ADF Model layer should contain during the course of application processing

Awareness of Oracle ADF processing will give you the means to selectively set breakpoints, examine the data loaded by the application, and isolate the contributing factors.

**Note:**

JSF web pages may also use backing beans to manage the interaction between the page's components and the data. Debug backing beans by setting breakpoints for them as you would with any other Java class file.

### 48.10.3 How to Optimize Use of the Source Editor

Once you have added the ADF source library to your project, you have access to the helpful Quick Javadoc feature (Ctrl+D) that the source editor makes available. Figure 48-49 shows Quick Javadoc for a method like `findSessionCookie()`.

**Figure 48-49 Using Quick Javadoc on ADF API in the Source Editor**

```java
public static SessionCookie findSessionCookie(HttpSession session,
                                          String application,
                                          String poolName,
                                          String configName,
                                          Properties poolProps,
                                          Properties cookieProps)

    // If one does not exist this method will create one.
    private
    return
    if (!
    String
    String
    Properties

    // This method will use the pool name and a named configuration (defined in a sfc file).
```
48.10.4 How to Set Breakpoints and Debug Using ADF Source Code

After loading the ADF source code, you can debug any Oracle ADF code for the current project the same way that you do your own Java code. This means that you can press Ctrl+Minus to type in any class name in Oracle ADF, and JDeveloper will open its source file automatically so that you can set breakpoints as desired.

48.10.5 How to Use Debug Libraries for Symbolic Debugging

When debugging Oracle ADF source code, by default you will not see symbol information for parameters or member variables of the currently executing method. For example, in a debugging session without ADF source code debug libraries, you may see unrecognizable names such as "_slot", as shown in Figure 48-50.

Figure 48-50  Local Symbols Are Hard to Understand Without Debug Libraries

These names are hard to decipher and make debugging more difficult. You can make debugging easier by using the debug versions of the ADF JAR files supplied along with the source while debugging in your development environment.

Note:
The supplied debug libraries should not be used in a test or production environment, since they typically have slightly slower runtime performance than the optimized JAR files shipped with JDeveloper.

The debug library JARs are versions of Oracle ADF JARs that have been compiled with additional debug information. When you use these debug JAR files instead of the default optimized JARs, you will see all of the information in the debugger. For example, the variable `evid` is now identified by its name in the debugger, as shown in Figure 48-51.
Before you begin:

It may be helpful to have an understanding of when to use Java code breakpoints instead of ADF declarative breakpoints. For more information, see Setting Breakpoints in Java Code and Groovy Script.

You will need to complete this task:

Before you replace the standard library JAR, make sure that JDeveloper is not running. If it's currently running, exit from the product before proceeding.

To replace the standard library JARs with the debug library JARs:

1. With JDeveloper closed, make a backup subdirectory of all existing optimized JAR files in the `./BC4J/lib` directory of your JDeveloper installation. For example, assuming `jdev11` is the JDeveloper home directory:

   ```
   C:\jdev11\BC4J\lib> mkdir backup
   C:\jdev11\BC4J\lib> copy *.jar backup
   ```

2. For each ADF library that you want debug symbols for while debugging, copy the `_g.jar` version of the matching library over the existing, corresponding library in the `C:\jdev11\BC4J\lib` directory.

   This is safe to do since you made a backup of the optimized JAR files in the backup directory in Step 2.

   Since debug libraries typically run a little slower than libraries compiled without debug information, this diagnostic message is to remind you not to use debug libraries for performance timing:

   ```
   **************************************************************************
   *** WARNING: Oracle BC4J debug build executing - do not use for timing ***
   **************************************************************************
   ```

3. To change back to the optimized libraries, simply copy the JAR file(s) in question from the `./BC4J/lib/backup` directory back to the `./BC4J/lib` directory.

48.10.6 What You May Need to Know About Setting Java Code Breakpoints

You first need to understand the different kinds of Java code breakpoints and where to create them.

To see the debugger Breakpoints window, choose Window and then Breakpoints in the main menu (or press Ctrl+Shift+R).
You can create a new Java code breakpoint by choosing Create Breakpoint from the context menu in the Breakpoints window. The Breakpoint Type dropdown list controls what kind of breakpoint you will create, as shown in Table 48-10.

**Note:**
You can also use the Create Breakpoint dialog to create an ADF lifecycle phase declarative breakpoint. For information about creating ADF declarative breakpoints, see How to Set and Use ADF Lifecycle Phase Breakpoints.

<table>
<thead>
<tr>
<th>Breakpoint Type</th>
<th>The Breakpoint Occurs Whenever</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exception</td>
<td>An exception of this class (or a subclass) is thrown.</td>
<td>An Exception breakpoint is useful when you don’t know where the exception occurs, but you know what kind of exception it is (for example, <code>java.lang.NullPointerException</code>, <code>java.lang.ArrayIndexOutOfBoundsException</code>, <code>oracle.jbo.JboException</code>). The checkbox options allow you to control whether to break on caught or uncaught exceptions of this class. The Browse button helps you find the fully qualified class name of the exception. The Exception Class combobox remembers the most recently used exception breakpoint classes. Note that this is the default breakpoint type when you create a breakpoint in the breakpoints window.</td>
</tr>
<tr>
<td>Source</td>
<td>A particular source line in a particular class in a particular package is run.</td>
<td>You rarely create a source breakpoint in the Create Breakpoint dialog, because it’s much easier to create it by first using the Navigate &gt; Go to Java Type menu (accelerator Ctrl +Minus), then scrolling to the line number you want — or using Navigate &gt; Go to Line (accelerator Ctrl+G) — and finally clicking in the breakpoint margin at the left of the line you want to break on. This is equivalent to creating a new source breakpoint, but it means you don’t have to type in the package, class, and line number by hand.</td>
</tr>
<tr>
<td>Method</td>
<td>A method in a given class is invoked.</td>
<td>The Method breakpoint is useful for setting breakpoints on a particular method you might have seen in the call stack while debugging a problem. If you have the source, you can set a source breakpoint wherever you want in that class, but this kind of breakpoint lets you stop in the debugger even when you don’t have source for a class.</td>
</tr>
</tbody>
</table>
### Table 48-10 (Cont.) Different Types of Java Breakpoints

<table>
<thead>
<tr>
<th>Breakpoint Type</th>
<th>The Breakpoint Occurs Whenever</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Class</td>
<td>Any method in a given class is invoked.</td>
<td>The Class breakpoint can be used when you might know the class involved in the problem, but not the exact method you want to stop on. This kind of breakpoint does not require source. The <strong>Browse</strong> button helps you quickly find the fully qualified class name you want to break on.</td>
</tr>
<tr>
<td>Watchpoint</td>
<td>A given field is accessed or modified.</td>
<td>The Watchpoint breakpoint can be used to find a problem if the code inside a class modifies a member field directly from several different places (instead of going through setter or getter methods each time). You can pause the debugger when any field is modified. You can create a breakpoint of this type by using the <strong>Toggle Watchpoint</strong> menu item on the context menu when pointing at a member field in your class’s source.</td>
</tr>
</tbody>
</table>

### 48.10.7 How to Edit Breakpoints for Improved Control

After creating a Java code breakpoint you can edit the breakpoint in the Breakpoints window by right-clicking it and choosing **Edit** in the context menu.

**Note:**
You can use the Edit Breakpoint dialog to edit an ADF declarative breakpoint. However, you cannot edit some of the other information such as the information in the **Definition** tab. You can launch the Edit Breakpoint dialog by choosing **Edit** from the context menu in the Breakpoints window. For information about creating ADF declarative breakpoints, see Setting ADF Declarative Breakpoints.

Some of the features you can use by editing your breakpoint are:

- Associate a logical "breakpoint group" name to group this breakpoint with others of the same group name. Breakpoint groups make it easy to enable/disable an entire set of breakpoints in one operation.

- Associate a debugger action to a breakpoint when the breakpoint is hit. The default action is to stop the debugger so that you can inspect the application states, but you can add a sound alert, write information to a log file, and enable or disable group of breakpoints.

- Associate a conditional expression with the breakpoint so that the debugger stops only when that condition is met. The expressions can be virtually any boolean expression, including:
  - `expr == value`
  - `expr.equals("value")`
- `expr instanceof fully.qualified.ClassName`

**Note:**
Use the debugger Watches window to evaluate the expression first to make sure it's valid.

### 48.10.8 How to Filter Your View of Class Members

You can use the debugger to filter the members that are displayed in the debugger window for any class. In the debugger's Data window, selecting any item and choosing **Preferences** from the context menu brings up a dialog that lets you customize which members appear in the debugger and (more importantly sometimes) which members **don't** appear. You can filter by class type to simplify the amount of scrolling you need to do in the debugger Data window. This is especially useful when you might be interested only in a handful of a class's members.

### 48.10.9 What You May Need to Know About Oracle ADF Breakpoints

If you loaded Oracle ADF source code, you can use the breakpoints listed in Table 48-11 to debug your application.

By looking at the Stack window when you hit these breakpoints, and stepping through the source, you can get a better idea of what's going on.

#### Table 48-11  Commonly Used ADF Breakpoints

<table>
<thead>
<tr>
<th>Breakpoint</th>
<th>Breakpoint Type</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>oracle.jbo.JboException</code></td>
<td>Exception</td>
<td>This breakpoint useful for setting a breakpoint on the base class of all ADF Business Components runtime exceptions.</td>
</tr>
<tr>
<td><code>oracle.jbo.DMLException</code></td>
<td>Exception</td>
<td>This is the base class for exceptions originating from the database, like a failed DML operation due to an exception raised by a trigger or by a constraint violation.</td>
</tr>
<tr>
<td><code>doIt()</code></td>
<td>Method</td>
<td>You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition action binding. See How to Set and Use Page Definition Action Binding Breakpoints. If you prefer to use this Java breakpoint, you can find it in the JUCtrlActionBinding class (oracle.jbo.uicli.binding package). This is the method that will execute when any ADF action binding is invoked, and you can step into the logic and look at parameters if relevant.</td>
</tr>
<tr>
<td><code>oracle.jbo.server.ViewObjectImpl.executeQueryForCollection</code></td>
<td>Method</td>
<td>This is the method that will be called when a view object executes its SQL query.</td>
</tr>
<tr>
<td><code>oracle.jbo.server.ViewRowImpl.setAttributeInternal</code></td>
<td>Method</td>
<td>This is the method that will be called when any view row attribute is set.</td>
</tr>
</tbody>
</table>
### Table 48-11 (Cont.) Commonly Used ADF Breakpoints

<table>
<thead>
<tr>
<th>Breakpoint</th>
<th>Breakpoint Type</th>
<th>Usage</th>
</tr>
</thead>
<tbody>
<tr>
<td>oracle.jbo.server.EntityImpl.setAttributeInternal</td>
<td>Method</td>
<td>You can also perform the same debugging function by setting an ADF declarative breakpoint on the page definition attribute value binding. See How to Set and Use Page Definition Value Binding Breakpoints. This is the method that will be called when any entity object attribute is set.</td>
</tr>
</tbody>
</table>

### 48.11 Debugging Groovy Expressions in Business Components

JDeveloper allows you to debug Groovy scripts/expressions. To start the debugger, right-click on the applicationmodule.xml file to start the Oracle ADF Model Tester or right click on the Java file containing the main method to start executing the Java program.

The .bcs file contains Groovy expressions/scripts. The .bcs file is associated with an entity object or view object. When Groovy expressions are debugged, if there is an exception, the debugger pauses in the .bcs file at the line where the exception occurred and displays the errors. If there is no exception, the debugger proceeds to execute the Groovy expressions, and displays the necessary computational data (in the data/smart data/watch etc windows). Just as you can set breakpoints in a Java source code file, JDeveloper allows you to place breakpoints in a .bcs file. When the debugger is run and if the debugger encounters a breakpoint in this .bcs file, the debugger pauses execution at the breakpoint.

The process of debugging Groovy scripts in a .bcs file is similar to that of a Java file. When the debugger is in the .bcs file, use the various step operations, namely Step Into, Step Over, and Step Out to control the execution of the Groovy scripts by the debugger. At any point when the debugger is in the .bcs file, either at a breakpoint, or when the debugger has paused execution at a line because you used the step operations, use the debugger log windows to view execution data.

#### 48.11.1 How to Debug Groovy Expressions

JDeveloper allows you to debug Groovy expressions. To debug Groovy expressions, right-click on the applicationmodule.xml file and select Debug to start the Oracle ADF Model Tester or right-click on the Java file containing the main method to start executing the Java program.

To start debugging Groovy expressions, do any of the following two steps.

1. **Right-click on an application module (applicationmodule.xml file) and select Debug to start the Oracle ADF Model Tester.**

2. **Right-click on the Java file containing the main method and select Debug from the context menu to start executing the Java program. Alternatively, double click on the Java file to open it; right-click inside the Java file and select Debug from the context menu.**

#### 48.11.2 How to Control Groovy Debugging

The application allows you to place breakpoints in the .bcs file and use the step operations (Step Into, Step Over, Step Out) to control the execution of the debugger.
To control Groovy debugging:

1. Double-click on the .bcs file to open it.

   Figure 48-52 shows breakpoints placed in the .bcs file. The debugger executes the Groovy scripts, and if the debugger encounters a breakpoint in the .bcs file, the debugger pauses at this breakpoint. You also use the Step Into, Step Over, Run to Cursor to control Groovy debugging.

   Refer to Managing Breakpoints to read more on breakpoints.

2. When the debugger has paused at the breakpoint in the .bcs file, use the Debug menu, toolbar icons, or keyboard equivalents to use step operations. They are namely Step Into, Step Over, and Step Out.

   Refer to How to Step Into a Method to read more about step operations.

   The application also allows you to run the debugger at the cursor location. Refer How to Run to the Cursor Location to read more.

   The application allows you to pause the debugger while it is running. You can then inspect the state of the program and then continue to run the debugger. Refer How to Pause and Resume the Debugger to read more on how to pause and resume the debugger.

   At any point you can terminate the debugging session. Refer How to Terminate a Debugging Session to read on how to terminate a debugging session.

48.11.3 What Happens When You Debug Groovy Expressions

   The application debugs Groovy scripts in a .bcs file. Place breakpoints in the .bcs file if required to pause the execution of the debugger at these breakpoints. Inspect the information in the data/watch/smart data etc windows whenever the debugger pauses at a breakpoint or when you step operations.

   The debugger executes the Groovy scripts and displays information in the data/watch/smart data etc windows. Figure 48-53 displays a breakpoint set at line 27, and
the debugger has paused at this line, which is the current execution line (indicated by the red arrow). The current execution line indicates a call to the method \texttt{modifyEname()}. This method attempts to modify the Ename attribute of the Emp entity.

**Figure 48-53  Breakpoint placed in Java file at line that references Groovy expressions**

A validator is defined for the Ename attribute. The validator is defined using Groovy script/expression. This Groovy script (along with other Groovy scripts defined for other use cases) reside in a \texttt{.bcs} file. So when you Step Into this method at line 27, the application accesses this \texttt{.bcs} file and executes the validator. **Figure 48-54** shows the debugger paused at line 23 in the \texttt{.bcs} file at a pre-set breakpoint, whilst executing the validator.
48.12 Regression Testing with JUnit

Testing your business services is an important part of your application development process. By creating a set of JUnit regression tests that exercise the functionality provided by your application module, you can ensure that new features, bug fixes, or refactorings do not destabilize your application. JDeveloper’s integrated support for creating JUnit regression tests makes it easy test your application. Its integrated support for running JUnit tests means that any developer on the team can run the test suite with a single mouse click, greatly increasing the chances that every team member can run the tests to verify their own changes to the system. Furthermore, by using JDeveloper’s integrated support for creating and running Apache Ant build scripts, you can easily incorporate running the tests into your automated build process as well. You can create a JUnit test for your application module, run it, and integrate the tests into an Ant build script.

JDeveloper provides the ability to generate JUnit test cases, test fixtures, and test suites. You can create test cases to test individual Java files containing single or multiple Java classes. You can create JUnit test fixtures that can be reused by JUnit test cases. You can group all these test cases into a JUnit test suite, which you can run together as a unit.

You can also use the JUnit BC4J Test Suite wizard to generate a test suite when there is an application module in the project. The wizard generates a test suite, test fixture, and a test case for each view object in the application module.

You can create a separate project to contain your regression tests or to integrate the test files into an existing project. If you are creating an ADF Business Components test, you should create a separate project for testing.

Creating separate projects for testing has the following advantages:

- The ability to compile the base project without having a dependency on JUnit
• The ability to package the base project for deployment without having to exclude the test classes.

If you are creating separate projects for JUnit testing, you should create directory structures that mirror the structure of the packages being tested. You may want to name the test classes using a naming convention that can easily identify the package being tested. For example, if you are testing myClass.java, you can name the test class myClassTest.java.

Although having separate projects has many advantages, in certain cases it may be easier to include the tests within the project.

You can use the Create Test wizards in the context of the project to create a JUnit test case, test fixture, or test suite. However, if you do not want to include these tests as part of the deployment, you may want to separate the tests out in their own project.

Tip:
If you don’t see the Create Test wizards, use JDeveloper’s Help > Check for Updates feature to install the JUnit Integration extension before continuing.

Each test case class contains a setUp() and tearDown() method that JUnit invokes to allow initializing resources required by the test case and to later clean them up. These test case methods invoke the corresponding setUp() and tearDown() methods to prepare and clean up the test fixture for each test case execution. Any time a test in the test case needs access to the application module, it uses the test fixture’s getApplicationModule() method. The method returns the same application module instance, saved in a member field of the test fixture class, between the initial call to setUp() and the final call to tearDown() at the end of the test case.

JDeveloper supports JUnit 4, which allows annotations to be used instead of explicitly having to name the methods setUp() and tearDown(). These annotations — @Before, @After — allow you to have multiple setup and teardown methods, including inherited ones if required.

The generated ExampleModuleConnectFixture is a JUnit test fixture that encapsulates the details of acquiring and releasing an application. It contains a setUp() method that uses the createRootApplicationModule() method of the Configuration class to create an instance of an application module. Its tearDown() method calls the matching releaseRootApplicationModule() method to release the application module instance.

Your own testing methods can use any of the programmatic APIs available in the oracle.jbo package to work with the application module and view object instances in its data model. You can also cast the ApplicationModule interface to a custom interface to have your tests invoke your custom service methods as part of their job. During each test, you will call one or more assertXXX() methods provided by the JUnit framework to assert what the expected outcome of a particular expression should be. When you run the test suite, if any of the tests in any of the test cases contains assertions that fail, the JUnit Test Runner window displays the failing tests with a red failure icon.

The JUnit test generation wizard generates skeleton test case classes for each view object instance in the data model, each of which contains a single test method named testAccess(). This method contains a call to the assertNotNull() method to test that the view object instance exists.

// In ViewInstanceNameTest.java test case class
public void testSomeMeaningfulName() {
Each generated test case can contain one or more test methods that the JUnit framework will execute as part of executing that test case. You can add a test to the test case simply by creating a public void method in the class whose name begins with the prefix test or use the annotation @Test.

48.12.1 How to Obtain the JUnit Extension

JUnit must be loaded as an extension to JDeveloper before it becomes available and appears in the menu system.

Before you begin:

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

To load the JUnit extension:

1. In the main menu, choose Help and then Check For Updates.

2. In the Source page of the Check for Updates dialog, select Search Update Centers and Official Oracle Extensions and Updates and click Next.

   If you have the JUnit zip file or if the JUnit selection does not appear in the Available Updates list, select Install From Local File to load the JUnit zip file.

3. In the Updates page, select JUnit Integration and click Next, as shown in Figure 48-55.

   Figure 48-55  Check for Updates Wizard for Adding JUnit Extension

4. On the License Agreements page, click I Accept and click Finish.
### 48.12.2 How to Create a JUnit Test Case

Before you create a JUnit test case, you must have created a project that is to be tested.

Before you begin:

It may be helpful to have an understanding of using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

To generate a JUnit test case:

1. In the Applications window, right-click the project in which you want to create a test case and choose **New** and then **From Gallery**.

2. In the New Gallery, expand **General**, select **Unit Tests** and then **Test Case**, and click **OK**.

3. In the Select the Class to Test page of the Create Test Case dialog, enter the class under test or click **Browse**.

4. In the Class Browser dialog, locate the class you want to test or enter the beginning letters in the **Match Class Name** field. The **Match Class** list will be filtered for easier identification.

   For example, entering **Summit** filters the list down to four items, as shown in Figure 48-56.

![Class Browser for Selecting Class Files to Test](image)

Select the class and click **OK** to close the dialog. Click **Next**.

5. Select the individual methods you want to test, and click **Next**.

   For example, in Figure 48-57, the four methods that are checked are to be tested.
6. In the Setup Test Case Class page, enter the name of the test case, the package, and the class it extends and select the list of built-in functions JUnit will create stubs for. Click Next.

For example, in Figure 48-58, JUnit will create a stub for the `setUp()` method for the `SummitViewObjectImplTest` test case in the `oracle.summit.base` package of the Summit sample application for Oracle ADF.

7. In the Select Test Fixtures page, select any test fixtures you want to add to the test case or click Browse.
8. Make sure that all the test fixtures you want to add to the test case are selected in the list and click Finish.

48.12.3 How to Create a JUnit Test Fixture

You should create a JUnit test fixture if you require more than one test for a class or method. A JUnit text fixture allows you to avoid duplicating test code that is needed to initialize testing.

Before you begin:

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

To generate a JUnit test fixture:

1. In the Applications window, right-click the project in which want to create a test fixture and choose New and then From Gallery.

2. In the New Gallery, expand General, select Unit Tests and then Test Fixture, and click OK.

3. In the Create Test Fixture dialog, enter the name of the test fixture, the package, and any class it extends.

4. Click OK.

48.12.4 How to Create a JUnit Test Suite

Before you create a JUnit test suite, you should have already created JUnit test cases that can be added to the test suite.

Before you begin:

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

To generate a JUnit test suite:

1. In the Applications window, right-click the project in which want to create a test suite and choose New and then From Gallery.

2. In the New Gallery, expand General, select Unit Test and then Test Suite, and click OK.

3. In the Setup Test Suite Class page of the Create Test Suite dialog, enter the name of the test suite, the package, and the class it extends. Click Next.

   For example, in Figure 48-59, an AllTests test suite is created that extends the java.lang.Object class.
4. In the Select Test Cases page of the Create Test Suite dialog, check that all the test cases you want included in the test suite have been selected. The test cases you have created will populate the list. Deselect any test cases that you do not want included. Click Finish.

48.12.5 How to Create a Business Components Test Suite

The test fixture that is created is a singleton class to reduce the number of connections. If you want to connect or disconnect for each test case, customize the test case using the JUnit 4 annotations @Before and @After.

The JUnit BC4J Test Suite wizard will generate tests for each view object in the application module. If the application module does not have exported methods, the wizard will also generate a test for the application module itself. A generated view object class has the format `view_objectVOTest.java` and is placed into a package with the format `package.view.viewobjectVO`, where `package` is the application module package. A generated application module test has the format `application_moduleAMTest.java` and is placed into a package with the format `package.applicationModule`. A generated test fixture class has the format `applicationmoduleAMFixture.java` and is placed in the same package as the application module test.

The generated all test suite class has the format `AllapplicationmoduleTest.java` and is placed into the package with the same name as the application module package name.

A test case XML file is also generated for each application module or view object test. The XML file contains test methods defined in the application module or view object test cases. It does not include the test methods from the base classes (if any) because there may be too many duplicates.

For instance, after you created a test suite for an application module named `StoreAAppModule` with view objects `Employees1View1` and `Employees1View2` in the package `StoreAPack`, the Applications window displays the test hierarchy as shown in Figure 48-20.
Before you begin:

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see Regression Testing with JUnit.

You will need to complete this task:

Create the application modules in the data model project, as described in Implementing Business Services with Application Modules.

To create a business components test suite:

1. In the main menu, choose File and then New and then From Gallery.

   You will create a separate project for the business components tests.

2. In the New Gallery, expand General, select Projects and then Java Application Project, and click OK.

3. In the Project Name page of the Create Java Project wizard, enter a name and the directory path for the test project, and click Next.

4. In the Project Java Settings page, enter the package name, the directory of the Java source code in your project, and output directory where output class files will be placed, and click Finish.

5. In the Applications window, double-click the application module you want to test.

6. In the overview editor, click the Java navigation tab.

7. In the Java page of the overview editor, click the Edit icon for the Java Class section.

8. In the Select Java Options dialog, select Generate Application Module Class and click OK.

9. In the Java page of the overview editor, click the Edit icon for the Class Interface section.

10. In the Edit Client Interface dialog, shuttle the methods you want to test to the Selected pane, and click OK.

11. In the Applications window, right-click the test project you have created and choose New and then From Gallery.

12. In the New Gallery, expand General, select Unit Tests and then Business Components Test Suite, and click OK.
13. In the Configure Tests page of the JUnit BC4J Test Suite wizard, select values for the following and click Next:

- **Business Component Project**: Select the project that has the application module you want to test.
- **Application Module**: Select the application module you want to test.
- **Configuration**: Choose a local or shared application module.
- **Test Base Class-Application Module Extends**: You can specify different base cases. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.
- **Test Base Class-View Object Extends**: You can specify which class the view object extends. The generated test case classes will extend from that base class where all public abstract methods in the base class will have simple and default implementation method bodies.

14. In the Summary page, verify the selections and click Finish.

### 48.12.6 How to Create Business Components Test Fixture

When you create a business components test suite, a business components test fixture is created with it. You can also create Business Components test fixtures independently.

A generated test fixture class has the format `applicationmoduleAMFixture.java` and put into a package with the format `package.applicationModule`, where `package` is the application module package.

Before you begin:

It may be helpful to have an understanding of the using JUnit regression testing to create test cases. For more information, see [Regression Testing with JUnit](#).

You will need to complete this task:

Create the application modules in the data model project, as described in [Implementing Business Services with Application Modules](#).

To create a business components test fixture:

1. In the main menu, choose **File** and then **New** and then **From Gallery**.

   You will create a separate project for the business components tests.

2. In the New Gallery, expand **General**, select **Projects** and then **Java Application Project**, and click **OK**.

3. In the Project Name page of the Create Java Project dialog, enter a name and the directory path for the test project, and click **Next**.

4. In the Project Java Settings page, enter the package name and the source and output directories, and click **Finish**.

5. In the Applications window, double-click the application module you want to test.

6. In the overview editor, click the **Java** navigation tab and then click the **Edit** icon for the **Java Class** section.
7. In the Select Java Options dialog, select **Generate Application Module Class**, and click **OK**.

8. In the Java page of the overview editor, click the **Edit** icon for the **Class Interface** section.

9. In the Edit Client Interface dialog, shuttle the methods you want to test to the **Selected** pane, and click **OK**.

10. In the Applications window, right-click the test project you have created and choose **New** and then **From Gallery**.

11. In the New Gallery, expand **General**, select **Unit Tests** and then **Business Components Test Fixture**, and click **OK**.

12. In the Configure Tests page of the JUnit BC4J Test Fixture wizard, select values for the following and click **Next**:

   - **Business Component Project**: Select the project that has the application module you want to test.
   - **Application Module**: Select the application module you want to test.
   - **Configuration**: Choose a local or shared application module.

13. In the Summary page, verify the test fixture class and click **Finish**.

### 48.12.7 How to Run a JUnit Test Suite as Part of an Ant Build Script

Apache Ant is a popular, cross-platform build utility for which JDeveloper offers design time support. You can incorporate the automatic execution of JUnit tests and test output report generation by using Ant's built-in `junit` and `junitreport` tasks. The following example shows a task called `tests` from an Ant `build.xml` file. It depends on the `build` and `buildTests` targets that Ant ensures have been executed before running the `tests` target.

```xml
<target name="testCustomizations" depends="compileExtensionClasses">
  <junit printsummary="yes" haltonfailure="yes">
    <classpath refid="customization.classpath">
      <pathelement location="${customization.build.dir}"/>
    </classpath>
    <formatter type="plain"/>
    <test name="oracle.customization.tests.AllTests"/>
  </junit>
</target>
```

The `junit` tag contains a nested `test` tag that identifies the test suite class to execute and specifies a directory in which to report the results. The `junitreport` tag allows you to format the test results into a collection of HTML pages that resemble the format of Javadoc.

To try running the JUnit test from Ant, select the `build.xml` file in the Applications window, and choose **Run Ant Target > tests** from the context menu.
This chapter describes considerations for renaming, moving, and deleting source files, configuration files, objects, attributes, and elements in a Fusion web application. In most cases, JDeveloper can perform the complete refactoring. However, in some cases, you might need to complete some manual steps to refactor.

This chapter includes the following sections:

- About Refactoring a Fusion Web Application
- Renaming Files
- Moving JSF Pages
- Refactoring pagedef.xml Bindings Objects
- Refactoring ADF Business Components
- Refactoring ADF Business Component Object Attributes
- Refactoring Named Elements
- Refactoring ADF Task Flows
- Refactoring the DataBindings.cpx File
- Refactoring Limitations
- Moving the ADF Business Components Project Configuration File (.jpx)

49.1 About Refactoring a Fusion Web Application

JDeveloper provides refactoring options that allow you to make changes to the name and location of attributes, named elements, files, and **ADF Business Components** objects that your application uses. These refactoring options synchronize your changes with other parts of the application that are dependent on the changes. For example, renaming an ADF Business Components object such as a **view object** using the **Rename** option renames any references to it in other XML source files.

In a Fusion Web Application, you can use the refactoring actions (move, rename, and delete) in JDeveloper to make changes to the names and locations of objects. These actions are available from the main menu under **Refactor**, as well as the context menu for each type of object in the Applications window. The move, rename, and delete operations are available for most (but not all) objects and file types. When an object or file is selected in the Applications window, the applicable refactoring operations are enabled in the Refactor menu.
Additionally, there are limitations to what you can refactor in JDeveloper. In some cases, such as moving a project configuration file, there are manual procedures that you can follow. For more information, see Refactoring Limitations.

49.1.1 Refactoring Use Cases and Examples

During the course of development, you will create objects such as entity objects, as needed, to satisfy the needs of the application. Then you might find that you need to subsequently need to delete an object that is no longer used, rename an object to fit a naming convention, or move a set of objects into a different package to consolidate their location. Using JDeveloper, you can refactor these objects so that they are updated and the references to these objects in other objects are also updated to maintain the integrity of the whole application.

49.1.2 Additional Functionality for Refactoring

You may find it helpful to understand other refactoring features available from JDeveloper. Following are links to other functionality that may be of interest.

- For additional information about using JDeveloper features for refactoring Java code, see the "Refactoring Java Projects" section of Developing Applications with Oracle JDeveloper.

49.2 Renaming Files

You can rename files, such as configuration files, using the following methods:

- In the Applications window, select the file and choose File > Rename from the main menu.
- In the Applications window, right-click the file and choose Refactor > Rename.
- In the source editor, select a class name, right-click it, and choose Rename.

To move a file between directories, use the Move menu item.

When you rename or move a file, all references to the file are updated as well. For example when you rename a page definition file, its entry in the DataBindings.cpx file is updated accordingly.

You cannot rename the XML file or Java files associated with an ADF Business Components object independently of the object, as these files must be kept in synch. For more information, see Refactoring ADF Business Components.

49.3 Moving JSF Pages

In addition to the other refactoring operations, you can change the package of a JSF page. In the Applications window, right-click a JSF page and choose Refactor > Move to move the page to another package. Moving the JSF page to another package updates:

- faces-config.xml files that reference the page and its package
- ADF task flows containing views associated with the page
- DataBindings.cpx mappings to the page
49.4 Refactoring pagedef.xml Bindings Objects

The `pagedef.xml` binding objects that you can refactor include bindings and executables. For more information, see Working with Page Definition Files.

Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. For more information, see About Refactoring a Fusion Web Application.

In JDeveloper, open the application that contains the objects you want to refactor.

To refactor `pagedef.xml` binding objects:

1. In the Applications window, select the page node on which you have added a bound object such as an ADF Form or selection list.

2. Right-click the page node and choose Go to Page Definition.

   If the page does not already have a page definition, the Create Page Definition dialog appears. Click OK to create a page definition for the page.

3. In the overview editor, click the Bindings and Executables tab.

   Data bindings such as list bindings and iterator bindings defined for the page display under Bindings and Executables, as shown in Figure 49-1.

   **Figure 49-1  Page Data Binding Definition Overview Tab**

4. In the Structure window, right-click a data binding or executable, choose Refactor and a refactoring option, such as Rename or Delete.

5. To display the usages between bindings, executables, and data controls, right-click a binding or executable and choose Find Usages.
49.5 Refactoring ADF Business Components

ADF Business Components includes objects such as view objects and entity objects. Table 49-1 shows support for refactoring ADF Business Components.

<table>
<thead>
<tr>
<th>Action</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Move</td>
<td>Moves the object to a different package or directory and updates all references.</td>
</tr>
<tr>
<td>Delete</td>
<td>JDeveloper shows all dependencies on the object and permits a forced delete. The application may not work at this point. You may need to resolve broken references.</td>
</tr>
<tr>
<td>Rename</td>
<td>ADF Business Components objects are defined by an XML file. The XML file has a file name identical to the object name. For example, the name of the XML file for a view object named Persons1View is Persons1View.xml. Renaming results in changing the Name attribute, renaming the XML file, and updating all references. For example, the name of an entity (Customer) is stored as an attribute in the XML file (name=Customer). The XML file has the same name the entity name (Customer.xml).</td>
</tr>
<tr>
<td>Find Usages</td>
<td>JDeveloper shows all dependencies on the object.</td>
</tr>
</tbody>
</table>

Note:

Refactoring does not cross abstraction layers. For example, when a view object is created based on the Dept entity object, it is named DeptView by default. Renaming the Dept entity object updates the entity usage in DeptView, but does not change the name of the view object.

Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. For more information, see About Refactoring a Fusion Web Application.

In JDeveloper, open the application that contains the object you want to refactor.

To refactor ADF Business Components objects:

1. In the Applications window, expand the project and then the Application Sources node and then the package containing the object you want to refactor.

2. Right-click the object and choose Refactor and a refactoring option.

   • To change the name of the object, choose Rename.

     The Rename dialog displays the current name of the object. Enter the new object name and click OK to proceed with the refactoring or Cancel to cancel.

     You can optionally select Preview and click OK to display the usages in the Log window, which allows you to proceed with the refactoring or cancel. When you
click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.

- To change the location of the object, choose Move.

The Move dialog displays the current location of the object. Enter the new package name, or click Browse to navigate to it. Click OK to proceed with the refactoring or Cancel to cancel.

- To remove the object, choose Delete.

The Confirm Delete dialog displays the name of the object and searches for usages. Click Show Usages to display where the object is used. Click Yes to proceed with the refactoring or No to cancel. Click Preview to display the results in the Log window, which allows you to proceed with the refactoring or cancel. When you click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.

By default JDeveloper searches in the current application for usages of the object. You can change the scope of the search by choosing from the Finding Usages In dropdown list, or by clicking the Manage Working Sets icon.

### 49.6 Refactoring ADF Business Component Object Attributes

Table 49-1 shows support for refactoring attributes of ADF Business Component entity objects and view objects.

<table>
<thead>
<tr>
<th>Action</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Move</td>
<td>Not supported.</td>
</tr>
<tr>
<td>Delete</td>
<td>JDeveloper shows all dependencies on the attribute and permits a forced delete. The application may not work at this point. You may need to resolve broken references.</td>
</tr>
<tr>
<td>Rename</td>
<td>Attributes share data elements represented in entity and view objects (see About Entity Objects for more information). References to the attribute are updated when you rename the attribute. Renaming results in changing the Name attribute and updating all references. This includes updating the service implementation of view attributes used in the generated service of an application module. Renaming an attribute does not change the data it represents, nor does it rename the underlying table column.</td>
</tr>
<tr>
<td>Find Usages</td>
<td>JDeveloper shows all dependencies on the attribute.</td>
</tr>
</tbody>
</table>

Before you begin:

It may be helpful to have an understanding of the options you have for refactoring. For more information, see About Refactoring a Fusion Web Application.

In JDeveloper, open the application that contains the attribute you want to refactor.

To refactor attributes:
1. In the Applications window, double-click the entity object or view object that contains the attribute you want to refactor.

2. In the overview editor, click the Attributes navigation tab.

3. In the Name column, right-click the attribute and choose a refactoring option.
   - To change the name of the attribute, choose Rename.
     The Rename dialog displays the current name of the attribute. Enter the new attribute name and click OK to proceed with the refactoring or Cancel to cancel.
     You can optionally select Preview and click OK to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.
   - To see where the attribute is used, choose Find Usages.
     The Log window displays usages of the attribute. When you click a usage in the Log window, the file that contains the usage is opened in the Source editor and the containing line is highlighted.
   - To remove the attribute, choose Delete.
     In the Confirm Delete dialog, click Show Usages to display where the attribute is used. Click Yes to proceed with the refactoring or No to cancel. Click Preview to display the results in the Log window, which allows you to proceed with the refactoring or cancel.
   - To change the type of the attribute, choose Change Type.
     In the Change Type dialog, choose the new type from the Type dropdown list, or click Browse to find the type. Click OK to proceed with the refactoring or Cancel to cancel.
     You can optionally select Preview and click OK to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.

49.7 Refactoring Named Elements

Named elements are any elements in the XML schema that can be referenced by a Name attribute. A named element is not an object or an attribute. Table 49-3 shows support for refactoring named elements in an XML schema.

<table>
<thead>
<tr>
<th>Action</th>
<th>Result</th>
</tr>
</thead>
<tbody>
<tr>
<td>Move</td>
<td>Not supported.</td>
</tr>
<tr>
<td>Delete</td>
<td>Not supported.</td>
</tr>
<tr>
<td>Rename</td>
<td>One exception to the definition of named elements is the design time element Attr, which does have a Name attribute. Attr is a name-value pair, is not accessible from the code editor, and should not be renamed.</td>
</tr>
<tr>
<td>Find Usages</td>
<td>JDeveloper shows all dependencies on the named element.</td>
</tr>
</tbody>
</table>

Before you begin:
It may be helpful to have an understanding of the options you have for refactoring. For more information, see About Refactoring a Fusion Web Application.

In JDeveloper, open the application that contains the named element you want to refactor.

To refactor named elements:

1. In the Applications window, double-click the entity object or view object that contains the named element you want to refactor.

2. In the editor window, click the Source tab, and search or scroll to find the named element.

   Named elements are indicated by Name="<element>" in the source code, for example:

   <Key Name="PersonsAffContactChk">

   A named element is not an object or attribute.

3. Right-click the named element you want to refactor and choose Refactor and a refactoring option.

   • To change the name of the element, choose Rename.
   
     The Rename dialog displays the current name of the element. Enter the new element name and click OK to proceed with the refactoring or Cancel to cancel.
     
     You can optionally select Preview and click OK to display the usages in the Log window, which allows you to proceed with the refactoring or cancel.

   • To remove the element, choose Delete.
   
     In the Confirm Delete dialog, click Show Usages to display where the element is used. Click Yes to proceed with the refactoring or No to cancel. Click Preview to display the results in the Log window, which allows you to proceed with the refactoring or cancel.

49.8 Refactoring ADF Task Flows

For more information, see Refactoring to Create New Task Flows and Task Flow Templates.

49.9 Refactoring the DataBindings.cpx File

The DataBindings.cpx file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime (see DataBindings.cpx Syntax for more information). This file is a registry used to quickly find all .cpx, .dcx, .jpx, and .xcfg files, which are themselves registries of metadata.

If you rename the DataBindings.cpx file to a new name, such as DataBindingsNew.cpx, the change is added to the adfm.xml file.

The following example shows the contents of the adfm.xml file after DataBindings.cpx is refactored to DataBindingsNew.cpx.

```
<?xml version="1.0" encoding="UTF-8" ?>
<MetadataDirectory xmlns="http://xmlns.oracle.com/adfm/metainf"
```
Additionally, to enable the application to access the correct bindings file, the ID value is changed to an ID similar to the one shown in the following example.

<Application xmlns="http://xmlns.oracle.com/adfm/application" version="11.1.1.49.28" id="DataBindingsNew" SeparateXMLFiles="false" Package="adf.sample.view" ClientType="Generic">

49.10 Refactoring Limitations

Table 49-4 summarizes the limitations of JDeveloper's refactoring support.

<table>
<thead>
<tr>
<th>Area</th>
<th>Limitation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Database</td>
<td>When a database artifact used in an ADF Business Components object is renamed, the object needs to be updated. This type of refactoring is currently not supported.</td>
</tr>
<tr>
<td>Service interface</td>
<td>A service interface defines a contract between two separate pieces of software. For example, the ADF Business Components service interface is responsible for exposing business components to the view and model layers. Changing the name of a service interface can cause a conflict. While developing the application, consider removing the service interface, refactoring the object, and regenerating the service interface. Additionally, if your service interface defines a find operation based on a view criteria that specifies bind variables, changing the number or order of the bind variables in the underlying view criteria will require that you regenerate the service interface. For more information, see Creating SOAP Web Services with Application Modules.</td>
</tr>
<tr>
<td>Java literal references</td>
<td>The Java code generated by ADF Business Components has literal references to the XML metadata. These literal references are updated during refactoring operations. Generated (type safe) methods are also updated. Also, the refactor delete operation is available for local Java variables. However, if the application code directly refers to the metadata, these references are not updated.</td>
</tr>
<tr>
<td>Domain</td>
<td>If a domain needs to be renamed or moved, you must create the new domain, then change the type of existing domain usages. For example, you might rename a domain called EmployeeID to EmployeeNumber. In addition, the entity Emp has an attribute called Empno that is of type EmployeeID. After creating the new domain EmployeeNumber, go to the attributes page for the entity, right-click Empno and choose Change Type. This switches Empno from EmployeeID to EmployeeNumber.</td>
</tr>
<tr>
<td>Security</td>
<td>Security policies in the policy store may reference the name of an entity object, attribute, page, or task flow. These policy definitions are not updated in response to the refactoring of the object itself.</td>
</tr>
</tbody>
</table>
### Table 49-4 (Cont.) Refactoring Limitations

<table>
<thead>
<tr>
<th>Area</th>
<th>Limitation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Resource Bundles</td>
<td>Entity object definitions can reference a resource in one or more arbitrary resource bundle (.properties) files that you create. You can use this file to define labels for the attributes of entity objects. However, if you rename the .properties file you created, JDeveloper will not update the entity object definitions to reflect the new file name. As an alternative to resource bundle files that you create, you can specify a project setting to generate a single, default resource bundle file for the data model project. In this case, JDeveloper will not allow you to rename this generated file. However, if you attempt to change the project-level default resource bundle file, JDeveloper will warn you about the change. The data model project will honor the new ADF Business Components project-level setting for any objects that have not yet been linked to the default resource bundle file; all existing Business Components that have already been linked to the original default file will continue to use it instead.</td>
</tr>
<tr>
<td>.jpx project configuration file</td>
<td>Renaming the ADF Business Components project configuration file (.jpx) is not supported. In previous versions of JDeveloper, ADF Business Components project configuration .jpx files were created only in the root package of the src directory of a project and were named with the same base name as the project. The ADF Business Components objects (entity objects, view objects, and application modules) were all created in the model package (for example, /model/AppModule.xml), but the /Model/.jpx is not. This may cause a reusability problem when attempting to package them in ADF JAR files for use on the class path. There may be name conflicts because several projects are named Model.</td>
</tr>
</tbody>
</table>

#### 49.11 Moving the ADF Business Components Project Configuration File (.jpx)

Although refactoring the ADF Business Components project configuration file (.jpx) is not supported, you may need to change its name or location to avoid conflicts when sharing your project contents as an ADF library. The .jpx file contains configuration information that JDeveloper uses in the design time to allow you to create the data model project with ADF Business Components. If you need to refactor this file, you must do so manually.

**Before you begin:**

It may be helpful to have an understanding of the options you have for refactoring. For more information, see [About Refactoring a Fusion Web Application](#).

To manually move the ADF Business Components project configuration file (.jpx):

1. Move the .jpx file to the new source tree location.

   For example, you can move the Model.jpx file from src/Model.jpx to src/newpackage/name/here/Model.jpx.

2. Change the .jpx file contents. The PackageName attribute of the root element JboProject needs to have the correct value.

   For example, you can specify PackageName="newpackage.name.here".
3. Change the `jbo.project` attributes in all `common/bc4j.xcfg` files that contain elements referred to in the `.jpx` file to include the new package name.

   For example:

   ```xml
   <AppModuleConfig name="ScottDeptAMLocal"
   ApplicationName="newpackage.name.here.ScottDeptAM"
   DeployPlatform="LOCAL" JDBCName="scottdb"
   jbo.project="newpackage.name.here.Model">
   ```

4. Change the contents of the JDeveloper project file (the `.jpr` file):

   - Set the new `.jpx` package location. If you later change the default package in the project properties, you will again raise a `NotFound` error for the `.jpx` file.

     For example:

     ```xml
     <value n="defaultPackage" v="newpackage.name.here"/>
     ```

   - Fix any `ownerURL` elements in the `ownerMap` that contain references to the old location of the `.jpx` file.

     For example:

     ```xml
     <url n="ownerURL" path="src/newpackage/name/here/Model.jpx"/>
     ```
This chapter describes how to package certain Oracle ADF components into the ADF Library for reuse in Fusion web applications. Reusable ADF components are application modules, business components (entity objects, view objects, associations), data controls, task flows, page templates, and declarative components.

This chapter includes the following sections:

- About Reusable Components
- Packaging a Reusable ADF Component into an ADF Library
- Adding ADF Library Components into Projects
- Removing an ADF Library JAR from a Project

50.1 About Reusable Components

In the course of application development, certain components will often be used more than once. Whether the reuse happens within the same application, or across different applications, it is often advantageous to package these reusable components into a library that can be shared between different developers, across different teams, and even across departments within an organization.

In the world of Java object-oriented programming, reusing classes and objects is just standard procedure. With the introduction of the model-view-controller (MVC) architecture, applications can be further modularized into separate model, view, and controller layers. By separating the data (model and business services layer) from the presentation (view and controller layers), you ensure that changes to any one layer do not affect the integrity of the other layers. You can change business logic without having to change the UI, or redesign the web pages or front end without having to recode domain logic.

Oracle ADF and JDeveloper support the MVC design pattern. When you create an application in JDeveloper, you can choose many application templates that automatically set up data model and user interface projects. Because the different MVC layers are decoupled from each other, development can proceed on different projects in parallel and with a certain amount of independence.

ADF Library further extends this modularity of design by providing a convenient and practical way to create, deploy, and reuse high-level components. When you first design your application, you design it with component reusability in mind. If you created components that can be reused, you can package them into JAR files and add them to a reusable component repository. If you need a component, you may look into the repository for those components and then add them into your project or application.

For example, you can create an application module for a domain and package it to be used as the data model project in several different applications. Or, if your application...
will be consuming components, you may be able to load a page template component from a repository of ADF Library JARs to create common look and feel pages. Then you can put your page flow together by stringing together several task flow components pulled from the library.

An ADF Library JAR contains ADF components and does not, and cannot, contain other JARs. It should not be confused with the JDeveloper library, Java EE library, or Oracle WebLogic shared library.

Table 50-1 lists the reusable components supported by ADF.

### Table 50-1  Oracle ADF Reusable Components

<table>
<thead>
<tr>
<th>Reusable Component</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Data control</td>
<td>Any data control can be packaged into an ADF Library JAR. Some of the data controls supported by Oracle ADF include application modules, Enterprise JavaBeans, web services, URL services, JavaBeans, and placeholder data controls.</td>
</tr>
<tr>
<td>Application module</td>
<td>When you are using ADF Business Components and you generate an application module, an associated application module data control is also generated. When you package an application module data control, you also package up the ADF Business Components associated with that application module. The relevant entity objects, view objects, and associations will be a part of the ADF Library JAR and available for reuse.</td>
</tr>
<tr>
<td>Business components</td>
<td>Business components are the entity objects, view objects, and associations used in the ADF Business Components data model project. You can package business components by themselves or together with an application module.</td>
</tr>
<tr>
<td>Task flows and taskflow templates</td>
<td>Task flows can be packaged into an ADF Library JAR for reuse. If you drop a bounded task flow that uses page fragments, JDeveloper adds a region to the page and binds it to the dropped task flow. ADF bounded task flows built using pages can be dropped onto pages. The drop will create a link to call the bounded task flow. A task flow call activity and control flow will automatically be added to the task flow, with the view activity referencing the page. If there is more than one existing task flow with a view activity referencing the page, it will prompt you to select the one to automatically add a task flow call activity and control flow. If an ADF task flow template was created in the same project as the task flow, the ADF task flow template will be included in the ADF Library JAR and will be reusable.</td>
</tr>
<tr>
<td>Page templates</td>
<td>You can package a page template and its artifacts into an ADF Library JAR. If the template uses image files and they are included in a directory within your project, these files will also be available for the template during reuse.</td>
</tr>
<tr>
<td>Declarative components</td>
<td>You can create declarative components and package them for reuse. The tag libraries associated with the component will be included and loaded into the consuming project.</td>
</tr>
</tbody>
</table>

You can also package up projects that have several different reusable components if you expect that more than one component will be consumed. For example, you can create a project that has both an application module and a bounded task flow. When
this ADF Library JAR file is consumed, the application will have both the application module and the task flow available for use. You can package multiple components into one JAR file, or you can package a single component into a JAR file. Oracle ADF and JDeveloper give you the option and flexibility to create reusable components that best suit you and your organization.

You create a reusable component by using JDeveloper to package and deploy the project that contains the components into a ADF Library JAR file. You use the components by adding that JAR to the consuming project. At design time, the JAR is added to the consuming project's class path and so is available for reuse. At runtime, the reused component runs from the JAR file by reference. For the procedure to add the JAR manually, see How to Add an ADF Library JAR into a Project Manually. For the procedure to add the JAR using the JDeveloper Resource Catalog, see How to Add an ADF Library JAR into a Project using the Resources Window.

Before you proceed to create reusable components, you should review the guidelines for creating reusable components.

50.1.1 Creating Reusable Components

Creating and consuming reusable components should be included in the early design and architectural phases of software projects. You and your development team should consider which components are candidates for reuse, not only in the current applications but also for future applications and including those applications being developed in other departments.

You and your team should decide on the type of repository needed to store the library JARs, where to store them, and how to access them. You should consider how to organize and group the library JARs in a structure that fits your organizational needs. You should also consider creating standardized naming conventions so that both creators and consumers of ADF Library JARs can readily identify the component functionality.

Tip:

If, in the midst of development, you and your team find a module that would be a good candidate for reuse, you can use the extensive refactoring capabilities of JDeveloper to help eliminate possible naming conflicts and adhere to reusable component naming conventions.

50.1.1.1 Naming Conventions

When you create reusable components, you should try to create unique and relevant names for the application, project, application module, task flow, connection, or any other file or component. Do not accept the JDeveloper wizard default names such as Application, Project, ViewController, AppModule, task-flow-definition.xml, or Connection. You want to try to have unique names to avoid naming conflicts with other projects, components, or connections in the application. Naming conflicts could arise from components created in the consuming application and those loaded from other JAR files. Table 50-2 lists the objects that you may be required to rename.

Table 50-2  Example Unique and Relevant Names for Reusable Components

<table>

</tbody>
</table>

#### 50.1.1.1 Naming Considerations for Packages

Be aware that some components use the default package name of the project without allowing the name to be explicitly set. In this situation, you must take extra care to avoid package name collisions. You can set the package name in the application creation wizard and you should check the names in the Project Properties dialog afterwards. If you don’t set the package name, it will default to a variant of the project name, typically with the first letter being lowercase. For example, a project with the name `Project1` will have a default package name of `project1`. You should manually change the package name to a more unique name before you proceed to build the project.

---

**Note:**

The basic package naming requirement is that ADF metadata registries (.dcx, .cpx, and so on) are generated based on the project’s package name, and you should avoid metadata naming conflicts between projects that will be combined at runtime.

---

When you are creating a reusable component’s web resource files (such as JSPs, HTMLs, and task flows), you should create them in their own relative directories. When the JAR is deployed into another application, there will be less chance for conflict between the reusable component’s files and the consuming application’s files.
Note:
You can override the staleness period setting of 364 days for all static web application resources in ADF Libraries by adding initialization parameters to the web.xml file. For more information, see web.xml.

50.1.1.2 Naming Considerations for Connections

Often, several modules in an application will connect to the same data source. You should standardize the connection name to the same data source to avoid confusion because there is only one namespace for connections across the application. This would require coordination with other developers, component producers, and component consumers. For example, if customers and suppliers both have a connection to the same database, the connection name should be standardized to an agreed upon name, such as orders_db.

ADF Library JARs (with connections) may be used in different applications with different connection requirements. ADF Library JAR producers should choose connection names that are at least representative of the connection source, if not the actual standardized connection name. Be aware that consumers of the JAR that was created with connections will be required to satisfy the connection requirements when they add the component to the application.

For example, for a database connection, choosing an endpoint host name is usually not appropriate. The most appropriate name is a complete representative for the schema. Acceptable example names for connections are oracle-appsdb and oracle-customersdb. You should realize that if many reusable components use different names for the same logical connection, then the consumer of the component will have to satisfy each one individually with duplicate information. The consumer will have to supply connection details for several different connection names, when in fact they all refer to the same instance.

50.1.1.3 Naming Considerations for Applications with EJB Projects

If an application has both EJB projects and a web application project with data binding, you should check to see that the EJB component names are not in conflict with any other web application project component names. The EJB project components may have global scope because the project is automatically added to the global class path of all web projects in the application. The web application project may mistakenly access a component with the same name in the EJB project rather than within its own project.

For example, if both an EJB project and a web-based project have a test1.jspx page, when the web-based project is run, it may try to run the EJB project test1.jspx page.

At runtime, JDeveloper detects if there are EJB projects and web application projects with data binding in the same application. If there are both types in the application, when the project is run and the server starts up, a warning message will appear in the Log window.

50.1.2 The Naming Process for the ADF Library JAR Deployment Profile

Before you package the project, you must create a deployment profile with the name and path for the JAR file. You should choose a name that follows you and your development team’s naming convention and that is descriptive of the function of the
component. You should realize that the consuming project may also include other JAR files from other software authors.

For example, if the component is a task flow for self-service paying, you might name it mycompany.hcm.pay.selfservice.taskflows.jar. Other examples are oracle.apps.hcm.pay.model.jar and mycompany.hcm.pay.model.overrides.jar.

When you create the deployment profile, JDeveloper will present a default name with the following format:

```
adflibidentifierN
```

Where `identifier` is random number up to three-digits and `N` is a number that starts with 1 and increments by 1 for each iteration of the profile.

For example, the default name for a profile may be `adflib7491` (random number is 749 and suffix is 1). The default name for the another profile may be `adflib51` (random number is 5 and suffix is 1).

You can change this default name to a name of your choice.

### 50.1.1.3 Keeping the Relevant Project

When you are creating reusable components, you should eliminate any projects that are not relevant to the reusable component. For example, if you want to create a reusable application module, you would need a data model project, but you would not need a user interface project. In this instance, if you had created an application with both a data model and a user interface project, you could delete the user interface project. Of course, you should rename the default name `Model` to something more relevant, such as `BackOfficeService`. Similarly, if you are creating a reusable task flow that is not databound, you can delete any data model project from the application.

### 50.1.1.4 Selecting the Relevant Feature

If you know the technology scope of your consuming projects, you can design your component with technologies that will be compatible. For example, if the consuming application uses only standard JSF Faces, then it may not be compatible with a declarative component that is built with ADF Faces.

When you create your application, you can define the features using the Create Application Wizard by selecting from the application template.

After the project has been created, you can define the technology using the Features page of the Project Properties dialog.

### 50.1.1.5 Selecting Paths and Folders

If you are using the file system to store your ADF Library JARs, you should select file system locations that can function as repositories. You may want to put groups of JARs into a common directory folder, for example, `C:\ADF\jdev\DevTeamADFRepository`. If your team or organization plans to share ADF Library JARs, you should consider setting up network-accessible repository folders, directories, or services. The Resources window has provisions to connect to different repository sources and make multiple connections. For more information about accessing ADF Library JARs using the Resources window, see Using the Resources Window.
50.1.1.6 Including Connections Within Reusable Components

If the project you are packaging into an ADF Library JAR includes a connection, that information can be included in the JAR and may be available to the consuming project. Oracle ADF uses connection architecture which defines a connection as two parts, the connection name and the connection details (or endpoint definition). JDeveloper will present the producer of the JAR the option to package the connection name only or to include connection details with the connection name.

If a connection is present in the project, the packaged ADF Library JAR will contain a `jar-connections.xml` file and a `jar-adf-config.xml` file. They will be added to the `META-INF` directory. The `jar-connections.xml` file contains the connection name and other relevant connection information. The `jar-adf-config.xml` file stores the information about the credentials used for the connections. If connection credentials were also specified, then a `jar-credential-jazn-data.xml` will also be included for the credential store. You can select the individual connections or connection types that you want to be packaged with the ADF Library JAR when you create the ADF Library JAR deployment profile. You make connection selections in the Create or Edit ADF Library Deployment Profile Properties dialog Connections page, as described in How to Package a Component into an ADF Library JAR.

When an ADF Library JAR is being added to a project, JDeveloper checks for conflicts between the application’s connections and the JAR’s connections. A dialog will be presented to allow you to decide whether to proceed with adding the JAR to the project. Connections defined in the ADF Library JAR may be added to the consuming project, depending on the following conditions:

- If the connection defined in the JAR is fully configured and there are no connection name conflicts with the consuming project, a new connection will be added.
- If the connection defined in the JAR is partially configured, a new connection will be added to the consuming project but it must be configured before use. Connection dialogs may appear to allow the user to enter connection information. This partially configured connection may be indicated by an incomplete icon.
- If the connection defined in the JAR has the same name as the application’s connection, it will not be added to the project. The application’s existing connection will be used.
- If the connection defined in the JAR has the same name as the application’s connection but is of different type, the JAR’s connection will not be added to the project. For example, if a database connection in the JAR and a URL connection in the application have the same name, the database connection will not be added to the application.

For instructions on how to add an ADF Library to a project that includes connections, see How to Add an ADF Library JAR into a Project using the Resources Window.

---

**Note:**

In the process of adding the ADF Library to a project, you will see one message displayed in the Log window for each connection defined in the JAR. The messages indicate the merge action taking place in the project.
50.1.2 Reusable ADF Components Use Cases and Examples

Packaging projects into ADF Library JARs allows components to be reused multiple times in the same or in different applications. Different development teams can create and consume projects and create libraries of reusable modules. ADF Library JARs support the M-V-C design pattern. You can create ADF Libraries and access them using drag and drop from the Resources window.

For instance, you can package up an application module into an ADF Library JAR and place it in a public folder for other team to use. Different implementation teams may access that JAR to create their applications. They may use the application module to create different pages for their use instead on having to create their own application modules. When there is a change in the model, the original developer can repack the application module and republish the ADF Library JAR. The other implementation teams can update their application using the updated ADF Library.

50.1.3 Additional Functionality for Reusable ADF Components

You may find it helpful to understand other ADF features before you work with reusable ADF components. Following are links to other functionality that may be of interest.

- You can package business components for reuse. For more information on application modules, see Getting Started with ADF Business Components.
- You can package application modules for reuse. For more information on application modules, see Implementing Business Services with Application Modules.
- You can package task flows for reuse. For more information on task flows, see Getting Started with ADF Task Flows.
- You can package page templates for reuse. For more information on task flows, see Getting Started with Your Web Interface.
- You can package page templates for reuse. For more information, see the “Using Declarative Components” section of the Developing Web User Interfaces with Oracle ADF Faces.

50.1.4 Common Functionality of Reusable ADF Components

When you package or consume an ADF Library JAR, you also include and consume the extension libraries that are associated with the project. When you consume an ADF Library, you can use the Resources window.

50.1.4.1 Using Extension Libraries

An ADF project usually includes a list of extension libraries that it needs to run. These libraries are loaded in the class path of the project. You can view a project's dependent libraries by selecting the Libraries and Classpath node of the Project Properties dialog. Some of the libraries that may appear are JSP Runtime, ADF Page Flow Runtime, Connection Manager, and Oracle JDBC.

When a project is packaged into an ADF Library JAR, its extension libraries are packaged with it. And when an ADF Library JAR is being consumed by another project, JDeveloper automatically resolves any extension library conflicts between them. During the consuming process, JDeveloper checks to see whether the
consuming project already has the extension libraries of the ADF Library JAR in its class path and loads only those libraries that it does not have. For example, if JSP Runtime already exists in the consuming project, it will not be loaded again if the ADF Library JAR also includes it. The consuming project's extension libraries will be a union of its own libraries and the libraries in the ADF Library JAR.

If the project you want to package into an ADF Library has a dependent project, you can include the dependent project's extension libraries directly in the JAR or, if the dependent project has a deployment profile, you can add the dependent project's JAR to the ADF Library. For more information about setting up the deployment process, see How to Package a Component into an ADF Library JAR.

For example, suppose that project View is being packaged into ADF Library adflibView1.jar and that has a dependency on the Model project. For project View, the Model project is a dependent project with the deployment profile option (adflibmodel1) selected, as shown in Figure 50-1.

Figure 50-1 Edit Dependencies Dialog with Deployment Profile Option

When the deployment profile is selected, the dependent project's JAR file will be added to the ADF Library JAR. As a result, the extension libraries of the dependent project will also be made available to any consuming project. In Figure 50-2, the ADF Library being packaged, adflibView1.jar, includes the dependent adflibModel.jar as listed under the Library Dependencies node.
Alternately, you can include the dependent project's artifacts and extension libraries directly into the ADF Library JAR.

For example, project View can also be packaged into ADF Library adflibView2.jar. It also has a dependency on the Model project. But in this second deployment profile, the Model project is a dependent project with the Build Output option selected (as opposed to the deployment profile (adflibmodel1) being selected), as shown in Figure 50-3.

Figure 50-3    Edit Dependencies Dialog Used to Built adflibview2.jar
When Build Output is selected, the dependent project’s classes and extension libraries will be added directly to the ADF Library JAR. Figure 50-4 shows the ADF Library `adflibView2.jar`, which includes artifacts of the Model project and its extension libraries. Note that the extension libraries under the `adflibView2.jar` Library Dependencies node are the same as the combined extension libraries under the `adflibView1.jar` and `adflibModel.jar` shown in Figure 50-2.

Figure 50-4 Resources Window Showing adflibView2.jar Extension Libraries

How you decide to package the dependent project depends on how you intend the ADF Library to be used. Including the dependent project as a JAR may be advantageous when the dependent project is itself a reusable component, or when it is a dependent project for several projects that will be packaged into an ADF Library JAR. In the example, the dependent project Model may be a dependent project for several view projects. On the other hand, packaging the dependent project as Build Output is straightforward and eliminates the need for multiple JARs.

Note:

If you are creating an ADF Library JAR that is included in a JDeveloper extension library, you should include the additional manifest JDevLibrary: `extension_library_name` entry in the JAR. When you use Add to Project from the Resources window to add a ADF Library JAR that has a JDevLibrary manifest entry, the JDeveloper extension library containing this JAR will be added instead of the ADF Library JAR itself.

50.1.4.2 Using the Resources Window

ADF Library JARs can be packaged, deployed, discovered, and consumed like any other Oracle Library component. Creating an ADF Library JAR is the action of packaging all the artifacts (and additional control files) of a project into a JAR. Consuming a reusable component from an ADF Library JAR is the action of loading that ADF Library JAR into the project’s set of libraries.
However, the easiest way to manage and use ADF Library JAR components is by using JDeveloper’s Resources window. With the Resources window, developers who want to consume reusable components can easily find and discover available components and add them to their projects. The Resources window provides search and browse functions across different data management systems to locate the component. It provides multiple connections to access different sources. It has a structure tree view for displaying different connections and the ADF Library JAR component types. Figure 50-5 shows the Resources window with several file system connections.

The Resources window tree structure displays each JAR as subcategories. Separate nodes are created for each type of reusable component. For example, application modules are under the Data Controls node, and task flows are under the ADF Task Flows node.

The tree structure for the ADF Library JAR lists any connection information under a Library Connections node and lists all the producing project’s extension libraries under the Library Dependencies node.

![Figure 50-5 Resources Window Showing ADF Library Structure](image)

### 50.2 Packaging a Reusable ADF Component into an ADF Library

Once you have decided that a certain component or components can be reused, create an application and a project to develop that component. Follow the guidelines in Creating Reusable Components to name your application, project, package, and other objects and files. A project corresponds to one ADF Library JAR. If you create multiple projects and want to reuse components from each of the projects, you may need to create an ADF Library JAR for each project. In other situations, you may be able to involve multiple components under one project to create a single ADF Library JAR. For example, you may be able to create application modules, business components (entity object, view objects, associations), task flows, and page templates all under one project and create one ADF Library JAR.
Creating an ADF Library JAR involves compiling the project and validating the components, creating a resource service file, control files, an adflibREADME.txt, and adding the relevant project files into a JAR. For more information about the ADF Library JAR, see What Happens When You Package a Project to an ADF Library JAR. If you are packaging a component that itself uses another ADF Library component, the final consuming project must have both ADF Library JARs added to the project. For example, say you created a reusable task flow that contains tables dropped from a data control in another ADF Library JAR. When you add the task flow from an ADF Library JAR into a consuming project, that project will also require the data control ADF Library JAR.

If you are packaging a component that has dependent JARs, such as third-party JARs, you have two options:

- If the consuming environment has control over the placement of JARs, you can place the ADF Library JAR and its dependent JARs in a JDeveloper Extension Library. The advantage of using a JDeveloper Extension Library is that it does not clutter the consuming project with specific references to the dependent JARs.

- If using JDeveloper Extension Library is not possible, you can place the dependent JARs in the same location as the ADF Library JAR and include a manifest classpath entry for each dependent JAR.

### 50.2.1 How to Package a Component into an ADF Library JAR

To package up a reusable component, you first create a deployment profile that specifies the archive type, the name of the JAR file, and the directory path where the JAR will be created. Then you deploy the project using the deployment profile.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Packaging a Reusable ADF Component into an ADF Library.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

Create a project and determine whether it has dependent projects and JAR that need to be packaged. For more information, see Packaging a Reusable ADF Component into an ADF Library.

To package and deploy a project into the ADF Library JAR:

1. In the Applications window, double-click the project that contains the component you want to make reusable.

2. In the Project Properties dialog, select Deployment and then click New.

3. In the Create Deployment Profile dialog, select ADF Library JAR file for Profile Type, enter a name or accept the default name for Deployment Profile Name, and click OK.
4. In the Project Properties dialog, select the deployment profile and click **Edit**.

5. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Library Dependencies** node, as shown in **Figure 50-7**.

**Figure 50-7 ADF Library JAR Deployment Profile Properties Dialog**

The Library Dependencies pane shows a list of dependent projects for the project being packaged. You can add the dependent project's build output directly into the packaging project's library, or you can add selected deployment profile archives to the class path.

a. To add dependent projects, click the **Edit** icon to bring up the Edit Dependencies dialog, as shown in **Figure 50-8**.

If you select **Build Output**, the dependent project's extension libraries will be added directly to the ADF Library JAR. If you select deployment profile, the dependent project's JAR file (which includes its own extension libraries) will be added to the ADF Library JAR. For more information about library dependencies, see **Using Extension Libraries**.

In this example, the **Model** project can be set as a dependency only as **Build Output**. However, the **ViewController** project can be set as a dependency either as **Build Output**, or as a deployment profile (SummitADF_ViewController_webapp).
b. For each dependent project, select the **Build Output** node for the project or select the dependent profile and click **OK**.

6. In the Edit ADF Library JAR Deployment Profile Properties dialog, select the **Connections** node, as shown in *Figure 50-9.*

You can select:

- **Connection Details (excluding secure content):** If the project has a connection, select this checkbox if you want to include any available connection details in addition to the connection name. Connection details include hostname, port number, sid, driver type, and user name. For more information, see Including Connections Within Reusable Components.

- **Connection Name Only:** Select this checkbox if you want to add the connection name without any connection details.

**Note:**

The connection options available depends on the JDeveloper role. **Connection Details (excluding secure content) and Connection Name Only** are the selections available for the Studio Developer role. If your JDeveloper is set to a different role, you may have different options and defaults.

In the Applications Connections tree structure, select the checkbox for the level of connection you want to include.
7. Select the **JAR Options** node, as shown in Figure 50-10, verify the default directory path or enter a new path to store your ADF Library JAR file.

If the ADF Library JAR is to be included in a JDeveloper extension library, create a text file with a `JDevLibrary: extension_library_name` entry and place the file in the project root directory. Click **Add** to locate and merge that file into the `Manifest.mf` file.

When you create your manifest text file, make sure the `JDevLibrary` entry starts in column 1 with a space after the colon, and that there is a blank line at the end of the file.
8. Select the **ADF Validation** node.

You can select:

- **Ignore Errors**: To create the JAR file even when validation fails. This is the default option.

- **Stop Processing**: To stop processing when validation fails.
9. Click OK to finish setting up the deployment profile.

10. In the Applications window, right-click the project and choose Deploy > deployment, where deployment is the name of the deployment profile.

11. In the Deploy dialog Deployment Action page, click Next and then click Finish. JDeveloper will create the ADF Library JAR in the directory specified in Step 7. You can check that directory to see whether the JAR was created.

50.2.2 What Happens When You Package a Project to an ADF Library JAR

When you deploy the library JAR, JDeveloper packages up all the necessary artifacts, adds the appropriate control files, generates the JAR file, and places it in the directory specified in the deployment profile. During deployment, you will see compilation messages in the Log window.

When you deploy a project into an ADF Library JAR, JDeveloper performs the following actions:

- Package the HTML root directory artifacts into the JAR. When the JAR is added to the consuming project, JDeveloper will make the reusable component’s public_html resources available by adding it to the class path.

- Add the adf.m.xml file to the JAR. If there are multiple META-INF/ADF.m.xml files in the workspace, only the ADF.m.xml in the project being deployed is added. JDeveloper modifies this file to include relevant content from any dependent project’s ADF.m.xml file.

- Add a service resources file, oracle.adf.common.services.ResourceService.sva, into the META-INF directory of the JAR. The addition of this file differentiates an ADF Library JAR file from standard JAR files. This file defines the service strategies of the JAR and
allows the Resources window to properly discover and display the contents of the JAR.

• Add a `Manifest.mf` file to the JAR. The `Manifest.mf` file is used to specify dependencies between JAR files, and to determine whether to copy and include the contents of a JAR file or to reference it. JDeveloper will create a default manifest file. For example:

  Manifest-Version: 1.0

• Adds a `jar-connections.xml` file to the JAR for components that require a connection and that use the connections architecture. Note that in the consuming application, connection information in configuration files that are defined in the class path and accessible at runtime may be merged together. If the same connection is named multiple times in the class path, the connection in the main application will be given priority.

Different types of reusable components have different artifact files and different entries in the service resource file.

**50.2.2.1 Application Modules Files Packaged into a JAR**

For application modules, JDeveloper adds these control files to the JAR:

- `oracle.adf.common.services.ResourceService.sva`
- `Manifest.mf`
- `adfm.xml`, and the business components `.jpx` file. The service resource file for an application module includes entries for the business components associated with the application module, as well as an entry for the application module data control.

The `jar-connections.xml` file may appear for components that use the connection architecture and that contain connection information regarding the data source.

**50.2.2.2 Data Controls Files Packaged into a JAR**

For data controls such as placeholder data controls, JDeveloper includes three control files in the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `DataControl.dcx` file. Data controls are used when the data source is not based on ADF Business Components, and so business components are not included in the JAR file, as is the case in an application module JAR file. The service resource file for a standard data control has an entry for the data control.

The JAR also includes the `Datacontrol.dcx` file from the project to describe the data control type.

**50.2.2.3 Task Flows Files Packaged into a JAR**

For task flows, JDeveloper includes three control files in the JAR: `oracle.adf.common.services.ResourceService.sva`, `Manifest.mf`, and `task-flow-registry.xml`. The service resource file for a task flow includes an entry that indicates that one or more task flows are in the JAR.

**50.2.2.4 Page Templates Files Packaged into a JAR**

For page templates, JDeveloper includes two control files in the JAR: `oracle.adf.common.services.ResourceService.sva` and `Manifest.mf`.

**50.2.2.5 Declarative Components Files Packaged into a JAR**

For declarative components, JDeveloper includes two control files in the JAR: `oracle.adf.common.services.ResourceService.sva` and `Manifest.mf`. 
50.2.3 How to Place and Access JDeveloper JAR Files

If you have JAR files that can be reused by other projects, such as third-part JAR files, you can use JDeveloper to place them in an accessible location and create a library file (.library) to designate them. The consumer can use JDeveloper to navigate to this location and add the JAR to the project.

An ADF Library JAR contains ADF components and does not and cannot contain other JARs.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Packaging a Reusable ADF Component into an ADF Library.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

Place the JAR files in a accessible location for both the producer and the consumer of these JAR files. For example, the directory may be on a network drive where other shared files are located. For more information, see Packaging a Reusable ADF Component into an ADF Library.

To place and access a JDeveloper Library JAR:

1. From the main menu, choose Tools > Manage Libraries.
2. In the Manage Libraries dialog, click Load Dir.
3. In the Load Directory dialog, select the directory where the secondary JAR files are located.
4. In the Manage Libraries dialog, click New.
5. In the Create Library dialog, enter a library name and click Add Entry.
   You have created a library file (with a .library extension). You should place library files in source control systems.
6. In the Select Path Entry dialog, select the JARs you want to add and click OK.
7. In the Create Library dialog, be sure that the Deployed by Default option is set correctly for your JAR, click OK and then click OK again.
8. In the consuming project.
   a. From the main menu, choose Tools > Manage Libraries.
   b. In the Manage Libraries dialog, click Load Dir.
   c. In the Load Directory dialog, select the directory where the secondary JAR files are located and click Select. This should be the same location specified in Step 3.
   d. Right-click the project and select Project Properties.
e. In the Project Properties window, select Libraries and Classpath and click Add Library.

f. In the Add Library dialog, select the library, click OK and then click OK again.

50.3 Adding ADF Library Components into Projects

After ADF Library JARs are created, they must be distributed to the developers who will use these JARs. Distributing the ADF Library JARs may include putting the JARs into a network file system to be searched, browsed, and discovered. It may include using other forms of data store or services to access and retrieve these JARs. Since ADF Library JARs are simply binary files, they can distributed like any other file such as ftp and email.

Once you have access to the ADF Library JARs, you can use JDeveloper to access them and add them to your consuming projects. Using the JDeveloper Resources window is the easiest and most efficient way. You can also use JDeveloper to manually add the JARs into the project by entering them into the class path.

When a project is packaged into an ADF Library JAR, it captures the list of dependent JARs the project needs for deployment and runtime. This list is based on the project's dependent profiles and the information in the project's Libraries and Classpath with Deployed By Default selected. When the ADF Library JAR is added to the consuming project, this list of dependent JARs is placed in a library called ADF Library Dependencies. This is a locked library in the consuming project and its content will not be shown in the Data Controls panel, Components window, or other places in JDeveloper. The library is maintained and updated as different ADF Library JARs are added and deleted from the project. If the dependencies have changed (for example, the producer project was rebuilt), then you can refresh the dependencies in the consuming project using a JDeveloper menu command.

Once reusable components have been added, how they are used depends on the type of component.

50.3.1 How to Add an ADF Library JAR into a Project using the Resources Window

You can use the Resources window to search, discover, and add the ADF Library JAR to your project.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Adding ADF Library Components into Projects.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

Create an ADF Library JAR in a repository folder. If you do not already have a Resources window connection to this repository, you must know the location of this folder. For more information, see Adding ADF Library Components into Projects.

To add a component to the project using the Resources Window:

1. From the main menu, choose Window > Resources.
2. In the Resources window, click the New icon, and then choose IDE Connections > File System.

3. In the Create File System Connection dialog, enter a name and the path of the folder that contains the JAR.

   For file path guidelines, see Selecting Paths and Folders.

4. Click OK.

   The new ADF Library JAR appears under the connection name in the Resources window.

5. To examine each item in the JAR structure tree, use tooltips. The tooltip shows pertinent information such as the source of the selected item.

   Figure 50-12 shows a Resources window with a tooltip message that shows package information for a business component.

   **Figure 50-12   Tooltip Message for a Connection in the Resources Window**

6. To add the ADF Library JAR or one of its items to the project, right-click the item and choose Add to Project. In the confirmation dialog that appears, click Add Library, as shown in Figure 50-13.

   **Figure 50-13   Confirm Add ADF Library Dialog**
If you had previously added that library JAR, you will get a Confirm Refresh ADF Library dialog asking you whether you want to refresh the library.

7. If the ADF Library JAR has changes to its dependencies, you can refresh the project with the new changes. From the Applications window, right-click the project and select **Refresh ADF Library Dependencies in project.jpr**.

For application modules and data controls, you have the option to drag and drop the application module or data control from the Resources window into the Data Controls panel.

---

**Note:**

JDeveloper will load whichever ADF Library JAR extension libraries are not already in the consuming project. Extension libraries from the ADF Library’s dependent JARs will also be checked and loaded if not already part of the consuming project. For more information, see Using Extension Libraries

---

### 50.3.2 How to Add an ADF Library JAR into a Project Manually

You can add an ADF Library JAR in the same way as you would other library JARs.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Adding ADF Library Components into Projects.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

1. Create an ADF Library JAR. For more information, see Adding ADF Library Components into Projects.

To add a component to a project manually:

1. In the Applications window, double-click the project to which the component is to be added.

2. In the Project Properties dialog, select the **Libraries and Classpath** node and then click **Add Library**.

3. In the Add Library dialog, click **New**.

4. In the Create Library dialog, in the **Location** dropdown list, select **Project** and enter a name for the ADF Library. The preferable name is "ADF Library". Select **Deploy by Default**, and click **Add Entry**.

5. In the Select Path Entry dialog, enter or browse to the ADF Library JAR file and click **Open**.

6. The Create Library dialog reappears with the path of the JAR file filled in under the **Class Path** node. Click **OK**.

7. The Add Library dialog reappears with the ADF Library entry filled in under the **Project** node. Click **OK**.
8. The Project Properties dialog reappears with the JAR file added to the list of libraries. Click OK.

50.3.3 What Happens When You Add an ADF Library JAR to a Project

When you add an ADF Library JAR to a project, either by using the Resources window or by manually adding the JAR, an ADF Library definition is created in the project. The ADF Library JAR file will be added to the class path of the project. The project will access and consume the components in the JAR by reference.

By default, the ADF Library Deployed by Default option in the Create Library dialog is set to true. If this option is set, when the application or module is further archived or built into a WAR file, the contents of the ADF Library JAR will be copied to that archive or WAR file. If the Deploy by Default option is not set, then the JARs in the ADF Library must be loaded in some other way, such as by deploying them in a shared library.

Figure 50-15 shows the empty Data Controls panel for a consuming project before the ADF Library was added.
Figure 50-16 shows the adflibview1 ADF Library being added to the consuming project.

Figure 50-16  Adding the ADF Library JAR to the Project

Figure 50-17 shows several data controls from the ADF Library added to the Data Controls panel in the consuming project.

Figure 50-17  Consuming Project Data Controls Panel with Added Application Modules

After adding the ADF Library JAR, you may notice some changes to some of the JDeveloper windows. These changes are different depending on the type of components being added. Table 50-3 lists the effects on several JDeveloper windows.

Table 50-3  JDeveloper Window After Adding an ADF Library

</tr>
</tbody>
</table>
50.3.4 What You May Need to Know About Using ADF Library Components

Although the procedure to add an ADF Library JAR to a project is standardized, the component type determines where it appears in JDeveloper and how it can be reused.

### 50.3.4.1 Using Data Controls

When you add a data control to a project, the data control appears in the Data Controls panel. If you are using the Resources window, you have the option of dragging and dropping the data control from the Resources window onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

### 50.3.4.2 Using Application Modules

When you add an application module to a project, the application module appears in the Data Controls panel. If you are using the Resources window, you have the option of dragging and dropping the application module item from the Resources window onto the Data Controls panel, and then dragging and dropping from the Data Controls panel onto the page.

Application modules are associated with business components. When the reusable application module was packaged, the JAR includes the business components used to create the application module. These components will be available for reuse.
50.3.4.3 Using Business Components

Business components can also be packaged and reused. The entity objects, view objects, and associations can be packaged together and added to a consuming project. By default, packaged application modules will include the business components in the JAR, but business components can be reused by themselves without the accompanying application module.

One way to reuse business components is to create new view objects using the entity objects from an ADF Library JAR. When you add view objects using the wizard, the entity objects will become available within the wizard to support view object generation. For instructions on creating view objects, see How to Create an Entity-Based View Object. When the wizard presents a screen for entity objects used to create view objects, the entity objects from the ADF Library will be available in the shuttle window, as shown in Figure 50-18.

Figure 50-18 Creating View Object Using Entity Objects from ADF Library

If the consuming project has the Initialize Project for Business Component option selected (in the Project Properties dialog Business Components page) before the ADF Library JAR is added, the business components within the JAR will automatically be made available to the project.

If you add the ADF Library JAR first, and then select Initialize Project for Business Component, JDeveloper will automatically load the business components.

50.3.4.4 Using Task Flows

Task flows added to a project will appear in the Components window when you are adding components to a JSF page. If you are using the Resources window, you can also drag and drop the task flow directly from the Resources window onto another task flow or page, as shown in Figure 50-19.
50.3.4.5 Using Page Templates

When you add a page template to a project, the template will not be exposed in the Applications window. You will not have direct access to individual supporting files, such as image files. However, the template retains its access to its supporting files inside the JAR and is fully reusable within the project. When you apply the template, it will retain all the images that were loaded with the template.

The page template is exposed and accessible when you create a new JSF page using the wizard. When the wizard presents you with the option to use a page template, the ADF Library template will appear in the dropdown list. For example, if you loaded a page template called SummitTemplate from an ADF Library, when you use the wizard to create a JSF page, SummitTemplate will appear in the wizard, as shown in Figure 50-20. For information on how to use page templates and create a JSF page, see Using Page Templates and the Developing Web User Interfaces with Oracle ADF Faces.
50.3.4.6 Using Declarative Components

When you add a declarative component to a project, the JSP tag libraries that contain the component will be added to the project. The tag libraries will appear in the Components window, and the declarative components will be available for selection. For information about creating and using declarative components, see the Developing Web User Interfaces with Oracle ADF Faces.

50.3.5 What You May Need to Know About Differentiating ADF Library Components

If you mix components created during application development with components imported from the ADF Library, you may be able to differentiate between them by using the tooltips feature of JDeveloper.

Move the cursor over an application module or data control and you will see the full path of the source. If you see the ADF Library JAR file in the path, that means the component source is the ADF Library.

**Note:**

The tooltip for items in the Data Controls panel varies depending on whether or not the node has ever been opened in this session. To ensure that you are seeing the most complete tooltip, you should expand the item.
50.3.6 What Happens at Runtime: How ADF Libraries are Added to a Project

After an ADF Library JAR has been added to a project and to the class path, it behaves like any other library file. During runtime, any component that uses the component in the ADF Library JAR will reference that object. The process is transparent and there is no need to distinguish between components that were developed for the project and those that are in ADF Library JARs. Figure 50-21 shows the ADF Library and the path to the JAR as defined for a project.

Figure 50-21 Edit Library Definition Dialog Showing the ADF Library in the Class Path

Note:

Once an ADF Library JAR is created, any Java source used to create the component is not available in the JAR. If you want your consumers to have access to the source, such as for debugging, they must be delivered separately (usually in ZIP files). The consumer can then designate those ZIP files as the related component source for the Source Path entry in their ADF Library Libraries and Classpath entry in their own projects.

50.4 Removing an ADF Library JAR from a Project

You can use the Resources window to remove an ADF Library JAR from a project, or you can manually remove the JAR using the Project Properties dialog. You can remove an ADF Library JAR only if the components in the project do not have any dependencies on the components in the ADF Library JAR.

When you remove a JAR, it will no longer be in the project class path and its components will no longer be available for use.
50.4.1 How to Remove an ADF Library JAR from a Project Using the Resources Window

The Resources window allows you to remove previously added ADF Library JARs from a project using a simple command.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Removing an ADF Library JAR from a Project.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

Add the ADF Library JAR using the Resources window. For more information, see Adding ADF Library Components into Projects.

To remove an ADF Library JAR from the project using the Resources Window:

1. From the main menu, choose **Window > Resources**.

2. In the Applications window, select the project that has the ADF Library JAR you want to remove.

3. In the Resources window, locate the ADF Library JAR you want to remove from the current project.

4. Right-click the JAR and choose **Remove from Project**.

50.4.2 How to Remove an ADF Library JAR from a Project Manually

When you remove an ADF Library JAR manually, be sure to remove the correct library. Be aware of other libraries that are critical to the operation of the project.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you package an ADF component. For more information, see Removing an ADF Library JAR from a Project.

You may also find it helpful to understand functionality that can be used with packaging an ADF component. For more information, see Additional Functionality for Reusable ADF Components.

You will need to complete this task:

Add the ADF Library JAR manually. For more information, see Adding ADF Library Components into Projects.

To remove an ADF Library JAR from the project manually:

1. In the Applications window, double-click the project.

2. In the Project Properties dialog, select the **Libraries and Classpath** node.

3. In the **Classpath Entries** list, select **ADF Library** and click **Edit**.

4. In the Edit Library Definition dialog, select the ADF Library JAR you want to remove under the **Class Path** node, and click **Remove**.
5. Click **OK** to accept the deletion, and click **OK** again to exit the dialog.
This chapter describes how to develop Fusion web applications that can be customized and subsequently deployed by a customer, using the customization features provided by Oracle Metadata Services (MDS) framework. It also covers how to implement customizations on such applications.

This chapter includes the following sections:

- About Customization and MDS
- Developing a Customizable Application
- Customizing an Application
- How to Package and Deploy Customized Applications
- Extended Metadata Properties
- Enabling Runtime Modification of Customization Configuration

For information on how to deploy customized applications, see Deploying the Application.

51.1 About Customization and MDS

Using the customization features provided by MDS, you can create applications that fall into the following customization patterns:

- Seeded customization
  Seeded customization of an application is the process of taking a generalized application and making modifications to suit the needs of a particular group, such as a specific industry or site. Seeded customizations exist as part of the deployed application, and endure for the life of a given deployment. This chapter describes how to create a customizable application, and then customize the application using JDeveloper.

- User customization (change persistence)
  User customization allows an end user to change the content of the application at runtime to suit individual preferences (for example, which columns are visible in a table), and have those changes "remembered" the next time the user opens the application. For information about user customization, see Allowing User Customizations at Runtime.

- Design time at runtime
  Using the features of Oracle WebCenter Portal, you can create applications that are customizable at runtime. This allows business analysts or administrators, using a web browser interface, to customize the application for their end users.
information about runtime customization, refer to the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper.

For more information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), refer to the section about managing the MDS repository in Administering Oracle Fusion Middleware.

51.1.1 Customization and Layers: Use Cases and Examples

A customized application contains a base application and one or more layers containing customizations. MDS stores the customizations in a metadata repository and retrieving them at runtime to merge the customizations with the base metadata to reveal the customized application. Since the customizations are saved separately from the base, the customizations are upgrade safe; a new patch to base can be applied without breaking customizations. When a customized application is launched, the customization content is applied over the base application.

For example, say you have a generalized payroll application with a validation rule that limits the salary field to 4000. Then you create a customization of that validation rule that limits the salary field to 3300. At runtime, the customization is applied to the base application and the validation rule for the salary field limits it to 3300.

A customizable application can have multiple customization layers. Examples of customization layers are industry and site. Each layer can have multiple customization layer values, but typically only one such layer value from each layer is applied at runtime. For example, the industry layer for a customizable application can contain values for healthcare and financial industries; but in the deployed customized application, only one of the values from this layer is used at a time.

Layer values from multiple customization layers can be applied, in a specified order of precedence, on top of the base metadata. For example, a customized application can contain customizations in the financial layer value of the industry layer and the Financial Company #1 layer value of the site layer. Each customization layer corresponds to a customization document that contains a set of instructions that change the underlying metadata.

The customization context of a customized application is defined by the set of customization layer values applied to it.

Figure 51-1 illustrates how layers are applied in a customized application.

Figure 51-1  Example of Layered Customization
To support this, you use JDeveloper to create customization classes, define layers and values, and specify the order of precedence. These processes are described in Developing a Customizable Application.

51.1.2 Static and Dynamic Customization Content

Customizations can be categorized as either static or dynamic. Static customizations have only one layer value in effect for all executions of the application, while dynamic customizations can have values that vary based on the execution context of the application. If a customization can vary for different users executing the application, then it is dynamic. If a customization has the same value for all users executing the application then it is static.

When you implement customizations in ADF Business Components objects, the customizations remain the same for entire runtime of the application. This is because these objects are loaded only once for an application and reused for the duration of the application. For example, you can have a customized validation rule in the Healthcare Company #1 value of the site layer that limits salaries for that site to 3300. This is static customization content.

However, you can also implement customizations at the controller or view level that allow the layer value to be determined at runtime, based on user roles (responsibilities) or other application-specific criteria. For example, you can design an application so that users from different organizations see different sets of fields on a given screen. This is dynamic customization content.

The determination of whether a customization is static or dynamic is made in the customization class. In the customization class, if the getCacheshint () method returns ALL_USERS, then the customization layer is static. For more information about CacheHint values, see What You May Need to Know About Customization Classes.

All objects could have a static customization layer, depending on how the customization classes are implemented. But for ADF Business Components objects, customizations can only be static.

51.1.3 Additional Functionality for Customization

You may find it helpful to understand other features before you start working with customization. Following are links to other functionality that may be of interest.

- For information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see to the section about managing the MDS repository in Administering Oracle Fusion Middleware.

- You can use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime. For information, see Allowing User Customizations at Runtime .

- The features of Oracle WebCenter Portal allow business analysts or administrators, using a web browser interface, to customize an application for their end users. For information about runtime customization, refer to the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper.

51.2 Developing a Customizable Application

To create a customizable application, create the base application and perform the following procedures:
To prepare an application for customization:

1. Create the customization classes that will be used, as described in How to Create Customization Classes.

2. Enable seeded customization in the application, as described in How to Enable Seeded Customizations for User Interface Projects.

3. Specify the customization classes in the adf-config.xml file, as described in How to Configure the adf-config.xml File.

4. You can optionally restrict runtime customizations on the application, as described in How to Edit Extended Metadata Properties.

5. After you have prepared the application for customization, you must prepare JDeveloper so you can use it to implement the customizations, as described in How to Configure Customization Layers.

51.2.1 How to Create Customization Classes

A customization class is the interface that MDS uses to define which customization applies to the base definition metadata. Each customization class defines a customization layer (for example, industry or site) and can contain multiple layer values. The customization classes that are used in the application must be available to JDeveloper when customizing the application, and included in the deployed application.

51.2.1.1 Customization Classes

A customization class evaluates the current context and returns a String result. This String result is used to locate the customization layer.

The customization class provides the following information:

- A name, that represents the name of the layer.

- An array of values, that represent the customization layer values. Typically, each layer returns a single value. If multiple values are returned, the customizations available in the MDS repository for those values are applied in the order in which they appear in the array. A null value or an array containing an empty string ("") indicates there is no customization layer to apply. For more information, see Implementing the getValue() Method in Your Customization Class.

- An IDPrefix, for objects created in the layer. When new objects are created in a customization layer they need a unique ID. The IDPrefix is added to the autogenerated identifier for the object to create an ID for the newly added object. Each layer needs a unique IDPrefix so that objects created at different customization layers will have unique IDs.

- A cache hint, for the layer defined by the customization class. The cache hint defines whether a layer is static or dynamic. If the getCacheHint() method returns ALL_USERS, then the customization layer is static. For more information about dynamic customizations, see Dynamic and Dynamic Customization Content. For more information about CacheHint values, see What You May Need to Know About Customization Classes.

Customizations can be used to tailor an application to suit a specific industry domain (verticalization). Each such domain denotes a customization layer and is depicted using a customization class.
To implement seeded customizations using your customization classes:

- The `cust-config` section (under `mds-config`) in the `adf-config.xml` must contain a reference to the customization classes (as described in `How to Configure the adf-config.xml File`).

  The customization configuration (`cust-config`) section provides the customization classes and their precedence for a customized application. See `How to Configure the adf-config.xml File`.

- The customization classes must be included in the application to support seeded customizations.

  For more information, see `Making Customization Classes Available to JDeveloper at Design Time`. At runtime, your customization classes must be available in the EAR-level application class loader.

- The layer values must be listed in the `CustomizationLayerValues.xml` file.

  This file is located in the `jdev_install\jdev` directory. The names of the layers in this file must be consistent with the customization classes. (For more information, see `How to Configure Customization Layers`.) JDeveloper uses this file to retrieve layer values at design time.

When JDeveloper is launched in the **Customization Developer** role, the Customization Context window displays the available customization layers and layer values. You can select the layer and value to which you want to apply customizations in the Customization Context window. For more information about working in the **Customization Developer** role, see `Introducing the Customization Developer Role`. The layer you choose to customize is called the **tip layer**. For more information, see `Introducing the Tip Layer`.

The following example shows a sample customization class. Note that all customization classes should have a single, no-argument constructor.

```java
package mycompany;

import java.io.IOException;
import java.io.InputStream;
import java.util.Properties;
import oracle.mds.core.MetadataObject;
import oracle.mds.core.RestrictedSession;
import oracle.mds.cust.CacheHint;
import oracle.mds.cust.CustomizationClass;

public class IndustryCC extends CustomizationClass {
  private static final String DEFAULT_LAYER_NAME = "industry";
  private String mLayerName = DEFAULT_LAYER_NAME;

  public IndustryCC() {
  }

  public CacheHint getCacheHint() {
    return CacheHint.ALL_USERS;
  }

  public String getName() {
    return mLayerName;
  }

  public String generateIDPrefix(RestrictedSession sess, MetadataObject mo) {
    return "I";
  }
}
```
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    // This needs to return the appropriate value at runtime.
    return new String[] {"financial"};
}

This example shows the four methods that define how the customization class will work: `getCacheHint()`, `getName()`, `generateIDPrefix()`, and `getValue()`.

The return value for `getCacheHint()` indicates to MDS how widely visible a metadata object with this customization is, and therefore its likely duration in memory. It also defines whether or not a layer is static or dynamic. In this example, the `getCacheHint()` method returns `ALL_USERS`, which means the customization layer is static. For more information about `CacheHint` values, see What You May Need to Know About Customization Classes.

The `getName()` method returns the name of the customization layer. A SiteCC customization class, for example, might return "site." In this example, the `getName()` method returns "industry."

The `generateIDPrefix()` method creates an IDPrefix. The IDPrefix is a unique, abbreviated string that identifies the name and value of the layer. It is used as the prefix of the ID for objects created in the customization layer. The default implementation (if no IDPrefix is specified) returns name of the layer concatenated with customization value. For performance reasons, the IDPrefix should be kept short (4 characters or less). Therefore, the default implementation should be overridden. The related `getIDPrefix()` method returns the IDPrefix of the customization layer. In this example, the `getIDPrefix()` method would return "I" (for "industry").

The `getValue()` method returns the customization value (or values) for the customization class. In this example, the `getValue()` method returns a single value, "financial," that defines the customization context when combined with the layer name. There are additional techniques for using the `getValue()` method described in Implementing the `getValue()` Method in Your Customization Class.

**Note:**

The possible layer values corresponding to a layer name are retrieved by JDeveloper in the Customization Developer role from the `CustomizationLayerValues.xml` file. The precedence of layers is defined by the order of the customization classes specified in the `adf-config.xml` file. The names of the layers must be consistent in these files and in the customization classes.

51.2.1.2 Implementing the `getValue()` Method in Your Customization Class

The `getValue()` method is used to retrieve the layer value(s) of the customization class based on the application context and the metadata. For example, calling `getValue()` on a SiteCC customization class might return an array with single entry "headquarters." Typically, the `getValue()` method returns an array with a single value, as described in Customization Classes.

You can also return multiple values from the `getValue()` method, as shown in the following example.
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    return new String[]{{"North America"}, {"US"}, {"CA"}};
}

When multiple values are returned, customizations applicable to all values are applied. Customizations are applied in the order in which they appear in the array. In this example, North America customizations are applied over the base application, then US customizations are applied, and finally CA.

**Note:**

Returning multiple values for a customization layer is an advanced concept that is typically unnecessary.

The `getValue()` method can return a layer value based on the current execution context for the current user, pulled either from static or thread local state maintained by the client, or from properties set by the client on the MDS session and based on the metadata object name. The following example shows this type of implementation.

```java
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    if (mo.getName().equals("/sample/abc.jspx")) {
        return new String[]{{"Headquarters"}};
    } else {
        return new String[]{{"RemoteSite"}};
    }
}
```

In this example, the `getValue()` method uses the `getName()` method on the metadata object to determine if the name of the metadata document is "/sample/abc.jspx". If so, `getValue()` returns Headquarters to apply headquarters customizations. If not, it returns RemoteSite to apply customizations for remote sites.

**Note:**

Coding the `getValue()` method to return a value based on the metadata object is an advanced concept that is typically unnecessary. Customization context for dynamic layers is typically determined through facets of the application context, such as user name or responsibility.

An additional technique that can be useful during the development cycle is to use an external properties file to specify layer values. The following example references a properties file (`customization.properties`) that stores the layer values.

```java
public String[] getValue(RestrictedSession sess, MetadataObject mo) {
    Properties properties = new Properties();
    String configuredValue = null;
    Class clazz = IndustryCC.class;
    InputStream is = clazz.getResourceAsStream("/customization.properties");
    if (is != null) {
        try {
            properties.load(is);
            String propValue = properties.getProperty(mLayerName);
            configuredValue = propValue;
        } catch (IOException ex) {
            ex.printStackTrace();
        }
    }
    return new String[]{{configuredValue}};
}
```

Developing a Customizable Application

Customizing Applications with MDS 51-7
```java
if (propValue != null){
    configuredValue = propValue;
}
} catch (IOException e) {
    e.printStackTrace();
}
finally {
    try {
        is.close();
    } catch (IOException e) {
        e.printStackTrace();
    }
}
return new String[]{configuredValue};
```

When an application using this technique is run in JDeveloper, you can change the layer value in the properties file and refresh the browser to see new customizations being applied. This customization class and properties file combination allows you to maintain the layer value in a separate file so you don't need to modify and recompile Java code to change it for a particular deployment. If you use a customization.properties file, it must be packaged with the customization classes so that they are loaded from the same class loader.

The following example shows a sample customization.properties file. When the IndustryCC class is loaded with this properties file, the layer value healthcare is applied.

```
#Configured values for the default layer values
industry=healthcare
site=headquarters
```

### 51.2.1.3 Creating a Customization Class

When creating customization classes, put them in a separate project. This allows you to deploy them to a JAR and to import the JAR into your customizable application. This approach increases modularity, making it easier to include the customization classes in multiple applications across your company, and easier to patch them centrally. For more information about this approach, see How to Consume Customization Classes.

Alternatively, you can put the customization classes in the data model project if you are creating customization classes that will be used in a single application only, or if you just want to run the application locally from JDeveloper or to deploy remotely with MDS configuration.

Make sure that there is only one copy of the customization classes in the application and that they are packaged in a JAR file so that they are loaded at the EAR-level application class loader. By default, adding project dependencies will add the customization classes to the WAR profile, which will not work correctly after the application is packaged and deployed. For more information about packaging your application for deployment, see How to Create Deployment Profiles.

Use the following procedure to create a customization class.

**Before you begin:**

It may be helpful to have an understanding of the features of customization classes. For more information, see Customization Classes.
You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will need to launch JDeveloper using the Studio Developer role, and open (or create) the application that will hold the customization classes.

To create a customization class:

1. From the main menu, choose File and then From Gallery.

2. In the New Gallery, expand General, select Projects and then Java Application Project, and click OK.

3. In the Create Java Project dialog, specify the appropriate settings for your project, and click Finish.

   **Note:**
   You should use a single project to hold all of your customization classes.

   For more information about the options in the Create Java Project dialog, see the online help.

4. In the Applications window, right-click your project and choose Project Properties.

5. In the Project Properties dialog, select Libraries and Classpath, and then click Add Library.

6. In the Add Library dialog, select MDS Runtime, and click OK, and then click OK to close the Project Properties dialog.

7. In the Applications window, right-click the project and choose New and then Java Class.

8. In the Create Java Class dialog, enter a name for the class and the appropriate package.

   **Note:**
   Customization classes are typically named for the layer name they return. For example, a customization class that returns the layer name industry would be named IndustryCC.

9. In the Extends field, enter oracle.mds.cust.CustomizationClass.

   For more information about this class, refer to the Javadoc.

10. Make sure that Implement Abstract Methods is selected and click OK.

11. Replace the code in the generated file with code like that described in Customization Classes.

12. Save your changes and rebuild the project.
This creates the customization class. The sample code uses the package name mycompany and the class name IndustryCC. You will need to change these as appropriate for your application.

51.2.2 What You May Need to Know About Customization Classes

As described in Customization Classes, the customization class defines a CacheHint which specifies the visibility of metadata objects in a customization layer, and therefore its likely duration in memory. This information is used by MDS to decide whether or not to cache a customization, and where to cache it. Any customization layers constructed using this customization class have this cache hint.

The following constants are supported values of CacheHint:

- **ALL_USERS** — The customization is applied globally (unconditionally) for a given deployment. This constant is used for static customization layers.
- **MULTI_USER** — The customization is applied to multiple users.
- **REQUEST** — The customization is applied for the duration of the request only.
- **USER** — The customization is applied for a single user to documents which are accessed throughout the user’s application session. (In web applications the application session is typically a servlet session.)

**Note:**
Customization classes are likely to be executed frequently, once for each document being accessed to get the layer name and layer value, so take care to ensure their efficiency.

51.2.3 How to Consume Customization Classes

After you have created your customization classes, you can use them at design time in the Customization Developer role, and at runtime in the application. To be consumed in an application or in JDeveloper, the classes must be packaged appropriately.

51.2.3.1 Making Customization Classes Available to JDeveloper at Design Time

After you create the customization classes, you must make them available to JDeveloper so that you can use them when implementing customizations while working in the Customization Developer role.

Because the customization classes are reusable components, you can create a separate project to contain them, and package them into their own JAR file. You can then import the JAR into the consuming application, which makes the customization classes available to JDeveloper. For more information about creating the customization classes in a separate project, see Creating a Customization Class. For more information about packaging the customization classes into a JAR file, see Adding Customization Classes into a JAR.

**Note:**
This procedure is not required if you created your customization classes in the data model project of the consuming application.
Use the following procedure to make the customization classes visible to the application, and then add the customization classes to the cust-config section of the adf-config.xml file, as described in How to Configure the adf-config.xml File.

Before you begin:

It may be helpful to have an understanding of how customization classes are packaged. For more information, see Customization Classes.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes in an external project, as described in Creating a Customization Class.
- Create a JAR using the procedure described in Adding Customization Classes into a JAR.
- Launch JDeveloper using the Studio Developer role, and open the application that you want to customize.

To use customization classes from an external project:

1. In the Applications window, click the Application Menu icon and choose Application Properties.
3. In the Add Archive or Directory dialog, select the JAR file you created that contains the customization classes, and click Open.
4. Click OK.

Now the customization classes are available to JDeveloper for customization, and for running your project locally in JDeveloper. They will also be packaged to the EAR class path when you package the application.

51.2.3.2 Making Customization Classes Available to the Application at Runtime

When you package and deploy your customized application, the customization classes must be available at the application level on the application’s class path.

When you define the deployment profiles for your application, you need to add the customization classes JAR file to the EAR assembly, and to avoid duplication, you need to make sure that the WAR profile does not include the customization classes JAR file. For more information, see Creating an Application Level EAR Deployment Profile.

51.2.4 How to Enable Seeded Customizations for User Interface Projects

Like all customizable components, the XML elements of a customizable metadata object must be uniquely identifiable by MDS, and therefore must have a unique, non-null identifier. The component’s identifier is used to refer to the element in the customization instructions in the customization layer. The ID property is the identifier for each type of component in an ADF Faces .jspx or .jsff file.
To allow for customizations on your JSF and JSP pages, you must enable seeded customizations in the application’s user interface project, which drives some defaults for your pages. This is not necessary for your model and controller projects.

---

**Note:**

MDS requires that pages be XML-based to be customized. Therefore, customizations are not allowed on .jsp files; use .jspx files instead.

Additionally, facelets files must have a .jsf extension to be customizable. MDS uses this extension to recognize it as a Facelets file.

---

Before you begin:

It may be helpful to have an understanding of how seeded customization works. For more information, see Customization and Layers: Use Cases and Examples.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to launch JDeveloper using the Studio Developer role, and open the application that you want to make customizable.

To enable seeded customizations in your user interface project:

1. In the Applications window, right-click the user interface project and choose Project Properties.

2. In the Project Properties dialog, select ADF View and then select the Enable Seeded Customizations checkbox, as shown in Figure 51-2.

3. Click OK.

4. Save the changes to your project.
51.2.5 How to Enable Seeded Customizations in Existing Pages

If you have pages in your project that were created in an earlier version of JDeveloper, you must make sure that these preexisting pages are also enabled for seeded customizations. This is only necessary if you migrated the application from an earlier version of JDeveloper and did not generate IDs during migration.

Before you begin:

It may be helpful to have an understanding of how seeded customization works. For more information, see Customization and Layers: Use Cases and Examples.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to launch JDeveloper using the Studio Developer role, and open the application that you want to make customizable.

To enable seeded customizations in an existing page:

1. Create an audit profile to implement ID tokens for all XML objects in your page:
   a. From the main menu, choose Tools > Preferences.
   b. In the Preferences dialog, select Audit > Profiles.
   c. On the Profiles page, click Rules and deselect all rules.
   d. Expand Application Development > ADF Faces > Component ID Rules.
   e. Select the rule Check for ID When ADF Faces is Present.
   f. From the Default Fix dropdown list, select Generate a unique ID.
Click **Save As**, then enter an identifiable name for the profile (such as Generate Unique IDs) and click **Save**.

Click **OK** to close the Preferences dialog.

2. In the Applications window, select the page for which you want to enable seeded customizations. Alternatively, you can select a project to run the audit on all the files it contains.

3. From the main menu, choose **Build > Audit**.

4. In the Audit dialog, select the profile you created to generate IDs and click **Run**.

5. Use the Log window to review issues and apply fixes.

6. When the audit is complete, save your changes.

### 51.2.6 How to Enable Customizations in Resource Bundles

If you plan to create new resource keys when implementing customizations, you can specify the affected resource bundles using the Application Properties dialog.

Before you begin:

It may be helpful to have an understanding of how seeded customization works. For more information, see *Customization and Layers: Use Cases and Examples*.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see *Additional Functionality for Customization*.

You will also need to launch JDeveloper using the **Studio Developer** role, and open the application that you want to make customizable.

To enable customizations in resource bundles:

1. From the Applications window context menu, choose **Application Properties**.

2. In the Application Properties dialog, click **Resource Bundles**, and then click **Add**.

3. In the Select Resource Bundle dialog, navigate to and select the resource bundles for which you want to enable customization.

4. Click **Open**.

5. In the Application Properties dialog, select the checkbox in the **Overridden** column of the **Bundle** table.

6. Click **OK**.

### 51.2.7 How to Configure the adf-config.xml File

The application's `adf-config.xml` file must have an appropriate `cust-config` element in the `mds-config` section. The `cust-config` element allows clients to define an ordered and named list of customization classes. You use the overview editor for the `adf-config.xml` file to add customization classes (see Figure 51-3).

Before you begin:

It may be helpful to have an understanding of how customization classes are created and packaged. For more information, see *Customization Classes*. 
You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes, as described in Creating a Customization Class.
- Create a JAR using the procedure described in Adding Customization Classes into a JAR.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.
- Launch JDeveloper using the Studio Developer role, and open the application that you want to customize.

To identify customization classes in the adf-config.xml file:

1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click adf-config.xml.
2. In the overview editor, click the MDS Configuration navigation tab and then click the Add icon.
3. In the Edit Customization Class dialog, search for or navigate to the customization classes you have already created.
4. Select the appropriate classes and click OK.
5. After you have added all of the customization classes, you can use the arrow icons to put them in the appropriate order.

Figure 51-3 shows the overview editor for the adf-config.xml file with two customization classes added.

Figure 51-3  adf-config.xml Overview Editor

The order of the customization-class elements defines the precedence of customization layers. For example, in the code shown in the following example, the IndustryCC class is listed before the SiteCC class. This means that customizations at the industry layer are applied to the base application, and then customizations at the site layer are applied.
51.2.8 What Happens When You Create a Customizable Application

When you create a customizable application, you have a base application that includes the pieces necessary for you or someone else to use as the basis for a customized application.

To perform the customization, you must open the application in JDeveloper using the Customization Developer role, as described in Customizing an Application.

51.2.9 What You May Need to Know About Customizable Objects and Applications

Oracle ADF components (such as controller, model, and business components objects) must have a unique identifier so that they can be customized. ADF components generated by JDeveloper are created with identifiers by default, with the exception of JSP and JSF pages in your user interface projects. To cause JDeveloper to generate identifiers for components on pages in your user interface projects, you must explicitly specify this at the project level (as explained in How to Enable Seeded Customizations for User Interface Projects).

Before you implement customizations in an application, make sure that all objects that you intend to customize have the necessary identifiers. In many cases, you can run an audit rule to catch and fix any omissions (as explained in How to Enable Seeded Customizations in Existing Pages).

Also, take care to ensure the efficiency of your customization classes, because they can be executed frequently, once for each document being accessed to get the layer name and layer value.

51.3 Customizing an Application

Using the Customization Developer role, you can create customizations in a customizable application.

51.3.1 Introducing the Customization Developer Role

The Customization Developer role is used to customize the metadata in a project. Customization features are available only in this role. When you are in the Customization Developer role, you can do the following:

- Create and update customizations
- Select and edit the tip layer of a customized application
- Remove existing customizations
When you are in the **Customization Developer** role, the source editor is read-only and the following JDeveloper features are disabled:

- Workspace migration
- Creation, deletion, and modification of application and IDE connections. You must configure connections in Default role before opening an application in Customization Developer role.

When working with an application in the **Customization Developer** role, new objects cannot be created, and noncustomizable objects cannot be modified. However, the following content types are customizable:

- Portal modules
- ADF modules, including ADF Faces, ADF Model, ADF Business Components, and ADF Controller

**Note:**

ADF Business Components objects are customizable only if a static customization class is selected in the Customization Context window. Otherwise, business components objects are read-only.

When working in the **Customization Developer** role, you cannot edit noncustomizable files, such as Java classes, resource bundles, security policies, deployment descriptors, and configuration files. Noncustomizable files are indicated by a lock icon when you are working in the **Customization Developer** role.

**Note:**

Facelets files must have a `.jsf` extension to be customizable. MDS uses this extension to recognize it as a Facelets file.

You are also restricted from modifying project settings and customizing certain ADF Business Components features, including service interfaces and business event definitions. Additionally, you cannot refactor, or make changes to customizable files that would, in turn, necessitate changes in noncustomizable files.

### 51.3.2 How to Switch to the Customization Developer Role in JDeveloper

The customization features of JDeveloper are available to you in the **Customization Developer** role. To work in this role, you can either choose it when you start JDeveloper or, if JDeveloper is already running, you can use the **Switch Roles** menu to switch to the **Customization Developer** role.

Before you begin:

It may be helpful to have an understanding of the features of the **Customization Developer** role. For more information, see **Introducing the Customization Developer Role**.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see **Additional Functionality for Customization**.

You will also need to launch JDeveloper.
To switch to the Customization Developer role in JDeveloper:

1. From the main menu, choose **Tools > Switch Roles > Customization Developer**.

**Note:**
You can optionally toggle the **Tools > Switch Roles > Always Prompt for Role Selection at Startup** menu item, to specify whether or not you want to choose the role when JDeveloper is launched. If deselected, JDeveloper launches in the role it was in when you last closed it.

### 51.3.3 Introducing the Tip Layer

When working in the **Customization Developer** role, the layer and layer value combination that is selected in the Customization Context window is called the **tip layer**. The changes you make while in the **Customization Developer** role are applied to this layer.

**Note:**
When working in the **Customization Developer** role, if the Customization Context window is not displayed, you can access it from the **Window** menu.

The metadata displayed in the JDeveloper editors is a combination of the base metadata and the customization layers up to and including the tip layer, according to the precedence set in **adf-config.xml**, with the values specified in the Customization Context window for each layer.

When working in the **Customization Developer** role, you can also see the noncustomized state of the application. When you select **View without Customizations** in the Customization Context window, there is no current tip layer. Therefore, what you see is the noncustomized state. While you are in this view, all customizable files show the lock icon (in the Applications window), indicating that these files are read-only.

When you make customizations in a tip layer, these customizations are indicated by an orange icon in the Properties window. A green icon indicates non-tip layer customizations. When you see an orange icon beside a property, you have the option of deleting that customization by choosing **Remove Customization** from the dropdown menu for that property.

### 51.3.4 How to Configure Customization Layers

To customize an application, you must specify the customization layers and their values in the **CustomizationLayerValues.xml** file so that they are recognized by JDeveloper.

When you open a customizable application in the **Customization Developer** role, JDeveloper reads the **adf-config.xml** file to determine the customization classes to use and their order of precedence. JDeveloper also reads the **CustomizationLayerValues.xml** file to determine the layer values to make available in the Customization Context window. If there are layer values defined in the **CustomizationLayerValues.xml** file that are not defined in the customization classes listed in the **adf-config.xml** file, they are not displayed in the Customization Context window.
Therefore, you can have a comprehensive list of layer values for all of your customization projects in the `CustomizationLayerValues.xml` file, and only those appropriate for the current application are available in the Customization Context window. Conversely, you could have a comprehensive list of customization classes for an application in the `adf-config.xml` file, and only the subset of layer values that you will work on in your `CustomizationLayerValues.xml` file.

**Note:**
At design time, JDeveloper retrieves customization layer values from the `CustomizationLayerValues.xml` file. But at runtime, the layer values are retrieved from the customization class.

The names of the layers and layer values that you enter in the `CustomizationLayerValues.xml` file must be consistent with those specified in your customization classes. The following example shows the contents of a sample `CustomizationLayerValues.xml` file.

```xml
<cust-layers xmlns="http://xmlns.oracle.com/mds/dt">
  <cust-layer name="industry" id-prefix="i">
    <cust-layer-value value="financial" display-name="Financial" id-prefix="f"/>
    <cust-layer-value value="healthcare" display-name="Healthcare" id-prefix="h"/>
  </cust-layer>
  <cust-layer name="site" id-prefix="s">
    <cust-layer-value value="headquarters" display-name="HQ" id-prefix="hq"/>
    <cust-layer-value value="remoteoffices" display-name="Remote" id-prefix="rm"/>
  </cust-layer>
</cust-layers>
```

For each layer and layer value, you can add an `id-prefix` token. This helps to ensure the uniqueness of the `id`, so that customizations are applied accurately. When you add a new element (such as a command button) to a page during customization, JDeveloper adds the `id-prefix` of the layer and layer value (determined by the selected tip layer) to the autogenerated identifier for the element to create an `id` for the newly added element in the customization metadata file. As the example above shows, the `site` layer has an `id-prefix` of "s" and the `headquarters` layer value has an `id-prefix` of "hq". So, when you select `site/headquarters` as the tip layer and add a command button to a page, the command button will have an `id` of "shqcb1" in the metadata customization file.

For each layer value, you can also add a `display-name` token to provide a human-readable name for the layer value. When you are working in the **Customization Developer** role, the value of the `display-name` token is shown in the Customization Context window for that layer value.

For each layer, you can optionally provide a `value-set-size` token that defines the size of the value set for the customization layer. This can be useful, for example, when using a design-time, application-specific `CustomizationLayerValues.xml` file. By setting `value-set-size` to "no_values" you can exclude runtime-only layers at design time.

```xml
<cust-layer name="runtime_only_layer" value-set-size="no_values"/>
```

You can define the customization layer values either globally for JDeveloper or in an application-specific file. If you use an application-specific file, it takes precedence over the global file. For more information on configuring layer values globally for JDeveloper, see **Configuring Layer Values Globally**. For more information on...
configuring application-specific layer values, see Configuring Workspace-Level Layer
Values from the Studio Developer Role.

51.3.4.1 Configuring Layer Values Globally

The following procedure describes how to configure the
CustomizationLayerValues.xml file globally for JDeveloper.

Before you begin:

It may be helpful to have an understanding of layers and layer values. For more
information, see How to Configure Customization Layers.

You may also find it helpful to understand additional customization functionality that
can be added to your applications. For more information, see Additional Functionality
for Customization.

You will also need to complete these tasks:

• Create your customization classes, as described in Creating a Customization Class.

• Make your classes available to JDeveloper, as described in Making Customization
Classes Available to JDeveloper at Design Time.

To configure design time customization layer values globally for JDeveloper:

1. Locate and open the CustomizationLayerValues.xml file.

You can find this file in the jdev subdirectory of your JDeveloper installation
directory (jdev_install\jdev\CustomizationLayerValues.xml).

2. For each layer, enter a cust-layer element, as described in How to Configure
Customization Layers.

3. For each layer value, enter a cust-layer-value element, as described in How to
Configure Customization Layers.

4. Save and close the CustomizationLayerValues.xml file.

5. After you have made changes to the global CustomizationLayerValues.xml file, you must restart JDeveloper.

51.3.4.2 Configuring Workspace-Level Layer Values from the Studio Developer Role

When configuring layer values for an application, you can use either the Studio
Developer role or the Customization Developer role. Note that when you configure
an application-specific CustomizationLayerValues.xml file, you can create and
modify layer values, but you cannot create additional customization layers. It is not
necessary to restart JDeveloper to pick up changes made to the application-specific
layer values.

When you create an application-specific CustomizationLayerValues.xml file,
JDeveloper stores it in an application-level directory (for example, workspace-
directory\.mds\dt\customizationLayerValues
\CustomizationLayerValues.xml). You can access this file in the Application
Resources panel of the Applications window, under the MDS DT node.

The following procedure describes how to configure the
CustomizationLayerValues.xml file for a specific application from the Studio
Developer role. This procedure can also be used from the Customization Developer
role.
Before you begin:

It may be helpful to have an understanding of layers and layer values. For more information, see How to Configure Customization Layers.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes, as described in Creating a Customization Class.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.
- Launch JDeveloper using the Studio Developer role, and open the application that you want to customize.

To configure design time customization layer values at the workspace level from the Studio Developer role:

1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click adf-config.xml.

2. In the overview editor, click the MDS Configuration navigation tab.

3. On the MDS Configuration page, below the table of customization classes, click the Configure Design Time Customization Layer Values link to open the workspace-level CustomizationLayerValues.xml file.

   When you click the link, the file opens in the source editor. If the override file doesn’t already exist, JDeveloper displays a confirmation dialog. Click Yes to create and open a copy of the global file.

4. In the file, specify layer values as necessary, as described in How to Configure Customization Layers.

5. Save your changes.

51.3.4.3 Configuring Workspace-Level Layer Values from the Customization Developer Role

You can also configure layer values for an application from the Customization Developer role. Note that when you configure an application-specific CustomizationLayerValues.xml file, you can create and modify layer values, but you cannot create additional customization layers. It is not necessary to restart JDeveloper to pick up changes made to the application-specific layer values.

When you create an application-specific CustomizationLayerValues.xml file, JDeveloper stores it in an application-level directory (for example, workspace-directory\.mds\dt\customizationLayerValues\CustomizationLayerValues.xml). You can access this file in the Application Resources panel of the Applications window, under the MDS DT node.

The following procedure describes how to configure the CustomizationLayerValues.xml file for a specific application from the Customization Developer role.

Before you begin:
It may be helpful to have an understanding of layers and layer values. For more information, see How to Configure Customization Layers.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes, as described in Creating a Customization Class.
- Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.
- Launch JDeveloper using the Customization Developer role, and open the application that you want to customize.

To configure design time customization layer values at the workspace level from the Customization Developer role:

1. In the Customization Context window, click the Configure application layer values link.
   When you click the link, the CustomizationLayerValues.xml file opens in the source editor. If the override file doesn't already exist, JDeveloper displays a confirmation dialog. Click Yes to create and open a copy of the global file.
2. Specify layer values as necessary, as described in How to Configure Customization Layers.
3. Save your changes.

   After you make changes to the application-specific CustomizationLayerValues.xml file while you are in the Customization Developer role, any tip layer you have selected in the Customization Context window is deselected. You can then select the desired tip layer.

51.3.5 How to Customize Metadata in JDeveloper

You use the same development procedures and techniques to customize metadata that you use when developing the base application. To implement customizations, however, you must be working in the Customization Developer role and specify the customization context by selecting a tip layer and layer value before editing the metadata. For an application to be customizable, customizations must be enabled in your project. For more information, see Developing a Customizable Application.

Before you begin:

It may be helpful to have an understanding of how customization works. For more information, see Customization and Layers: Use Cases and Examples, and Customizing an Application.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

- Create your customization classes, as described in Creating a Customization Class.
• Create a JAR using the procedure described in Adding Customization Classes into a JAR.

• Make your classes available to JDeveloper, as described in Making Customization Classes Available to JDeveloper at Design Time.

• Update the `adf-config.xml` file, as described in How to Configure the `adf-config.xml` File.

• Enable seeded customizations in your application, as described in How to Enable Seeded Customizations for User Interface Projects, and How to Enable Seeded Customizations in Existing Pages.

• Configure the applications customization layers, as described in How to Configure Customization Layers.

• Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.

To customize metadata in JDeveloper:

1. In the Customization Context window, select the layer and value for which you want to implement customizations.

   The **Customization Context** (displayed at the bottom of the Customization Context window) changes to reflect your selection, as shown in Figure 51-4.

   ![Figure 51-4 Customization Context Window with site/headquarters Selected as the Tip Layer](image)

   **Note:**

   The selection you make in the Customization Context window indicates the context for the customizations that you will implement in JDeveloper. This selection does not directly impact the runtime for the application. At runtime, the customization context is returned from your customization classes. For more information, see How to Create Customization Classes.

2. Edit the metadata as you typically would during development. For example, double-click an entity object. Then edit the object using the overview editor.

   While you use the same techniques for editing metadata during customization that you would during development, certain restrictions apply. For example, some string properties, such as button labels, cannot be edited directly in the Properties window: they must be edited using the Select Text Resource dialog or the Expression Builder. For more information about restrictions to editing during...
customization, see Introducing the Customization Developer Role. For information about using the Expression Builder, see Opening the Expression Builder from the Properties Window.

Even though you use the overview editor to implement customizations, you do not make changes to the base metadata file. Your changes are stored separately in a customization metadata file.

---

**Note:**

To see the uncustomized base metadata, you can select View without Customizations in the Customization Context window.

---

3. You can optionally choose Remove Customization from the dropdown menu for a property (in the Properties window) to clear the existing customization.

---

**Note:**

In the Properties window, tip layer customizations are indicated by an orange icon, while properties that are not customized in the current tip layer are indicated by a green icon. A customization can only be removed in the context in which it was added. So you can remove only those customizations that have an orange indicator in the Properties window.

---

4. From the main menu, choose File > Save to save your changes.

After you have completed your customizations, you can run and test the customized application.

### 51.3.6 What Happens When You Customize an Application

When you implement customizations in an application, JDeveloper creates a metadata file for the customizations and a subpackage to store them in.

The metadata file contains the customizations for the customized object, which are applied over the base metadata at runtime. The new metadata file is named the same as the base file for the object with an additional .xml extension. For example, if you implement customizations for the browseOrders.jsff page, the customization metadata file is named browseOrders.jsff.xml. Or if you implement customizations on the OrderItems entity object, the base metadata file is named OrderItems.xml and the customization metadata file is named OrderItems.xml.xml.

The customization metadata files are stored in a subpackage hierarchy that is created at the same level as the object you customize. The first-level package is named mdssys, and it contains a package named cust. The cust package contains a package for each customization layer for which you have implemented customizations.

For example, say you have a base application that has a package called oracle.summit.model.entities containing your entity objects, and you have a customization layer named site with two layer values: headquarters and remoteoffices. Then you implement customizations for the OrderItems entity object at the headquarters layer value. When you implement these customizations, JDeveloper creates the subpackage hierarchy
oracle.summit.model.entities.mdssys.cust.site.headquarters and stores the customization metadata files there.

Similarly, for pages in your user interface project, JDeveloper creates a directory structure to store the customization metadata files. For example, if you customize the BrowseOrders.jsff page in the Web Content node of your user interface project, JDeveloper creates the directory structure mdssys/cust/site/headquarters under Web Content and stores the customization metadata file there.

### 51.3.7 How to Customize ADF Library Artifacts in JDeveloper

In the **Customization Developer** role, you can use JDeveloper to customize artifacts in an ADF library. This need can arise when, for example, one development team produces task flows as part of a framework service and makes them available to other teams as an ADF library. Then another development team uses one of the task flows in a consuming application, and needs to fine-tune it to fit the requirements of the application.

#### 51.3.7.1 Customizing an ADF Library Artifact

You can add an ADF library to your project in the **Customization Developer** role just as you would add it in the **Studio Developer** role. However, in the **Customization Developer** role, content from an ADF library appears as editable to allow you to implement customizations, whereas in the **Studio Developer** role it is read-only. For more information about working with ADF libraries, see [Reusing Application Components](#).

Before you begin:

It may be helpful to have an understanding of how customization works. For more information, see [Customization and Layers: Use Cases and Examples](#), and [Customizing an Application](#).

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see [Additional Functionality for Customization](#).

You will also need to complete these tasks:

- Create your customization classes, as described in [Creating a Customization Class](#).
- Create a JAR using the procedure described in [Adding Customization Classes into a JAR](#).
- Make your classes available to JDeveloper, as described in [Making Customization Classes Available to JDeveloper at Design Time](#).
- Update the `adf-config.xml` file, as described in [How to Configure the adf-config.xml File](#).
- Enable seeded customizations in your application, as described in [How to Enable Seeded Customizations for User Interface Projects](#), and [How to Enable Seeded Customizations in Existing Pages](#).
- Configure the applications customization layers, as described in [How to Configure Customization Layers](#).
- Launch JDeveloper using the **Customization Developer** role, and open the application that you want to customize.
To customize an ADF library artifact:

1. In the Applications window, click the Applications Window Options icon and choose Show Libraries.

   This displays the libraries in the Applications window, so that you can explore them and access their artifacts.

2. Add the desired library to your project if it is not already shown among the libraries in the Applications window.

   For information about how to do this, see Adding ADF Library Components into Projects.

3. Customize the artifacts just as you would customize other content in your project.

   For example, you can drag and drop taskflows from a library to .jspx or .jsff pages in a consuming project, drag and drop taskflows from a library to a page or fragment in another library, drag and drop library content or taskflows from the Resource catalog, drag and drop data controls from Data Controls panel to .jspx or .jsff pages in a library, edit business components, and drag and drop a data control from a library to the Data Controls panel and then drop to a page in another palette. All of these actions result in customizations of the library.

51.3.7.2 Specifying a Location for ADF Library Customizations

The location where ADF library customizations are stored is project-dir\libraryCustomizations by default. If your workspace contains multiple projects, you should change this to a workspace-level location for each project (for example, workspace-dir\.mds\ADFLibraryCustomizations).

You can change the location of ADF library customizations on the Project Source Paths > ADF Library Customizations page of the Project Properties dialog. If you change this location after you have implemented customizations on an ADF library, you must move the customization metadata files to the new location. To do this, use the file system to move the customization metadata (XML) files from the old directory to the new one.

If you have more than one project in the workspace with existing ADF library customizations that need to be moved to the common location, move the customizations to the new location one project at a time. For each project, change the location of ADF library customizations in the Project Properties dialog, and then move the customization metadata files from the old location to the new location. To mitigate conflicts where an ADF library artifact has customizations in more than one project, you have following options:

- From both projects, open the ADF Library artifact for which there are conflicting customizations, and decide upon which customizations you want. Preserve the customizations you want to keep and delete the others.

- If both customizations are important, open the ADF library artifact from the first project and implement the customizations that were previously done in second project. Then save the customizations in the first project and remove the customizations from the second project.

Do not open ADF library customization metadata files from multiple projects in a text editor and merge their contents. This can corrupt the customization metadata file.

Additionally, the location where ADF library customizations are stored is automatically included when you create a MAR deployment profile. If you change this
location after you have created a MAR profile, you must also change the corresponding entry in the contributors list on the User Metadata file group page of the Edit MAR Deployment Profile Properties dialog before packaging. Alternatively, you can re-create the MAR profile to pick up this change. For more information about creating a MAR deployment profile, see How to Create Deployment Profiles.

51.3.8 How to View ADF Library Runtime Customizations from Exported JARs

When working in the JDeveloper Customization Developer role, you can view runtime customizations implemented on ADF library artifacts contained in an exported JAR.

Before you begin:

It may be helpful to have an understanding of how customization works. For more information, see Customization and Layers: Use Cases and Examples, and Customizing an Application.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete these tasks:

• Create your customizable application, as described in Developing a Customizable Application.

• Deploy the application and implement runtime customizations on it, then export the runtime customizations to a JAR file. For more information, see the Administering Oracle WebCenter Portal.

• Launch JDeveloper using the Customization Developer role, and open the customizable application.

To make runtime customizations viewable from JDeveloper:

1. From the Applications window context menu, choose Application Properties.

2. In the Application Properties dialog, select Customization Libraries.

3. Click Browse, and navigate to the location of the exported JAR file.

4. Select the JAR file and click Select.

5. Click OK.

Now the JAR is available so that JDeveloper can look up customizations on ADF library artifacts. When you open an object that contains ADF library artifacts, JDeveloper looks for customizations in this JAR file and displays them if appropriate. JDeveloper decides what to display for a given artifact in a given customization context as follows:

• If the artifact has neither runtime customizations nor seeded customizations associated with it, the artifact from the ADF library is displayed.

• If the artifact has only either runtime customizations or seeded customizations associated with it (but not both), the customized artifact is displayed.

• If the artifact has both runtime customizations and seeded customizations associated with it, the seeded customization takes precedence and is displayed.
Additionally, when you run the application locally from JDeveloper, the runtime customizations are displayed. However, the runtime customizations are not included in any packaging of the application for deployment.

### 51.3.9 What Happens When You Customize ADF Library Artifacts

During the development of enterprise applications, there might be artifacts (such as task flows) that can be reused in multiple applications. To facilitate reuse of these common artifacts, they can be packaged into an ADF library and distributed. This allows you to add the ADF library to the list of libraries that the consuming application depends on. Then when the application is packaged, the customizations from all such ADF libraries are included in the MAR, which is later deployed to the MDS repository. Note, however, that ADF library customizations are added to the MAR deployment profile when you create the profile, which is not automatically updated when customizations are implemented after creating the profile. To pick up these subsequent customizations, use the **Update Profile** button on the MAR Options page of the Edit MAR Deployment Profile Properties dialog.

---

**Note:**

The ADF library provider should take care to ensure that no name conflicts arise due to customizations in the library. In the event that name conflicts arise between customizations packaged in an ADF library and the customizations from the consuming project, the customizations from the ADF library are ignored.

---

When you implement customizations on objects from an ADF library, the customization metadata is stored by default in a subdirectory of the project called `libraryCustomizations`. And although you create ADF library customizations at the project level, they are merged together during packaging to be available at the application level at runtime. Essentially, ADF libraries are JARs that are added at the project level, which map to library customizations being created at the project level. However, although projects map to web applications at runtime, the MAR (which contains the library customizations) is at the EAR level, so the library customizations are seen from all web applications.

Therefore, you can customize an ADF library artifact in only one place in an application for a given customization context (customization layer and layer value). Customizing the same library content in different projects for the same customization context would result in duplication in MAR packaging. To avoid duplicates that would cause packaging to fail, implement customizations for a given library in only one project in your application.

---

**Note:**

Using the same location for ADF library customizations for all of the projects in your application can help to avoid duplicate customization. For more information, see Specifying a Location for ADF Library Customizations.

---

For example, say the ADF library you are using contains a page fragment `text.jsff`. In the consuming application, customize this library page in only one project. By doing so, customizations are available for all projects in the application that consume this library at runtime.
You are also restricted from customizing an object from an ADF library when your project already contains an object with the same name. In case of duplication, you must fix the projects by deleting one of the duplicate documents or deleting one and manually merging the differences into the other.

Similarly, if the ADF library contains seeded customizations for an artifact within a given customization context (customization layer and layer value), you cannot implement customizations for that artifact within the same customization context. In this situation, the ADF library artifact is read-only. You can, however, implement customizations for the artifact within other customization contexts.

For example, say the ADF library you are using contains seeded customizations for the Headquarters layer value in the Site layer. When you select this as your tip layer in the Customization Context window, the customized objects in that ADF library are read-only. However, if you select Site/Remote Site 1 as your tip layer, then the objects are customizable.

---

**Note:**

When the consuming application implements customizations on content from an ADF library, the customizations are written to the local project directories, but they are not automatically injected with the `web-app-root` during packaging. For more information, see Creating a MAR Deployment Profile.

---

### 51.3.10 What Happens at Runtime: How Customizations are Applied

At runtime, the application applies the customization metadata files over the base application in the order of precedence defined in the `cust-config` section of the `adf-config.xml` file.

The layer value is retrieved from the customization class at runtime and evaluated in the context the application is running, and the appropriate customizations for that layer value are applied.

### 51.3.11 What You May Need to Know About Customized Applications

When you are customizing an application, you might be using integrated source control or customizing resource strings. When you use these features, there is additional information you need to know.

#### 51.3.11.1 Customization and Integrated Source Control

When working in the Customization Developer role, your source control integration complements the process of customization. If JDeveloper is configured to automatically check out and add new files to source control and you attempt to customize a base document that is available from a source control system, JDeveloper behaves in the following way:

- If the corresponding customization file is not already available, then a new customization file is created in source control and the customizations are written to it.
- If the corresponding customization file exists, it is checked out and customizations are written to it.
• If the corresponding customization file exists and it is already checked out or not yet in version control, customizations are written to it without any further version control operation.

Since the base document is not modified in the **Customization Developer** role, the base document is not checked out.

If JDeveloper is not configured to automatically check out or add new files to source control, you must manually make the customization files editable and check in newly created customization files to source control. For more information about using source control in JDeveloper, see section **Using a Source Control System**.

### 51.3.11.2 Editing Resource Bundles in Customized Applications

During the course of customizing your application, you might want to customize the content to use different resource bundle keys or define and use new resource keys.

You can open a customizable application in the **Customization Developer** role and use the Properties window to customize the usages of resource bundle strings. You can change a document to use another already existing resource key in a resource bundle, or create a new resource. For more information about resource bundles, see **Working with Resource Bundles**.

New resource keys (created in the **Customization Developer** role) are saved to an application-level override bundle (in XLIFF format), and JDeveloper adds an entry to the `adf-config.xml` file like the one shown in the following example to configure the application-level override bundle.

You must also configure the `adf-config.xml` file to support the overriding of the base resource bundle. As the following example shows, you must tag the `bundleId` element with `override="true"` to make it overrideable. After it is marked as overridden, customizations of that bundle are stored in the application’s override bundle.

```xml
<adf-resourcebundle-config xmlns="http://xmlns.oracle.com/adf/resourcebundle/config">
  <applicationBundleName>
    path-to-resource-bundle/bundle-name
  </applicationBundleName>
  <bundleList>
    <bundleId override="true">
      package.BundleID
    </bundleId>
  </bundleList>
</adf-resourcebundle-config>
```

**Note:**

If an application is not configured for customization, you can open it in the **Customization Developer** role and define new resource keys by choosing **Application > Edit Resource Bundles** from the main menu. However, you cannot change a document to use the new resource keys if it is not configured for customization.

### 51.4 How to Package and Deploy Customized Applications

After you customize the application, you will want to deploy it. Before you deploy the customized application, you must follow the configuration procedures for setting up your MDS repository, as described in *Administering Oracle Fusion Middleware*. 
An enterprise application can contain model and user interface projects, and both types of projects can contain customized metadata. The customized metadata is packaged into a MAR for deployment. By default, the customizations from both types of projects are added to a single MAR. For information about how to create a MAR profile, see Creating a MAR Deployment Profile.

51.4.1 Implicitly Creating a MAR Profile

When you use JDeveloper to package a Fusion web application, JDeveloper creates an auto-generated MAR profile that includes default metadata (such as customizations), when either of the following conditions are met.

- The Enable User Customizations > Across Sessions using MDS checkbox is selected on the ADF View settings page of the Project Properties dialog for the user interface project.

- The MDS configuration section of the adf-config.xml file contains a <metadata-store-usage> element that is marked as deploy-target="true", as shown in the following example.

```
<metadata-namespaces>
  <namespace path="/oracle/apps" metadata-store-usage="repos1"/>
</metadata-namespaces>
<metadata-store-usages>
  <metadata-store-usage id="repos1" deploy-target="true">
  ...
  </metadata-store-usage>
</metadata-store-usages>
```

51.4.2 Explicitly Creating a MAR Profile

For customizations created in JDeveloper to take effect in the application when it is deployed, these customizations need to be made available to the application at runtime. There are two techniques you can use to accomplish this:

- Package the customizations along with the application using a MAR profile. Create a MAR profile that includes the customization metadata. The MAR profile should be included in the deployed EAR file to ensure that the customizations are available at runtime. Your customization classes must be packaged in the EAR file such that they are in the application-level class loader.

  **Note:**

  If you have only seeded customizations, you do not need to create a MAR profile to import them into the MDS repository unless you also want to support runtime customizations. If you have seeded customizations and do not have cross-session persistence enabled, the seeded customizations will be packaged in the EAR file by default and loaded from the class path.

- Import the customizations to the runtime repository used by the application. You typically use this approach if customizations to library metadata need to be applied to an application that is deployed separately. Using this approach, you
package the customizations into a JAR file and then use the command importMetadata with Oracle WebLogic Scripting Tool (WLST) to import them to the MDS runtime repository. For more information about this and other WLST commands, see the WLST Command Reference for Infrastructure Components.

If your application has customizations on objects from an ADF library, the customization metadata is implicitly included when you create the MAR profile. If you change the location of ADF library customizations in the Project Properties dialog, you must re-create the MAR profile before packaging.

If you plan to use design time at runtime capabilities to add or edit resource keys in the override bundle at runtime, the override bundle must be packaged as part of the MAR profile. By default, the override bundle is packaged as part of the auto-generated MAR profile if the application contains seeded customizations. However, if the application doesn’t contain seeded customizations, you must explicitly create the MAR deployment profile to package the override bundle. When the MAR profile is created explicitly, the override bundle is added and included by default as part of the user metadata.

When you package and deploy the completed customized application, you should do so from the Studio Developer role, rather than from the Customization Developer role. For information about how to create a MAR profile, see How to Create Deployment Profiles.

51.5 Extended Metadata Properties

Extended metadata is data that describes the metadata content. The extended metadata file contains additional information about the metadata file. One use of this extended information is to identify which parts of the metadata can be customized at runtime (design time at runtime customizations) and who can customize them. For more information about this use of extended metadata properties, see How to Enable Customization for Design Time at Runtime.

You can open a metadata file (such as a .jspx file) in JDeveloper and use the Properties window to view and edit its extended metadata properties. When you open a metadata file, its extended metadata properties are displayed in the Properties window. These properties can be edited to add metadata information at either of the following levels:

- File-level: These properties are displayed in the Properties window when the root element is selected in the Structure window.
- Element-level: These properties are displayed in the Properties window when an element is selected in the Structure window. The selected element should have a non-null identifier.

Extended metadata properties are supported for file types that support customizations and can be packaged in a MAR, such as .jsff and .jspx files.

Extended metadata for a metadata document is stored in an associated resource description framework (RDF) file. RDF is a W3C standard used to define an XML framework for defining metadata. The RDF file associated with the metadata document is created when the first property value is specified using the Properties window. Extended metadata properties are editable only when JDeveloper is in the Studio Developer role. RDF files are read-only in the Customization Developer role.

The RDF file is stored in the mdssys directory. For example, if the metadata being described is stored in the file system as /myapp/data/page1.jspx, the corresponding extended metadata document would be stored as /myapp/data/
The extended metadata document must then be packaged with the corresponding metadata base file and added to the same deployment profile. For more information about creating a MAR deployment profile, see How to Create Deployment Profiles.

---

**Note:**

Don’t edit the extended metadata documents directly. Use the Properties window.

---

### 51.5.1 How to Edit Extended Metadata Properties

You can use extended metadata properties to provide additional metadata information that is not covered in the metadata file (such as a `.jspx` file). When you open the metadata file in JDeveloper, extended metadata properties are displayed in the Properties window, which you can use to edit these properties when you are using JDeveloper in the **Studio Developer** role.

For example, suppose you want to deliver a metadata file in some form to external customers. Along with metadata file, you need to provide additional information about the file, such as the creator, subject, description, format, and rights. You can accomplish this by creating an extended metadata property file for your metadata file.

**Before you begin:**

It may be helpful to have an understanding of how extended metadata is used. For more information, see Extended Metadata Properties.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Customization.

You will also need to complete this task:

• Launch JDeveloper using the **Studio Developer** role, and open the application.

**To edit extended metadata properties:**

1. In the Applications window, select the object for which you want to edit extended metadata properties.

2. In the Structure window, select the appropriate element (typically the root element).

3. In the Properties window, expand the appropriate node to edit the properties.

   To display the Properties window with the values for the selected component, choose **Window > Properties** from the main menu.

4. Edit the value for the desired property and press Enter.

5. From the main menu, choose **File > Save** to save your changes.

If you have edited extended metadata properties for a metadata file, you must package your extended metadata (or RDF) files with the metadata files when you deploy the application.
51.5.2 How to Enable Customization for Design Time at Runtime

You can also use extended metadata properties to provide information about which parts of the metadata can be customized at runtime and who can customize the metadata content.

By default, all components that you can add to a .jspx page are preconfigured to allow runtime customization to support implicit user personalization (such as changing the order of columns in a table).

All pages and fragments that you create are also configured to allow customization by default. Some WebCenter Portal components (such as panelCustomizable) also allow customization in their type definition. For more information about user customization, see Allowing User Customizations at Runtime. For more information about WebCenter Portal components, see the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper.

Components that are preconfigured to allow customization need no further modification to enable design time at runtime customizations. If you use them in a .jspx page, then they are customizable by default.

Depending on the requirements of your application, you will need to modify customization properties in the following situations:

- For components that are configured to allow customization, you can override the default settings to disallow customization.
- For components that are not configured to allow customization and metadata objects (such as .jspx pages), you can override the settings to allow customization.
- For components that are configured to allow customization, you can optionally restrict who is allowed to perform customizations at runtime.

If you edit customization properties, you must package your extended metadata (RDF) files with the metadata files when you deploy the application.

Additionally, you can restrict customizations on an entire subtree of components by marking the root of the subtree to disallow customizations. You can then mark individual components of that subtree as customizable to allow customizations for those specific components.

51.5.2.1 Editing Customization Properties in the Properties window

In the Customization group in the Properties window, there are two properties that allow you to specify whether customizations for an object are permitted at runtime and who is permitted to do them. The CustomizationAllowed property can be set on any element to specify whether or not it can be customized. The CustomizationAllowedBy property controls which users can customize the element. These settings are not enforced when you are implementing seeded customizations using JDeveloper, but are instead enforced when the application is customized at runtime (design time at runtime customizations).

For example, say you have a .jspx page with a form that contains two panels, and you need to allow runtime customization for content in Panel1, but not Panel2. You would set CustomizationAllowed to true for Panel1, and set it to false for Panel2. If you need to allow runtime customization on an entire page, you would set CustomizationAllowed to true for the .jspx page root.
Before you begin:

It may be helpful to have an understanding of how extended metadata is used. For more information, see **Extended Metadata Properties**.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see **Additional Functionality for Customization**.

You will also need to complete these tasks:

- Create your customizable application, as described in **Developing a Customizable Application**.
- Launch JDeveloper using the **Studio Developer** role, and open the application.

To edit customization properties:

1. In the Applications window, select the object for which you want to edit customization properties.
2. In the Structure window, select the appropriate element.
3. In the Properties window, expand the **Customization** node to edit the customization properties.

   To display the Properties window with the values for the selected component, choose **Window > Properties** from the main menu.
4. Edit the property value and press Enter.

   For example, to allow runtime customizations on a .jspx file, select the file and set the **CustomizationAllowed** property to true.
5. From the main menu, choose **File > Save** to save your changes.

### 51.5.2.2 Using a Standalone Annotations File to Specify Type-Level Customization Properties

You can optionally use a standalone annotations file to specify whether or not customizations are allowed for a given type of component. This file allows you to set customization properties on element types, rather than on instances. You can override the setting for a given type by explicitly setting true or false on a specific instance. The following example shows the contents of a sample standalone annotations file.

```xml
<?xml version="1.0" encoding="UTF-8"?>
<grammarMetadata xmlns="http://xmlns.oracle.com/bali/xml/metadata"
xmlns:md="http://xmlns.oracle.com/bali/xml/metadata"
xmlns:mmd="http://xmlns.oracle.com/bali/xml/metadata/model"
xmlns:mds="http://xmlns.oracle.com/mds"
namespace="http://www.oracle.com/mds/restrictCustomizations">
  <elementMetadata elementName="orderDetail">
    <attributeMetadata attributeName="itemTypeRef">
      <mds:customizationAllowedBy>sales admin</mds:customizationAllowedBy>
    </attributeMetadata>
    <attributeMetadata attributeName="description">
      <mds:customizationAllowed>true</mds:customizationAllowed>
      <mds:customizationAllowedBy>hr</mds:customizationAllowedBy>
    </attributeMetadata>
    <attributeMetadata attributeName="title">
      <mds:customizationAllowed>true</mds:customizationAllowed>
    </attributeMetadata>
  </elementMetadata>
</grammarMetadata>
```
If you use a standalone annotations file, you must register it with MDS in the adf-config.xml file. Create a mdsc:standalone-definitions section in the mdsc:type-config section of the adf-config.xml file, as shown in the following example.

```xml
<?xml version="1.0"?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
            xmlns:mdsc="http://xmlns.oracle.com/mds/config">
  <mdsdata>
    <mdsc:mds-config version="11.1.1.000">
      <mdsc:type-config>
        <mdsc:type-definitions>
          <mdsc:url>jar:file:/c:/jdev/lib/oafwk.jar!/oracle/apps/schemas/oa.xsd</mdsc:url>
          <mdsc:mds>/oracle/mds/TypeSeven.xml</mdsc:mds>
          <mdsc:mds>/oracle/mds/TypeEight.xml</mdsc:mds>
          <mdsc:file>typefile7.xsd</mdsc:file>
          <mdsc:file>typefile8.xsd</mdsc:file>
        </mdsc:type-definitions>
      </mdsc:type-config>
    </mdsc:mds-config>
  </mdsdata>
</adf-config>
```

### 51.6 Enabling Runtime Modification of Customization Configuration

You can prepare your customized application to accept overrides to the customization configuration (the cust-config section of the adf-config.xml file) at runtime on
a per-session basis, thus allowing the user to change the way customizations are applied for a given session (or web request).

Consider a scenario where an application is configured with a site layer and a user layer and you want to make design time at runtime customizations to the site layer. If you use the application's customization configuration (defined in the adf-config.xml file), any customizations that you implement are applied to the user layer. So, you need to be able to adjust the customization configuration for a given session to allow your customizations to be applied to the site layer.

Or perhaps you have a requirement that an administrator wants to see the base metadata document with the site layer customizations alone. For cases like this, you need to specify a modified customization configuration, other than what was originally specified in application's adf-config.xml file.

For each web request, Oracle ADF creates an MDS session. For any MDS customization configuration modifications that apply to a session (web request), the user could programmatically provide modified MDS session options with a new customization configuration to Oracle ADF that would be applied on top of the original MDS configuration while creating a MDS session.

To implement this functionality, use the following ADF interfaces for sessionOptionsFactory:

• oracle.adf.share.mds.SessionOptionsFactory is the interface you use to specify modified MDS session options for a web request in a Fusion web application.

    SessionOptionsFactory :: oracle.mds.core.SessionOptions
    createSessionOptions(oracle.mds.core.SessionOptions defaultOptions)

    You implement this method to return the modified MDS sessionOptions to ADF.

• oracle.adf.share.config.ConfigUtils is the public class you can use to register your session options factory with ADF.

    ConfigUtils :: public static void setSessionOptionsFactory(ADFContext context, SessionOptionsFactory factory)

    See your ADF API documentation for further detail on these interfaces.

Note:

If you are using Oracle WebCenter Portal’s Composer components, you can use the ComposerSessionOptionsFactory interface to specify modified MDS session options with Oracle WebCenter Portal’s Composer.

    ComposerSessionOptionsFactory :: public SessionOptions
    createSessionOptions(SessionOptions defaultOptions, String mode);

    oracle.adf.view.page.editor.webapp.WebCenterComposerFilter loads your ComposerSessionOptionsFactory implementation from the current thread context class loader. See the Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper for more information.

You register your sessionOptionsFactory with Oracle ADF so that ADF can get modified session options from your implementation before the MDS session is created in request lifecycle.
Alternatively, you can register your `sessionOptionsFactory` with Oracle WebCenter Portal’s Composer in a filter implementation.

The following example shows how you can implement `sessionOptionsFactory`. This example sets a modified customization configuration for the session to use the site customization layer alone regardless of the customization configuration specified in the `adf-config.xml` file. See the Javadoc for `oracle.mds` for more information.

```java
package mycompany;

import oracle.adf.share.mds.SessionOptionsFactory;
import oracle.mds.config.CustClassListMapping;
import oracle.mds.config.CustConfig;
import oracle.mds.config.MDSConfigurationException;
import oracle.mds.core.SessionOptions;
import oracle.mds.cust.CustClassList;
import oracle.mds.cust.CustomizationClass;

public class MySessionOptionsFactory implements SessionOptionsFactory {

    public MySessionOptionsFactory() {
        super();
    }

    /**
     * Called to allow the application code to create a new SessionOptions object.
     * The application code should make sure to read the values from the
     * `defaultOptions` object as part of construction of their new object and make
     * sure they only override the intended values.
     * @param defaultOptions
     * @return modified MDS session options
     */
    public SessionOptions createSessionOptions(SessionOptions defaultOptions) {
        // create new mds Customization configuration
        CustConfig custconfig = null;

        // create customization class array. Just put SiteCC implementation as we
        // wish to apply site customizations alone.
        CustomizationClass[] custclassarray = new CustomizationClass[] {new SiteCC()};

        CustClassList custclasslist = new CustClassList(custclassarray);

        // specify the base metadata package namespace mapping on which site
        // customizations would apply
        CustClassListMapping[] mappings =
            new CustClassListMapping[] {
                new CustClassListMapping("mycompany/package",
                null, null, custclasslist)};

        // create new customization configuration
        try{
            custconfig = new CustConfig(mappings);
        }
        catch (Exception ex){
            //do nothing
        }

        // now return modified sessionOptions to ADF with new mds customization
        // configuration. Only use newly created customization configuration in here.
        // For rest of option, use whatever available in defaultOptions.
        return new SessionOptions(defaultOptions.getIsolationLevel(),
            defaultOptions.getLocale(),
            custconfig,
            defaultOptions.getVersionContext(),
            custconfig,  // customization configuration
            defaultOptions.getIsolationLevel(),
            defaultOptions.getLocale(),
            custconfig,
            defaultOptions.getVersionContext(),
        );
    }
}
```

defaultOptions.getVersionCreatorName(),
defaultOptions.getCustomizationPolicy(),
defaultOptions.getServletContextAsObject());
}
Allowing User Customizations at Runtime

This chapter describes how to use the ADF Faces change persistence framework to create JSF pages that users can customize at runtime.

This chapter includes the following sections:

- About User Customizations
- Enabling Runtime User Customizations for a Fusion Web Application
- Configuring User Customizations
- Controlling User Customizations in Individual JSF Pages
- Implementing Custom User Customizations
- Creating Implicit Change Persistence in Custom Components

52.1 About User Customizations

Certain ADF Faces components have attributes that can be saved for a specific user. For example, the value of the disclosed attribute on a panelBox component can be saved for a specific user during the current session. Say the myOrders page in an application contains four panelBox components that display order information. By default, they are expanded, as shown in Figure 52-1.
Figure 52-1  panelBox Components Are Expanded by Default

However, suppose a user decides to collapse one of the boxes, as shown in Figure 52-2.

Figure 52-2  panelBox Component Remains Collapsed

About User Customizations
Because this application is configured to allow user customizations, then during the user's session, anytime that user returns to the page, the Payment Information box remains collapsed. You need only to enable user customizations for the project in order for these changes to be persisted to the user's session.

**Note:**

The user session begins when the user logs in to the application, and ends when the user leaves the application. It is possible that while using an application, the user could navigate across application boundaries (for example, to a peer application) and thereby leave the application, at which point the user session would end.

Table 52-1 shows the attribute value changes persisted by an ADF Faces application, after you configure the application to allow user customizations.

**Table 52-1  Implicitly Persisted Attribute Values**

<table>
<thead>
<tr>
<th>Component</th>
<th>Attribute</th>
<th>Affect at Runtime</th>
</tr>
</thead>
<tbody>
<tr>
<td>panelBox</td>
<td>disclosed</td>
<td>Users can display or hide content using an icon in the header. Detail content will either display or be hidden, based on the last action of the user.</td>
</tr>
<tr>
<td>showDetail</td>
<td></td>
<td></td>
</tr>
<tr>
<td>showDetailHeader</td>
<td></td>
<td></td>
</tr>
<tr>
<td>showDetailItem</td>
<td></td>
<td></td>
</tr>
<tr>
<td>showDetailItem (used in a panelAccordion component)</td>
<td>flex</td>
<td>The heights of multiple showDetailItem components are determined by their relative value of the flex attribute. The showDetailItem components with larger flex values will be taller than those with smaller values. Users can change these proportions, and the new values will be persisted.</td>
</tr>
<tr>
<td>showDetailItem (used in a panelAccordion component)</td>
<td>inflexibleHeight</td>
<td>Users can change the size of a panel, and that size will remain.</td>
</tr>
<tr>
<td>panelSplitter</td>
<td>collapsed</td>
<td>Users can collapse either side of the splitter. The collapsed state will remain as last configured by the user.</td>
</tr>
<tr>
<td>panelSplitter</td>
<td>splitterPosition</td>
<td>The position of the splitter in the panel will remain where last moved by user.</td>
</tr>
<tr>
<td>richTextEditor</td>
<td>editMode</td>
<td>The editor will display using the mode (either WYSIWYG or source) last selected by the user.</td>
</tr>
<tr>
<td>calendar</td>
<td>activeDay</td>
<td>The day considered active in the current display will remain the active day.</td>
</tr>
<tr>
<td>Component</td>
<td>Attribute</td>
<td>Affect at Runtime</td>
</tr>
<tr>
<td>------------</td>
<td>--------------</td>
<td>----------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>calendar</td>
<td>view</td>
<td>The view (day, week, month, or list) that currently displays activities will be retained.</td>
</tr>
<tr>
<td>panelWindow</td>
<td>contentHeight</td>
<td>Users can change the height of a panelWindow or dialog popup component, and that height will remain.</td>
</tr>
<tr>
<td>dialog</td>
<td></td>
<td></td>
</tr>
<tr>
<td>panelWindow</td>
<td>contentWidth</td>
<td>Users can change the width of a panelWindow or dialog popup component, and that width will remain.</td>
</tr>
<tr>
<td>dialog</td>
<td></td>
<td></td>
</tr>
<tr>
<td>button</td>
<td>windowHeight</td>
<td>When users change the contentHeight attribute value of a panelWindow or dialog component, any associated windowHeight value on a command component is also changed and will remain.</td>
</tr>
<tr>
<td>link</td>
<td></td>
<td></td>
</tr>
<tr>
<td>commandMenuItem</td>
<td></td>
<td></td>
</tr>
<tr>
<td>commandNavigationItem</td>
<td></td>
<td></td>
</tr>
<tr>
<td>button</td>
<td>windowWidth</td>
<td>When users change the contentWidth attribute value of a panelWindow or dialog component, any associated windowWidth value on a command component is also changed and will remain.</td>
</tr>
<tr>
<td>link</td>
<td></td>
<td></td>
</tr>
<tr>
<td>column</td>
<td>displayIndex</td>
<td>ADF Faces columns can be reordered by the user at runtime. The displayIndex attribute determines the order of the columns. (By default, the value is set to -1 for each column, which means the columns will display in the same order as the data source). When a user moves a column, the value on each column is changed to reflect the new order. These new values will be persisted.</td>
</tr>
<tr>
<td>column</td>
<td>frozen</td>
<td>ADF Faces columns can be frozen so that they will not scroll. When a column’s frozen attribute is set to true, all columns before that column (based on the displayIndex value) will not scroll. When you use the table with a panelCollection component, you can configure the table so that a button appears that allows the user to freeze a column.</td>
</tr>
</tbody>
</table>
### Table 52-1  (Cont.) Implicitly Persisted Attribute Values

<table>
<thead>
<tr>
<th>Component</th>
<th>Attribute</th>
<th>Affect at Runtime</th>
</tr>
</thead>
<tbody>
<tr>
<td>column</td>
<td>nowrap</td>
<td>The content of the column will either wrap or not. You need to create code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from true to false.</td>
</tr>
<tr>
<td>column</td>
<td>selected</td>
<td>The selected column is based on the column last selected by the user.</td>
</tr>
<tr>
<td>column</td>
<td>visible</td>
<td>The column will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a context menu that allows a user to toggle the value from true to false.</td>
</tr>
<tr>
<td>column</td>
<td>width</td>
<td>The width of the column will remain the same size as the user last set it.</td>
</tr>
<tr>
<td>table</td>
<td>filterVisible</td>
<td>ADF Faces tables can contain a component that allows users to filter the table rows by an attribute value. For a table that is configured to use a filter, the filter will either be visible or not, based on the last action of the user. You will need to write code that allows the user to change this attribute value. For example, you might create a button that allows a user to toggle the value from true to false.</td>
</tr>
<tr>
<td>dvt:areaGraph</td>
<td>timeRangeMode</td>
<td>The time range for the data displayed on a graph time axis can be specified for all data visualization graph components. By default, all data is displayed. The time range can also be set for a relative time range from the last or first data point, or an explicit time range. You will need to write code that allows the user to change this attribute value. For example, you might create a dropdown list to choose the time range for a graph.</td>
</tr>
<tr>
<td>Component</td>
<td>Attribute</td>
<td>Affect at Runtime</td>
</tr>
<tr>
<td>--------------------</td>
<td>-----------</td>
<td>---------------------------------------------------------------------------------------------------------------------------------------------------</td>
</tr>
<tr>
<td>dvt:ganttLegend</td>
<td>visible</td>
<td>The legend for data visualization project, resource utilization, and scheduling Gantt chart components will either be visible or not inside the information panel. You will need to write code that allows the user to change this attribute value, for example, a hide and show button to display the legend.</td>
</tr>
<tr>
<td>dvt:hierarchyViewer</td>
<td>layout</td>
<td>The data visualization hierarchy viewer component supports nine hierarchy layout options including a top-to-bottom vertical, tree, circle, radial, and so on. Users can change the layout in the map control panel and the last selected layout will be retained.</td>
</tr>
<tr>
<td>dvt:map</td>
<td>mapZoom</td>
<td>This data visualization geographic map component attribute specifies the beginning zoom level of the map. The zoom levels are defined in the map cache instance as part of the base map. You will need to write code that allows the user to change this attribute value.</td>
</tr>
<tr>
<td>dvt:map</td>
<td>srid</td>
<td>This data visualization geographic map component attribute specifies the srid (spatial reference id) of all the coordinates of the map, which includes the center of the map, defined by startingX and startingY, and all the points in the point theme. You will need to write code that allows the user to change this attribute value.</td>
</tr>
<tr>
<td>dvt:map</td>
<td>startingX, startingY</td>
<td>This data visualization geographic map component attribute specifies the X and Y coordinate of the center of the map. The srid for the coordinate is specified in the srid attribute. If the srid attribute is not specified, this attribute assumes that its value is the longitude of the center of the map. You will need to write code that allows the user to change this attribute value.</td>
</tr>
</tbody>
</table>
### 52.1.1 Runtime User Customization Use Cases and Examples

You can configure an application so that the value of the attributes listed in Table 52-1 can be persisted across sessions using the MDS repository. For example, if an application allowed persistence to the MDS repository, then a user could collapse the Payment Information box, as shown in Figure 52-2, and it would be collapsed the next time that user entered the application.

**Note:**

Before you can enable persistence to the repository, you must first follow all MDS configuration procedures as documented in *Administering Oracle Fusion Middleware*.

Along with the automatic persistence available through ADF Faces, you can create your own custom user customization capabilities for the following types of changes:

- Changing an attribute value
• Adding or removing a facet
• Adding or removing a child component
• Reordering child components
• Moving a child component to a different parent

If you want to create these types of custom user customizations, you need to add code (for example, in an event handler) that will call the APIs to handle the persistence.

Enabling an application to use the change persistence framework requires that you first enable your application to allow user customizations. Part of this process is determining where those changes should be persisted, either to the session or the MDS repository.

If you choose to persist changes to the session, by default all values as shown in Table 52-1 will be saved for the user’s session. However if you choose to persist changes to a repository, you must explicitly configure which of these attribute values will be persisted to the repository. Instead of persisting all these attribute values, you can restrict changes so that only certain attribute value changes for a component are persisted, or so that only specific instances of the components persist changes.

**Note:**

You cannot persist changes to a component that is contained inside (anywhere in the subtree) of *af:forEach* or *af:iterator* tags using the *addComponentChange()* method. While such structure results in multiple copies of a component in the view tree, each component has only a single representation in the JSP document. However, the *addDocumentChange()* method does allow persistence for such components. For more information, see the discussion of the *DocumentChange* and *ComponentChange* classes in *What You May Need to Know About the Change Persistence Framework API*.

For any applications that persist changes to an MDS repository, when you deploy your application, you must create a metadata archive (MAR) profile in the application’s EAR assembly. For more information, see *How to Create Deployment Profiles*.

### 52.1.2 Additional Functionality for Runtime User Customization

You may find it helpful to understand other features before you start working with user customizations. Following are links to other functionality that may be of interest.

• For information about the MDS architecture and metadata repositories (database- and file-based) and archives (EAR, MAR), see to the section about managing the MDS repository in *Administering Oracle Fusion Middleware*.

• The MDS framework allows you to create customizable applications that can be customized and subsequently deployed by a customer. For information, see *Customizing Applications with MDS*.

• The features of Oracle WebCenter Portal allow business analysts or administrators, using a web browser interface, to customize an application for their end users. For information about runtime customization, refer to the *Developing WebCenter Portal Assets and Custom Components with Oracle JDeveloper*.
52.2 Enabling Runtime User Customizations for a Fusion Web Application

Enabling an application to allow user customizations (whether for the default changes that some ADF Faces components provide, or for custom capabilities that you create) requires that you configure your application to use the change persistence framework and that you also determine where those changes should be persisted (either the session or the MDS repository).

Note:
If you are planning on persisting changes to the MDS repository, before configuring an ADF Faces application to use change persistence, you must first follow all MDS configuration procedures as documented in Administering Oracle Fusion Middleware.

52.2.1 How to Enable User Customizations

You enable your application to use the change persistence framework by editing the web.xml and adf-config.xml files.

Before you begin:
It may be helpful to have an understanding of the features of runtime user customization. For more information, see Enabling Runtime User Customizations for a Fusion Web Application.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the Studio Developer role, and open (or create) the application in which you want to enable runtime user customization.

To enable user customizations:

1. In the Applications window, double-click the web project in your application.

2. In the Project Properties dialog, select the ADF View node.

3. On the ADF View page, select the Enable User Customizations checkbox. If you want the changes to be persisted to only the session, select the For Duration of Session radio button. If you want the changes to persist to the MDS repository, select Across Sessions Using MDS.

4. If you choose to persist to the repository, you now need to declare each component tag and associated attribute values that you want persisted to the repository (if you choose to persist only to the session, all values will be persisted).

For procedures to accomplish this task, see Configuring User Customizations. Once that configuration is complete, you can override those settings on a per component instance basis. For procedures, see Controlling User Customizations in Individual JSF Pages.

Note:
If you have created custom user customization capabilities as documented in
Implementing Custom User Customizations, then you also need to declare
those attribute values or operations.

### 52.2.2 What Happens When You Enable User Customizations

When you elect to save changes only to the session, JDeveloper adds the
CHANGE_PERSISTENCE context parameter to the web.xml file, and sets the value to
session. This context parameter registers the ChangeManager class that will be
used to handle persistence. If you instead elect to save the changes to the MDS
repository, the value is set to
oracle.adf.view.rich.change.FilteredPersistenceChangeManager, as
shown in the following example.

```xml
<context-param>
  <param-name>org.apache.myfaces.trinidad.CHANGE_PERSISTENCE</param-name>
  <param-value>
    oracle.adf.view.rich.change.FilteredPersistenceChangeManager
  </param-value>
</context-param>
```

**Tip:**

If needed, you can manually set this value to
oracle.adf.view.rich.change.MDSDocumentChangeManager if you
do not want any customizations to be restricted based on configurations in the
adf-config.xml file or on the individual JSF pages, and you always want
the changes to be persisted to the MDS repository and not the session.

When you elect to persist to the repository, JDeveloper also does the following:

- Adds the following JARs to the class path if they don't exist:
  - javatools-nodep.jar
  - facesconfigmodel.jar
  - taglib.jar
- Adds another context parameter to web.xml to register the
  MDSJSPProviderHelper class to handle merging MDS customization documents
  with the base JSP document, as shown in the following example.

```xml
<context-param>
  <param-name>oracle.adf.jsp.provider.0</param-name>
  <param-value>oracle.mds.jsp.MDSJSPProviderHelper</param-value>
</context-param>
```

- Adds the ADF Faces Change Manager Runtime 11 library to the project.
- In the adf-config.xml descriptor file, sets the persistent-change-manager
element to the MDSDocumentChangeManager, which is the class that will be used
to persist the changes. The following example shows the configuration for
persisting to the MDS repository.

```xml
<persistent-change-manager>
  <persistent-change-manager-class>
    oracle.adf.view.rich.change.MDSDocumentChangeManager
  </persistent-change-manager-class>
</persistent-change-manager>
```
• Creates JSF JSP pages as XML documents. For more information, see Controlling User Customizations in Individual JSF Pages.

Additionally, when you elect to save the changes to the MDS repository, and you include facelets in your application, JDeveloper adds the faceletCache context parameter to the web.xml file. The value of this parameter is set to oracle.adfinternal.view.faces.facelets.rich.MDSFaceletCache, as shown in the following example.

```xml
<context-param>
  <param-name>com.sun.faces.faceletCache</param-name>
  <param-value>oracle.adfinternal.view.faces.facelets.rich.MDSFaceletCache</param-value>
</context-param>
```

The facelets cache enhances the performance of your application and the cache capacity can be configured in MDS on the server. For more information, see Administering Oracle Fusion Middleware.

52.3 Configuring User Customizations

If you choose to persist changes to an MDS repository, you must decide which of the attribute values that are by default persisted to the session (as shown in Table 52-1) should also be persisted to the repository. Alternatively, you can configure which changes you do not want persisted.

**Tip:**

Often, a system administrator is the one to set the configurations in the adf-config.xml. The persist and dontPersist attributes on a component allow page authors to override that setting as needed.

For example, suppose you decide that you don't want the value for the width attribute on columns to be persisted to the repository, but you do want all other default attribute changes for columns to be persisted. You must explicitly set the other default column values that you want to be persisted, and you also must explicitly configure the application to NOT persist the width attribute.

**Note:**

If you have created custom user customization capabilities as documented in Implementing Custom User Customizations, then you must explicitly declare those attribute values or operations as well.

You set (and unset) these values using the overview editor for the adf-config.xml file. Figure 52-3 shows the overview editor where only certain attribute values for the column component will be persisted.
Once set, you can override persistence for a specific component on a page. For example, suppose you want to disallow change on the `width` attribute on only one table's columns. You want the rest of the tables in the application to persist changes to that attribute. You would configure the columns to globally persist changes to the `width` attribute, but then for that one table, you would override the global configuration directly on the JSF page. For more information, see Controlling User Customizations in Individual JSF Pages.

**Note:**
If you've enabled just session persistence, then all attribute values shown in Table 52-1 will be persisted to the session. There is no way to override this either globally or on an instance.

### 52.3.1 How to Configure Change Persistence

By default, when you configure your application to use any type of change persistence (that is, to either the session or a repository), the values of all attributes shown in Table 52-1 will always be persisted to the user's session. If you configured your changes to be persisted to a repository, then you must declare the attributes whose values should be persisted to that repository. If there are any values that you don't want persisted, then you need to configure those values as well.

Before you begin:

It may be helpful to have an understanding of how runtime user customization are persisted. For more information, see Configuring User Customizations.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.
You will need to launch JDeveloper using the Studio Developer role, and open (or create) the application in which you want to enable runtime user customization.

To declare attribute value persistence to a repository:

1. In the Application Resources panel, expand the Descriptors and ADF META-INF nodes, and then double-click adf-config.xml.

2. In the overview editor, click the View navigation tab.

3. In the View page, in the Tag Persistence section, in the Components table, select the component whose changes you want to persist (or not persist) to the repository.

If the component does not appear in the table, click the Add icon to select and add it.

**Note:**
The filter rules specified in the adf-config.xml file are applicable only when you have chosen to persist to the MDS repository (see How to Enable User Customizations). These rules do not apply for persistence within session scope.

If persistence fails for any reason (for example if one of the filter rules fails or there are MDS repository errors), then the values will be stored only within the session scope.

The Attributes table displays all the attributes for the selected component whose values can be persisted.

4. In the Attributes table, select Persist Changes for each of the attributes whose values you want persisted. Deselect any if you do not want the values persisted.

**Note:**
If you are implementing custom user customizations (see Implementing Custom User Customizations), then you will need to edit the adf-config.xml manually to add the configuration. See What Happens When You Configure Change Persistence for an example on how to configure user customizations.

### 52.3.2 What Happens When You Configure Change Persistence

When you select the component tags and attribute values to be persisted in the adf-config.xml file, JDeveloper enters tag library information for the components and attributes that are to be persisted. The following example shows the entry for persisting the value of the disclosed attribute on the panelBox component.

```xml
<taglib-config>
  <taglib uri="http://xmlns.oracle.com/adf/faces/rich">
    <tag name="panelBox">
      <attribute name="disclosed">
        <persist-changes>
          true
        </persist-changes>
      </attribute>
    </tag>
  </taglib>
</taglib-config>
```
52.4 Controlling User Customizations in Individual JSF Pages

Once you have enabled your application to allow user customizations, you can control user customizations for specific components on the page.

By default, the framework persists changes for all component instances, based on the configuration in the \( \text{adf-config.xml} \) file. You can override this default behavior by explicitly setting what should be persisted and what should not be persisted on each component instance using the \text{persist} and \text{dontPersist} attributes.

\begin{quote}
\textbf{Note:}

The filter rules specified using the \text{persist} and \text{dontPersist} attributes are applicable only when you have chosen to persist to the MDS repository (see \text{How to Enable User Customizations}). These rules do not apply for persistence within session scope.

If persistence fails for any reason (for example if one of the filter rules fails or there are MDS repository errors), then the values will be stored only within the session scope.
\end{quote}

The following components support the \text{persist} and \text{dontPersist} attributes:

- \text{panelBox}
- \text{showDetail}
- \text{showDetailHeader}
- \text{showDetailItem}
- \text{column}
- \text{tree}
- \text{treeTable}
- \text{panelSplitter}
- \text{calendar}
- \text{dvt:projectGantt}

52.4.1 How to Control User Customizations on a JSF Page

You can override any globally set persistence configuration for a component using its `persist` and `dontPersist` attributes.

**Tip:**

Often, a system administrator is the one to set the configurations in the `adf-config.xml`. The `persist` and `dontPersist` attributes allow page authors to override that setting as needed.

Before you begin:

It may be helpful to have an understanding of how runtime user customizations can be restricted on an individual page. For more information, see Controlling User Customizations in Individual JSF Pages.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the Studio Developer role, open the application, and open the page for which you want to modify user customization behavior.

To implement user customizations on a JSF Page:

1. In the Applications window, double-click the page that contains components that will be persisting changes.

2. If you want to persist all persistable attributes for a component:
   a. In the Properties window, expand the Advanced section.
   b. From the dropdown list for the Persist field, select All Available.

3. If you do not want to persist any attributes, repeat Step 2 for the Don'tPersist field.

4. If more than one attribute can be persisted for the component, and you do not want to persist all of them:
   a. In the Properties window, from the dropdown menu to the right of the Persist field, choose Edit.
   b. In the Edit Property dialog, shuttle any attributes to be persisted from Available to Selected.

5. If you do not want to persist an attribute value, repeat Step 4 for the Don't Persist field.

**Note:**

The filter rules specified using the `persist` and `dontPersist` attributes take precedence over any `adf-config.xml` configuration set for global component-level restrictions.

Values specified for the `dontPersist` attribute take precedence over values specified for the `persist` attribute. For example, if for a `panelBox`
component you set disclosed as the value for both the persist and dontPersist attributes, the value of the disclosed attribute will not be persisted.

If you set the value of the persist or dontPersist attribute to All Available, then any values entered as choices using the Edit dialog and the shuttle will be ignored and all available attribute values will be persisted or not persisted.

52.4.2 What Happens at Runtime: How Changes are Persisted

When an application is configured to persist changes to the session, any changes made during the session are recorded in a session variable in a data structure that is indexed according to the view ID and the component's ID attribute value. Every time the page is requested, in the subsequent create View or Restore View phase, all changes are applied in the same order as they were added. This means that the changes registered through the session will be applied only during subsequent requests in the same session.

When an application is configured to persist changes to the MDS repository, any changes made during the session are recorded by mutating the Document Object Model that MDS maintains for the JSP document behind the view. A JSF phase listener registered by ADF controller triggers a commit on the MDS session during the appropriate lifecycle phase, resulting in the change document being persisted in the MDS store. Every time the page is requested, Oracle's JSP engine seeks the JSP document from an MDS JSP provider, which provides a flattened document after merging the stored changes to the base document. MDS records the change against the unique value of the component's ID attribute.

Tip:

If changes are applied in response to a partial submit of the page (for example, a button with the partialSubmit attribute set to true), the component for which changes are applied must be set as the value for the partialTarget attribute.

Additionally, be aware that when you run the application from JDeveloper in the Integrated WebLogic Server, MDS creates a local file-based repository to persist metadata customizations. In contrast, when the application is deployed to a test or production environment, customizations are persisted to the configured MDS repository. For more information about MDS repository configuration, see the Administering Oracle Fusion Middleware. For more information about deploying an application, see Deploying the Application.

52.4.3 What You May Need to Know About Using Change Persistence on Templates and Regions

How changes are persisted for components on templates or regions is handled differently, depending on whether the changes are persisted to the session or to the MDS repository. With session persistence, changes are recorded and restored on components against the viewId for the given session. As a result, when the change is applied on a component that belongs to a region or page template, that change is applicable only in scope of the page that uses the region or template. It does not span all pages that consume the region or template. For example, suppose you have pageOne.jspx and pageTwo.jspx, and they both contain the region defined in
region.jsff, which in turn contains a showDetail component. When pageOne.jspx is rendered and the disclosed attribute on the showDetail component changes, the implicit attribute change is recorded and will be applied only for pageOne.jspx. If the user navigates to pageTwo.jspx, no attribute change is applied.

When you persist changes to the MDS repository, MDS records and restores customizations for a document identified by a combination of the JSP page path and customization name/value configuration setting as set on the customization class (for more information, see Customization Classes). As a result, for a given page that is rendered, when MDS applies a change on a component within a region or template, it is applicable for all pages that consume the region or template and that have the same customization name and value as the source page.

In the previous example, assume that the showDetail component uses the ID of myShowDetail. When pageOne.jspx is rendered and the disclosed attribute on the showDetail component changes, the attribute change is recorded for region.jsff (and not the page that consumes it). This change is applied when any page that contains the region is rendered, as long as the ID remains the same.

52.5 Implementing Custom User Customizations

In addition to the user customization capabilities built in to certain ADF Faces components, you can create your own custom user customization capabilities. The change persistence framework supports the following types of user customizations:

- Changing an attribute value
- Adding or removing a facet
- Adding or removing a child component
- Reordering child components
- Moving a child component to a different parent

To create custom user customizations, you must create a customization class for each type of user customization and then configure your application to use that class. You also need to set up the layers of customization for your application. For more information about both of these procedures, see Developing a Customizable Application.

Once those prerequisites are satisfied, you add logic that calls methods on the ADF Faces classes that handle persisting change either to the session or the MDS repository. To handle the change, you create code that uses the APIs from one of the ADF Faces specialized component change classes. For most cases, you add this code to the event handler method on a managed bean associated with the page the persisting component is on. If you want all instances of a component to persist the same change, you need to add this code for each page on which that component appears.

If you are creating a custom component, you can implement user customizations for the component by adding code directly to the custom component class. In that case, you will need to add the code only to the component class, and not once for each instance of the component. For more information, see Creating Implicit Change Persistence in Custom Components.
### 52.5.1 What You May Need to Know About the Change Persistence Framework API

To better understand what you need to do to create custom user customizations, it may help to have a deeper understanding of the change persistence and MDS frameworks. When you elect to persist changes to the MDS repository, the change persistence framework works in conjunction with the MDS framework. Where and how the customizations are saved are determined by how you set up your MDS repository, your customization layers, and your customization classes. Details about the MDS framework and the repository and how to use it are covered in *Customizing Applications with MDS*.

The change persistence framework uses the underlying change manager classes from Apache MyFaces Trinidad (in the `org.apache.myfaces.trinidad.change` package) along with a few ADF Faces-specific classes (in the `oracle.adf.view.rich.change` package). The instance of the registered ChangeManager class is accessible through the RequestContext object. It is responsible for gathering changes as they are created and added during a request, and then persisting them. The SessionChangeManager class is an implementation of ChangeManager which handles persistence within a session only, while the MDSDocumentChangeManager class is an implementation that persists to the MDS repository only. The FilteredPersistenceChangeManager class is an implementation of ChangeManager that stores the changes that pass the filter rules into the repository using the registered persistence change manager. Any change that does not get persisted to the repository will be persisted to the session when FilteredPersistenceChangeManager is used.

Additional classes are used to describe the changes to a component. You use these APIs to handle persisting any changes to components other than the implicit value changes the ADF Faces framework provides (as shown in Table 52-1). ComponentChange is the base class for all classes used to implement specific changes that act on the JSF component hierarchy, such as adding or removing a facet or a child component. These changes are automatically applied during subsequent creation of the view, in the same order in which they were added. Classes that extend the ComponentChange class and that also implement the DocumentChange interface can directly persist changes to the MDS repository. Classes that do not implement the DocumentChange interface can persist changes only to the session.

Table 52-2 describes the specialized classes that handle specific customizations. If “yes” appears in the Repository column, then the class implements the DocumentChange interface and it can persist changes to the MDS repository.

<table>
<thead>
<tr>
<th>Class Name</th>
<th>Repository</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>AddChildDocumentChange</td>
<td>Yes</td>
<td>Adds a child or complex child (dvt:) component using document mark up. While applying this change, the child or complex child component is created and added to the document.</td>
</tr>
<tr>
<td>AddComplexChildDocumentChange</td>
<td>Yes</td>
<td></td>
</tr>
<tr>
<td>AddComplexChildAttributeChange</td>
<td>Yes</td>
<td>Adds a complex child (dvt:) component attribute.</td>
</tr>
</tbody>
</table>
**Table 52-2 (Cont.) Classes Used to Handle Change Persistence**

<table>
<thead>
<tr>
<th>Class Name</th>
<th>Repository</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>AttributeComponentChange</td>
<td>No</td>
<td>Changes the value of an attribute.</td>
</tr>
<tr>
<td>ComplexAttributeComponentChange</td>
<td>Yes</td>
<td></td>
</tr>
<tr>
<td>AttributeDocumentChange</td>
<td>Yes</td>
<td>Changes the value of a facet attribute.</td>
</tr>
<tr>
<td>ComplexAttributeDocumentChange</td>
<td>Yes</td>
<td></td>
</tr>
<tr>
<td>MoveChildComponentChange</td>
<td>Yes</td>
<td>Moves a child from one container to another.</td>
</tr>
<tr>
<td>RemoveChildComponentChange</td>
<td>Yes</td>
<td>Removes a child component.</td>
</tr>
<tr>
<td>RemoveComplexChildAttributeComponentChange</td>
<td>Yes</td>
<td>Removes a complex child (dvt:) component attribute.</td>
</tr>
<tr>
<td>RemoveComplexChildAttributeDocumentChange</td>
<td>Yes</td>
<td></td>
</tr>
<tr>
<td>SetFacetChildComponentChange</td>
<td>No</td>
<td>Adds a child component to the facet using a document markup. While applying this change, the markup will be added to the document.</td>
</tr>
<tr>
<td>SetFacetChildDocumentChange</td>
<td>Yes</td>
<td>Adds a child component to a facet. While applying this change, the DOM element corresponding to the child component is added to the document. If the facet doesn't exist, it will be created. If the facet does exist, all of its content will be removed and the new content added.</td>
</tr>
<tr>
<td>RemoveFacetComponentChange</td>
<td>Yes</td>
<td>Removes a facet.</td>
</tr>
<tr>
<td>ReorderChildrenComponentChange</td>
<td>Yes</td>
<td>Reorders children of a component.</td>
</tr>
</tbody>
</table>

Aside from a ChangeManager class, you may also need to implement and register the DocumentChangeFactory interface with the ChangeManager class. If the DocumentChangeFactory implementation can provide an equivalent DocumentChange for a ComponentChange, the ChangeManager will use it to persist the DocumentChange to the repository.

### 52.5.2 How to Create Code for Custom User Customizations

You need to add code to handle any explicit changes you want to create, and to configure the components on the JSF page to handle customization. As with the default user customizations, you also must register the custom changes in the adf-config.xml file.

**Note:**

When the changes are expressible in more than one form, the change must be recorded in the form with highest precedence. For example:
• Attribute change for a component: The attribute can be specified on the component tag or it can be expressed using the `<f:attribute>` tag. In a JSF JSP document, `<f:attribute>` takes lesser precedence over the attribute specified on the component tag. Therefore, the attribute change on the component tag will be recorded for customization.

• Column header text in a column component: The header text for the column can be specified using either the `headerText` attribute or using header facet. In this case, the facet component will have precedence.

Before you begin:

It may be helpful to have an understanding of the features of custom runtime user customization. For more information, see Implementing Custom User Customizations.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the Studio Developer role, open the application, and open the page for which you want to modify user customization behavior.

To create custom user customizations:

1. Create a managed bean for the page that contains the component, as described in Using a Managed Bean in a Fusion Web Application.

   For more information regarding managed beans and how they are used as backing beans for JSF pages, see the "Creating and Using Managed Beans" section in Developing Web User Interfaces with Oracle ADF Faces.

2. Add code to the event handler method for the component that will be used to make the change. This code should obtain the component that contains the change. It should then use the component and the appropriate APIs to create, record, and persist the change.

   The following example shows the code on the action event handler for a command button for a change that will be persisted to the MDS repository. When a user clicks the button, that source graphic file changes. The event handler method accesses the component and changes the source attribute for the graphic. It then calls the private `addAttributeChange` method, which first uses the component API to record the change, and then uses the `AttributeComponentChange` class to set the new source attribute value.

```java
public void modifyObjectImage(ActionEvent event) {
    UIComponent uic = event.getComponent().findComponent("oi1");
    String source = "/images/mediumAd.gif";
    uic.getAttributes().put("source", source);
    _addAttributeChange(uic, "source", source);
}
```

```java
private static void _addAttributeChange(UIComponent uic, String attribName, Object attribValue) {
    FacesContext fc = FacesContext.getCurrentInstance();
    ChangeManager cm =
        RequestContext.getCurrentInstance().getChangeManager();
    ComponentChange cc =
        new AttributeComponentChange(attribName, attribValue);
    cm.addChange(cc);
}
```
cm.addComponentChange(fc, uic, cc);
}

**Note:**

When you persist changes, in addition to explicitly recording a change on the component (which is done in the example above using `uic.getAttributes().put("source", source)` method), you must also directly apply the change using the component API, as was done using the private `_addAttributeChange(uic, "source", source)` method. Applying the change in this way allows the user to see the change in response to the same request. If the change is recorded on the component, then the change will not be seen until a subsequent request.

Additionally, if you know that the component will always persist to the repository regardless of any restricted change persistence settings, you can instead call the `AdfFacesContext.getCurrentInstance().getPersistentChangeManager()` method.

3. The ChangeManager class provides support for automatically converting an AttributeComponentChange into an AttributeDocumentChange, thereby allowing persistence to a repository. However, if you need to convert another type of change and you use a specialized change manager class that does not implement the DocumentChange class, you need to create a custom DocumentFactory implementation that converts the component change to a document change.

**Note:**

Automatic conversion of AttributeComponentChange into an AttributeDocumentChange assumes that the component attribute is represented as an attribute of the same name on the associated element in the JSPX document.

Only those attribute values that are expressible in the JSPX document can be persisted using AttributeDocumentChange. In other words, CharSequence, Number, Boolean and ValueExpression are the only supported data types.

Only values that implement java.io.Serializable can be persisted using AttributeComponentChange.

4. If you create a custom DocumentFactory implementation, you need to register it with the appropriate change manager class using the following method in your bean:

```java
public static void registerDocumentFactory(String targetClassName, String converterClassName)
```

Where `targetClassName` is the name of the ComponentChange class and `converterClassName` is the name of your DocumentChangeFactory extension that is capable of converting the target ComponentChange into a DocumentChange. The semantics of name for these classes is same as that of `getName()` in the java.lang.Class class.
5. If the class you use to create the component change adds a child that has a subtree of components, and you want to persist the changes to the repository, you must create a DocumentFragment to represent the change.

The following example shows how to use the AddComponentDocumentChange specialized class to create a DocumentChange object and use a DocumentFragment to represent the change.

```java
public void appendChildToDocument(ActionEvent event)
{
    UIComponent eventSource = event.getComponent();
    UIComponent uic = eventSource.findComponent("pg1");
    // only allow the image to be added once
    if (_findChildById(uic,"oi3") != null)
        return;
    FacesContext fc = FacesContext.getCurrentInstance();
    DocumentFragment imageFragment = _createDocumentFragment(_IMAGE_MARK_UP);
    DocumentChange change = new AddChildDocumentChange(imageFragment);
    ChangeManager apm = RequestContext.getCurrentInstance().getChangeManager();
    apm.addDocumentChange(fc, uic, change);
}
```

**private static final String** _IMAGE_MARK_UP =
"<af:objectImage id='oi3' height='100' width='120' 
"source='http://www.somewhere.com/someimage.jpg' 
"xmlns:af='http://xmlns.oracle.com/adf/faces'/>";

```java
private static DocumentFragment _createDocumentFragment(String markUp)
{
    // prepend XML declaration
    markUp = "<?xml version = '1.0' encoding = 'ISO-8859-1'?>" + markUp;
    DocumentBuilderFactory factory = DocumentBuilderFactory.newInstance();
    factory.setNamespaceAware(true);
    factory.setValidating(false);
    DocumentBuilder builder;
    try
    {
        builder = factory.newDocumentBuilder();
    }
    catch (ParserConfigurationException pce)
    {
        _LOG.log(Level.WARNING, "Unable to get XML Parser:", pce);
        return null;
    }
    try
    {
        // use a version explicitly with ISO-8859-1 instead
        byte[] markupBytes = markUp.getBytes();
        Document newDoc = builder.parse(new ByteArrayInputStream(markupBytes));
        DocumentFragment fragment = newDoc.createDocumentFragment();
        // add the document's root element to the fragment
        fragment.appendChild(newDoc.getDocumentElement());
        return fragment;
    }
    catch (SAXException se)
    {
        _LOG.log(Level.WARNING, "Unable to parse markup:" + markUp, se);
        return null;
    }
    catch (IOException ioe)
    {
    }
```
LOG.log(Level.WARNING, "IO Problem with markup:" + markUp, ioe);
return null;
}
}

6. Register the user customizations in the adf-config.xml file, as documented in Configuring User Customizations. If the custom changes are of any type other than AttributeDocumentChange, you will need to manually edit the adf-config.xml file and indicate that all changes are allowed for the component, as shown in the following example.

```xml
<tag name="inputText">
  <attribute name="label">
    <persist-changes>true</persist-changes>
  </attribute>
  <persist-operations>ALL</persist-operations>
</tag>
```

52.6 Creating Implicit Change Persistence in Custom Components

When you create a custom component, you may decide that you want certain attribute values on that component to be persisted whenever change persistence is enabled in an application. Setting implicit change on a custom component is similar to setting explicit change persistence on existing components. You add code that executes the actual persistence, but instead of you placing that code on a managed bean, that code can be handled directly by the component class. If your component's attribute values are synchronized with the server using events, then you can use the broadcast method to persist the changes. If the attribute value that you want to persist does not use events, then you need to add code in the renderer and component class.

52.6.1 How to Set Implicit Change Persistence For Attribute Values that Use Events

When an attribute value uses events, you need to add code to the component class. Before you begin:

It may be helpful to have an understanding of how persistence is implemented in custom components. For more information, see Creating Implicit Change Persistence in Custom Components.

You may also find it helpful to understand additional customization functionality that can be added to your applications. For more information, see Additional Functionality for Runtime User Customization.

You will need to launch JDeveloper using the Studio Developer role, and open the application.

To set implicit change persistence for attribute values that use events:

1. In the Applications window, double-click the custom component class Java file.

2. Add code to the broadcast method that will use the specialized class to create a new ComponentChange object and then call the ChangeManager to add the change.

   The following example shows the code added to the UIXShowDetail class that persists a change to the disclosed attribute. In this case, the AttributeComponentChange class is used.

   ```java
   public class UIXShowDetail extends UIXComponentBase
   ```
public void broadcast(FacesEvent event) throws AbortProcessingException
{
    super.broadcast(event);
    ...
    if (event instanceof DisclosureEvent)
    {
        boolean isDisclosed = ((DisclosureEvent) event).isExpanded();
        setDisclosed(isDisclosed);
        //Record a Change for 'disclosed' attribute
        AttributeComponentChange aa =
            new AttributeComponentChange('disclosed', isDisclosed ? Boolean.TRUE :
            Boolean.FALSE);
        AdfFacesContext adfContext = AdfFacesContext.getCurrentInstance();
        adfContext.getChangeManager().addComponentChange(getFacesContext(), this,
        aa);
        ...
    }
    ...

52.6.2 How to Set Implicit Change Persistence For Other Attribute Values

When an attribute does not use events, you need to place code in the component’s
renderer class.

Before you begin:

It may be helpful to have an understanding of how persistence is implemented in
custom components. For more information, see Creating Implicit Change Persistence
in Custom Components.

You may also find it helpful to understand additional customization functionality that
can be added to your applications. For more information, see Additional Functionality
for Runtime User Customization.

You will need to launch JDeveloper using the Studio Developer role, and open the
application.

To set implicit change persistence for other attribute values:

1. In the Applications window, double-click the custom component’s render class
Java file.

2. Use the findTypeConstants method, which takes a ClientMetadata instance
and use the addPersistedProperty method to mark certain properties as
persisted. The following example shows code from the renderer class used for the
ADF Faces PanelSplitter component, which implicitly persists the
splitterPosition attribute value.

    // Code from PanelSplitterRenderer.java
protected void findTypeConstants(
    FacesBean.Type type,
    ClientMetadata metadata)
{
    super.findTypeConstants(type, metadata);
    metadata.addRequiredProperty(
        _orientationKey = type.findKey("orientation"));
    metadata.addRequiredProperty(
        _positionedFromEndKey = type.findKey("positionedFromEnd"));
    metadata.addRequiredProperty(
        _disabledKey = type.findKey("disabled"));
metadata.addRequiredProperty(
    _splitterPositionKey = type.findKey("splitterPosition"));
metadata.addPersistedProperty(_splitterPositionKey);
}

3. In the JavaScript component peer class, define the attribute value to be persisted, using the `setProperty` function. This function needs to be invoked with the attribute name (as defined in the renderer in the previous step), the value, and "true", meaning the value of the attribute will be set. The following example shows code from the `panelSplitter` class that sets the splitter position.

// Code from AdfDhtmlPanelSplitterPeer.js file where we set the splitter position

var component = this.getComponent();
component.setProperty("splitterPosition",position, true);
// position is the value to be set
Using the Active Data Service

This chapter describes how to work with the ADF Model layer and Active Data Service (ADS) to provide real-time updates to ADF Faces components.

This chapter includes the following sections:

- About the Active Data Service
- Configuring the Active Data Service
- Configuring Components to Use the Active Data Service
- Using the Active Data Proxy
- What You May Need to Know About Maintaining Read Consistency
- Using the Active Data with a Scalar Model

53.1 About the Active Data Service

The Fusion technology stack includes Active Data Service (ADS), which is a server-side push framework that allows you to provide real-time data updates for ADF Faces components. You bind ADF Faces components to a data source and ADS pushes the data updates to the browser client without requiring the browser client to explicitly request it. For example, you may have a table bound to attributes of an ADF data control whose values change on the server periodically, and you want the updated values to display in the table. You can configure your application and the component so that whenever the data changes on the server, the ADF Model layer notifies the component and the component rerenders the changed data with the new value highlighted, as shown in Figure 53-1.

Figure 53-1  Table Displays Updated Data as Highlighted

53.1.1 Active Data Service Use Cases and Examples

Using ADS is an alternative to using automatic partial page rendering (PPR) to rerender data that changes on the backend as a result of business logic associated with the ADF data control bound to the ADF Faces component. Whereas automatic PPR
requires sending a request to the server (typically initiated by the user), ADS enables changed data to be pushed from the data store as the data arrives on the server. Also, in contrast to PPR, ADS makes it possible for the component to rerender only the changed data instead of the entire component. This makes ADS ideal for situations where the application needs to react to data that changes periodically.

To use this functionality, you must configure the application to use ADS. If your application services do not support ADS, then you also need to create a proxy of the service so that the components can display the data as it updates in the source.

Any ADF Faces page can use ADS. However, you can configure only the following ADF Faces components and ADF Data Visualization (DVT) components to work with active data:

- activeImage
- activeOutputText
- chart (all types)
- gauge (all types)
- pivotTable
- tree
- treeTable
- geoMap (mapPointTheme only)
- sunburst
- treemap

For specific information about ADS support for DVT components, see "Active Data Support" in Developing Web User Interfaces with Oracle ADF Faces.

Additionally, note that collection-based components (such as table, tree, and pivotTable) support ADS only when the outputText component or sparkChart is configured to display the active data; other components are not supported inside the collection-based component.

### 53.1.2 Limitations of the Active Data Service Framework

The framework for ADS has the following limitations.

- ADS does not support active data on ADF Faces table components with filtering enabled. Once a table is filtered at runtime, active data cannot be displayed.

- ADS does not time out from user inactivity by default. To ensure that an active session is not maintained indefinitely, you can configure the `web.xml` context-parameter `oracle.adf.view.rich.poll.TIMEOUT` to specify how long ADS should run before it times out from user inactivity. For more information, see How to Configure Session Timeout for Active Data Service.

- ADS does not restart if the user attempts to navigate away from the browser page and then chooses to stay on the page by canceling the exit action in the browser-displayed warning dialog. To workaround this limitation, ADF Faces provides client listener support to handle `beforeunload` events for browsers that support displaying a Confirm on Page Exit dialog. The ADF document that handles this
event will allow the user to cancel the exit before ADS stops processing. For more information, see What You May Need to Know About Navigating Away From the ADS Enabled Page in Developing Web User Interfaces with Oracle ADF Faces.

- ADS executes on a non-request thread and does not support the forced execution of component-level EL expressions. Therefore EL expressions on ADF Faces components that you may use to calculate component properties (such as fill color in a chart configured to use active data) will not be executed when the component value is updated by ADS. To execute EL in this scenario, you should calculate the property value in the model and use EL to bind the component property to the model. Alternatively, your page may apply JavaScript inline to apply the property value change after the active data update occurs. This latter solution effectively forces ADF Faces to rerender the component.

**Note:**
The ADF DVT components may impose additional limitations. For details, see "Active Data Support" in Developing Web User Interfaces with Oracle ADF Faces.

### 53.1.3 Active Data Service Framework

The framework for ADS contains a number of components that work together to send the active data from the source to the UI component. When a data event occurs, if the associated ADF Model layer binding is configured for active data, the Active Data model delivers the data to the Event Manager. The Event Manager then retrieves the data and invokes the Push Service, which delivers the data to the correct component, based on how the service is configured (for more information, see Data Transport Modes). The component then applies the new data pushed from the server. Figure 53-2 shows the ADS framework.
In order to use the Active Data Service, you need to have a data store that publishes events when data is changed, and you need to create business services that react to those events. By default, ADF Business Components does not react to data events. The Active Data Proxy framework allows all types of data sources, including ADF Business Components, to work with ADS. It combines the ActiveDataModel with the JSF model, so that you need to override functionality only on this proxy rather than on both the ActiveDataModel and the JSF model.

The following comprise the ADS framework:

- **ActiveDataModel interface**: Abstraction of the active data model. Its responsibilities include:
  - Starting and stopping active data
  - Keeping track of the current active data event ID
  - Letting the renderer know whether the model needs active data or not.

- **Event Manager**: A server-side component that works with the ADF Model layer. It is responsible for the following:
  - Listening to binding events
  - Retrieving active data
  - Managing active data encoding
  - Invoking the Push service to send the encoded active data
Push service: A delivery channel that interacts with the Event Manager on the server side and with the Active Data Manager on the client side. It provides the following:

- Establishing and maintaining the connection between the server and the client
- Transmitting the active data over this connection from the server to the client
- Ensuring that active data gets delivered within desired parameters and forcing component update if not

Active Data Manager: A client-side component that distributes the active data to the correct component. Specifically, it is responsible for the following:

- Delivering events from the server side that are coming through the channel, using an event delivery service
- Handling multiple browser windows through a shared channel
- Dispatching active data events to rich client components, so that the components can render the change accordingly

Active Data Proxy: A proxy that allows all types of data sources to enable push functionality. Specifically, the proxy is responsible for the following:

- Implementing and delegating ActiveDataModel functionality
- Delegating to JSF models
- Listening to data change events from the data source
- Generating active data events based on the data change events

53.1.4 Data Transport Modes

Active data is sent to the client using data streaming (push) or one of two types of data polling. With data streaming, there is only one request, which stays open. When a data change event occurs, a partial response is sent (the response is not closed), the client is notified, and the associated component is updated to show the new data, as shown in Figure 53-3.

![Figure 53-3 Streaming Mode](image)

With data polling, the application is configured to poll the data source at specified intervals, as shown in Figure 53-4. With each request, a response is sent and closed, whether or not a data change event has occurred. If the data has changed, then the client is notified and the component is updated.
Figure 53-4  Poll Mode

Long polling is similar to streaming. When the page is rendered, a request is sent to the active channel. However, a response is not returned until there is a data change event. At that point, the connection is closed. As soon as the connection is closed, a new connection is initiated, which results in the connection being active most of the time: there are no specific intervals. Long polling results in the majority of data change events being received when they occur, because the connection is already established and ready to send a response to the client, as shown in Figure 53-5.

Figure 53-5  Long Polling Mode

For more information, see What You May Need to Know About Configuring an ADS Transport Mode.

To use ADS, you need to configure your application to determine the method of data transport, as well as other performance options. You also need to configure the bindings for your components so that they can use ADS. If you are using ADF Business Components, you need to modify your model to implement the ActiveModel interface to register itself as the listener for active data events using the Active Data Proxy.

Tip:
Oracle offers Oracle Business Activity Monitoring (BAM), which is a complete solution that provides the ability to create an active data store. For more information, see the Developing SOA Applications with Oracle SOA Suite.

53.2 Configuring the Active Data Service

You need to configure ADS to determine the data transport mode, as well as to set other configurations, such as a latency threshold and reconnect information.

Note:
If you enable ADS but do not configure it, the ADS framework will use the default values shown in Table 53-1.

53.2.1 How to Configure the Active Data Service

Configuration for running the Fusion web application with ADS in JDeveloper and Integrated WebLogic Server is done in the adf-config.xml file. For more information about the adf-config.xml file, including how to create one if you need to, see the "Configuration in adf-config.xml" section of Developing Web User Interfaces with Oracle ADF Faces.

**Note:**
To support automatic replication and failover for web applications within a clustered environment, Oracle WebLogic Server supports mechanisms for replicating HTTP session state across clusters. You can configure Oracle Application Development Framework (Oracle ADF) to ensure the Fusion web application's state can be restored from any server in the cluster. To support failover for pages configured to display active data, it is necessary to enable failover for the ADF Business Components application module and to enable ADF Controller to track changes to the ADF memory scopes. With these ADF settings configured, when failover occurs, the ADF server will detect the failover and request all pages configured to display active data to refresh themselves, after that ADS restarts and data is pushed to the client. For details about how to enable failover for the Fusion web application in a high availability environment, see the High Availability Guide.

Before you begin:
It may be helpful to have an understanding of the ADS configuration choices. For more information, see Configuring the Active Data Service.
You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see About the Active Data Service.
To configure the Active Data Service:

1. In the Application Resources panel, expand the Descriptors and ADF Meta-INF nodes, and then double-click adf-config.xml.

2. Click the Source tab to open the file in the source editor, and create an entry for each of the elements shown in Table 53-1.
### Table 53-1 ADS Configuration Elements in adf-config.xml

<table>
<thead>
<tr>
<th>Element</th>
<th>Description</th>
<th>Default Value (in milliseconds)</th>
<th>Minimum Value (in milliseconds)</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;transport&gt;</td>
<td>The method by which data will be delivered to the client. Value values are:</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>• streaming (default)</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>• polling</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>• long-polling</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>For more information, see What You May Need to Know About Configuring an ADS Transport Mode.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>&lt;latency threshold&gt;</td>
<td>Latency threshold in milliseconds. Active data messages with network delays greater than this threshold will be treated as late.</td>
<td>10000</td>
<td>1000</td>
</tr>
<tr>
<td>&lt;keep-alive-interval&gt;</td>
<td>Frequency in milliseconds for sending keep-alive messages when no events are generated.</td>
<td>10000</td>
<td>5000</td>
</tr>
<tr>
<td>&lt;polling-interval&gt;</td>
<td>When &lt;transport&gt; set to polling, frequency in milliseconds of the poll request.</td>
<td>5000</td>
<td>1000</td>
</tr>
<tr>
<td>&lt;max-reconnect-</td>
<td>Maximum period of time in milliseconds a client will attempt to reconnect the push channel to the server upon getting disconnected.</td>
<td>1800000 (30 minutes)</td>
<td>0</td>
</tr>
<tr>
<td>attempt-time&gt;</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>&lt;reconnect-wait-time&gt;</td>
<td>Time interval in milliseconds to wait between reconnect attempts.</td>
<td>10000</td>
<td>1000</td>
</tr>
</tbody>
</table>

**Performance Tip:**

Keep the following in mind when configuring the ADS.

- Set the latency threshold to more than 1000 to avoid frequent component refreshing.
- Set the keep-alive interval and reconnect wait time to be less than the browser’s keep-alive timeout.
- Set the max reconnect time to be less than your web server’s session timeout.
The following example shows a sample configuration that has content pushed to the client.

```xml
  <ads:adf-activedata-config xmlns="http://xmlns.oracle.com/adf/activedata/config">
    <transport>streaming</transport>
    <latency-threshold>5000</latency-threshold>
    <keep-alive-interval>10000</keep-alive-interval>
    <max-reconnect-attempt-time>90000</max-reconnect-attempt-time>
    <reconnect-wait-time>8000</reconnect-wait-time>
  </ads:adf-activedata-config>
</adf-config>
```

3. Synchronize the clocks on the data server and on the application server. If these are not synchronized, then events may appear to ADS to have occurred in the future.

53.2.2 What You May Need to Know About Configuring an ADS Transport Mode

ADS can use one of three transport modes to deliver active data to the component: streaming, polling, or long polling.

When you configure ADS to use the streaming mode, data is pushed to the client whenever a change event is raised by the data. On the client side, after the push channel is established, if there is no activity within the time of the value for the `latency-threshold` element plus the `keep-alive-interval`, an establish-channel-request will be sent out repeatedly based on the value of the `reconnect-wait-time` element, until the amount of time passed reaches the value of the `max-reconnect-attempt-time` element. After that, the connection will be considered disconnected. For example, given the values shown in How to Configure the Active Data Service, if there is no activity in 15,000 milliseconds, an establish channel request will be sent out every 8,000 milliseconds for up to 90,000 milliseconds. After that, the connection will be considered disconnected.

On the server side, the server disconnects the push channel and starts a timer to clean up with a `cleanup-delay-time` when there is an empty active data message or when it fails to send out an active data message. The `cleanup-delay-time` is calculated as `max-reconnect-attempt-time + 30 * 1000 ms`. Its default value is 30 minutes.

When you configure ADS to use the polling mode, on the client side the polling request is scheduled to be sent out repeatedly after the value of the `polling-interval` element has been reached. If no response is received after the value of the `max-reconnect-attempt-time` has elapsed, the connection is treated as disconnected and no more requests will be sent. After receiving a polling response, if the time the response has taken is greater than the `polling-interval` element, the service sends the next request out right away. If it is less, the next request will be sent as scheduled.

For the server side, the session ends after the polling response is returned. At that point, a timer with a `cleanup-delay-time` is set up to trigger cleanup. If a new request comes in before the timer fires, the old timer is canceled, and new timer is created.

When you configure ADS to use the long polling mode, requests are made as they are in streaming mode; however, as soon as the connection is treated as disconnected, a new connection is initiated. The result is a significant reduction in latency.
Table 53-2 compares the three different modes.

<table>
<thead>
<tr>
<th>Comparison Benchmark</th>
<th>Streaming</th>
<th>Polling</th>
<th>Long-Polling</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Latency</strong></td>
<td>Very good.</td>
<td>Poor, depending on the polling interval.</td>
<td>Good.</td>
</tr>
<tr>
<td></td>
<td>Directly after an event occurs on the server side, a partial response is sent to the client. If there is another event, immediately, it is also sent as a partial response. There is almost no latency with this approach.</td>
<td>If the polling interval is short (for example, 0.5 seconds), it will slow down the network because the connections are repeatedly opened. It is also expensive on the client- and server-side resources.</td>
<td>However, when there is a new event immediately after a response has been closed, there is some latency until the new data appears on the client side. On average, this is not a problem.</td>
</tr>
<tr>
<td><strong>HTTP Proxy</strong></td>
<td>Poor.</td>
<td>Good.</td>
<td>Good.</td>
</tr>
<tr>
<td></td>
<td>For some older servers, because the response is never released, when a proxy is sitting between client and server, it is possible that the proxy will buffer responses. This is an unfortunate optimization that prevents real-time data from flowing into the browser. Long polling should be used if a proxy is used.</td>
<td></td>
<td></td>
</tr>
<tr>
<td><strong>Number of live connections</strong></td>
<td>Poor.</td>
<td>Good.</td>
<td>Poor.</td>
</tr>
<tr>
<td></td>
<td>Many concurrent connections, as the stream is always live.</td>
<td>Connections are live only during the actual poll. Note however that if there is a high polling rate then the number of concurrent connections will also be high.</td>
<td>Many concurrent connections, as the stream is almost always live.</td>
</tr>
<tr>
<td><strong>Communication channel</strong></td>
<td><strong>HTTP GET</strong></td>
<td><strong>XMLHttpRequest (XHR)</strong></td>
<td><strong>XMLHttpRequest (XHR)</strong></td>
</tr>
<tr>
<td></td>
<td>This can result in the display of a &quot;busy&quot; cursor or the animation of a browser’s &quot;throbber&quot; icon.</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
53.2.3 How to Configure Session Timeout for Active Data Service

By default, applications that you configure to use ADS will not time out. In polling mode, the client periodically sends polling request to server. In long polling mode, the client sends a new polling request immediately after a polling request is returned from the server. In streaming mode, the server holds the GET request response and will indefinitely write active data to it. Due to the behavior of each data transport mode, ADS will maintain the application session active whether or not the user interacts with the application.

To prevent this situation of maintaining an active session indefinitely due to ADS, the web.xml configuration file contains the oracle.adf.view.rich.poll.TIMEOUT context-parameter, which specifies how long ADS should run before it times out from user inactivity. The ADS client is considered eligible to time out if there is no keyboard or mouse activity. The default timeout period is set at ten minutes. So if the user remains inactive for ten minutes, that is, does not use the keyboard or mouse, then ADS will stop polling or will abort its connection with server, and from that point on, the application participates in the standard server-side session timeout. For example, if the server-side session timeout is 65 minutes, and the polling timeout parameter is set to 15 minutes, then it is expected that the session should expire when the user is inactive for more than 80 minutes.

You can override this timeout setting for a specific web page using the ADF Faces poll component timeout attribute. The poll component allows you to deliver a heartbeat to the server to prevent users from being timed out of their session for specific pages. For more information about the oracle.adf.view.rich.poll.TIMEOUT context-parameter and individual web pages, see the "Using Polling Events to Update Pages" section of Developing Web User Interfaces with Oracle ADF Faces.

Before you begin:

It may be helpful to have an understanding of the ADS configuration choices. For more information, see Configuring the Active Data Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see About the Active Data Service.

To configure the Active Data Service to timeout after session becomes inactive:

1. In the Applications window, in the user interface project, expand the Web Content and WEB-INF nodes, and then double-click web.xml.

2. In the overview editor for the web.xml file, click the Application navigation tab and in the Context Initialization Parameters section, click the Create icon to add the polling timeout parameter as follows:

   Name: Enter the context parameter oracle.adf.view.rich.poll.TIMEOUT.

   Value: Enter the amount of time in milliseconds after which all pages configured to use active data will time out and ADS will stop. To disable ADF time out due to user inactivity, enter -1. The default value for ADS to timeout is 600000 milliseconds (ten minutes).

53.3 Configuring Components to Use the Active Data Service

How you configure components to use ADS depends on whether or not you must use the Active Data proxy. If your application uses a data store that publishes events when data is changed, and your business services react to those events (for example, if your application uses BAM), then you do not need to use the Active Data proxy.
If your business services do not react to those events (for example, if your application uses ADF Business Components), then you must use the Active Data proxy and follow different procedures for configuring your components.

### Note:
If your business service requires the use of the Active Data proxy, then you can only use the following components with active data:

- table
- tree
- treeTable
- ADF Data Visualization chart, gauge, mapPointTheme, pivotTable, pivotFilterBar, sunburst, and treemap components

### 53.3.1 How to Configure Components to Use the Active Data Service Without the Active Data Proxy

To use ADS without the proxy, you need to set a value on the binding element in the corresponding page definition file.

**Before you begin:**
It may be helpful to have an understanding of the ADS configuration choices. For more information, see Configuring Components to Use the Active Data Service.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see About the Active Data Service.

To configure a component to display active data without the Active Data proxy:

1. From the Data Controls panel, drag and drop a collection onto a JSF page, and from the context menu, choose the desired component.

2. If you are dropping the collection as an ADF bound tree or tree table, you need to ensure the following:
   - That the binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
   - That the binding rule contains a single attribute.
   - That the table does not use filtering.
   - That the tree component’s nodeStamp facet contains a single outputText tag and contains no other tags, as described in What You May Need to Know About Displaying Active Data in ADF Trees.

3. From the Application window, right-click the page and choose Go to Page Definition.

   The editor for the page definition file opens for the selected page.

4. In the Structure window, select the node that represents the attribute binding for the component.
5. In the Properties window, expand the **Advanced** section, and select **Push** from the **ChangeEventPolicy** dropdown menu.

**Tip:**
You can use the **statusIndicator** component to indicate the server state. For more information, see the “Displaying Application Status Using Icons” section of *Developing Web User Interfaces with Oracle ADF Faces*.

53.3.2 How to Configure Components to Use the Active Data Service with the Active Data Proxy

To use ADS with the proxy, you need bind the value of your component to decorator class that will use the proxy. For more information about this class, see *Using the Active Data Proxy* to set a value on the binding element in the corresponding page definition file.

**Before you begin:**

It may be helpful to have an understanding of the ADS configuration choices. For more information, see *Configuring Components to Use the Active Data Service*.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see *About the Active Data Service*.

To configure a component to display active data with the Active Data proxy:

1. From the Data Controls panel, drag and drop a collection onto a JSF page, and from the context menu, choose the desired component.

2. If you are using an ADF bound tree or tree table, you need to ensure the following:
   - That the binding represents homogeneous data (that is, only one rule), although an accessor can still access a like accessor.
   - That the binding rule contains a single attribute.
   - That the table does not use filtering.
   - That the tree component’s **nodeStamp** facet contains a single **outputText** tag and contains no other tags, as described in *What You May Need to Know About Displaying Active Data in ADF Trees*.

3. From the Application window, right-click the page and choose **Go to Page Definition**.

   The editor for the page definition file opens for the selected page.

4. In the Structure window, select the node that represents the attribute binding for the component.

5. In the Properties window, change the value attribute to be bound to a decorator class that you will create for use with the proxy.

   For more information, see *Using the Active Data Proxy*. 

53.3.3 What You May Need to Know About Displaying Active Data in ADF Trees

When you create an ADF Faces tree (or tree table) component, you configure a nodeStamp facet, which is a holder for the component used to display the data for each node of the tree. Each node is rendered (stamped) once, repeatedly for all nodes. Because of this stamping behavior, only certain types of components are supported as children inside an ADF Faces tree component. When the tree component is not bound to an active data source, all components that have no behavior are supported. However, when you configure the tree to use ADS, only the outputText component is supported inside of the nodeStamp facet, as shown in the following example. The nodeStamp facet must not contain any other tags. So, for example, active data will not work if you add panelGroupLayout tags to the nodeStamp facets of a tree configured to use ADS.

```xml
<f:facet name="nodeStamp">
    <af:outputText value="#{row.str2}"/>
</f:facet>
```

53.3.4 What Happens at Runtime: How Components Render When Bound to Active Data

After you configure your application and the component for ADS, whenever the data changes on the server, the component is notified and rerenders with only the changed data. In contrast, a component not configured for either active data or automatic PPR will need to be explicitly refreshed after a data change occurs. The explicit refresh will refetch all data that is visible on the client, including data that has not changed. Consequently, this will force the entire component to rerender. Additionally, when the component is bound to an active data source (with active data policy "Push"), the component rerenders with the new value highlighted.

53.3.5 What You May Need to Know About Running ADS in a Google Chrome Browser

When the Fusion web application runs in the Google Chrome web browser and a user presses Ctrl+N (or Ctrl+T) to open a new window (or tab) and then copies the URL from the original window into the new window, active data in the original window will stop streaming. According to the Google Chrome process model, the new browser window will be created in a separate process and both windows will share the same HTTP session. However, because browser windows that are created in two separate processes cannot communicate with each other, ADS will become out of sync between the client and server and will stop streaming. As a workaround, to allow active data in multiple Google Chrome windows, before copying the URL from the original window into the new window users must press Ctrl-Shift-N to open the browser window in incognito mode (private browsing). Because Ctrl-Shift-N opens the window in a separate process and a separate HTTP session, ADS will not attempt to synchronize between the windows and streaming will be unaffected.

53.4 Using the Active Data Proxy

You use the active data proxy when your business services do not react to data events. If you want your components to update based on events passed into ADF Business Components, then you need to use the Active Data Proxy.

**Tip:**

If your application uses BAM for the business service, then you do not need to use the Active Data Proxy.
Note:
If your business service requires the use of the Active Data Proxy, then you can only use the following components with active data:

- table
- tree
- treeTable
- ADF Data Visualization mapPointTheme, pivotTable, pivotFilterBar, sunburst, and treemap components

53.4.1 How to Use the Active Data Proxy

You will create a Java class that subclasses one of the following decorator classes:

- ActiveCollectionModelDecorator class
- ActiveGeoMapDataModelDecorator class

These classes are wrapper classes that delegate the active data functionality to a default implementation of ActiveDataModel. The ActiveDataModel class listens for data change events and interacts with the Event Manager. Specifically, it does the following:

- Starts and stops the active data and the ActiveDataModel object, and registers and unregisters listeners to the data source.
- Wraps the JSF model interface. For example, the ActiveCollectionModelDecorator class wraps the CollectionModel class.
- Generates active data events based on data change events from the data source.
- Manages listeners from the Event Manager and pushes active data events to the Event Manager.

You need to implement methods on this Java class that registers itself as the listener of the active data source and gets the model to which the data is being sent.

Note:
The Active Data framework does not support complicated business logic or transformations that require the ADF runtime context, such as a user profile or security. For example, the framework cannot convert an ADF context locale-dependent value and return a locale-specific value.

As an example of complicated business logic, say you have logic that allows a user to move an order from open status to pending. This change results in an update event, which should cause the order to be removed from a data object called "Open Orders." The framework cannot handle this event type transformation based on business logic. Instead, you need to have your data source handle this before publishing the data change event.

Before you begin:
It may be helpful to have an understanding of the active data proxy. For more information, see Using the Active Data Proxy.

You may also find it helpful to understand functionality that can be added using other Oracle ADF features. For more information, see About the Active Data Service.

You will need to complete this task:

Implement the logic to fire the active data events asynchronously from the data source. For example, this logic might be a business process that updates the database, or a JMS client that gets notified from JMS.

To use the active data service:

1. Create a Java class that extends the decorator class appropriate for your component. The following example shows a class created for a table.

   ```java
   package view;

   import oracle.adf.view.rich.model.ActiveCollectionModelDecorator;
   import oracle.adf.view.rich.activedata.ActiveDataEventUtil;
   import oracle.adf.view.rich.activedata.JboActiveDataEventUtil;

   /**
    * This code wraps the existing collection model in the page and implements the
    * ActiveDataModel interface to enable ADS for the existing page.
    */
   public class DeptModel
       extends ActiveCollectionModelDecorator
   {
   }
   
   2. Implement the method that returns the model. The following example shows an implementation of the getCollectionModel() method that relies on expression language (EL) to avoid needing to typecast to an internal class. The method returns the DepartmentsView1 collection from the binding container.

   ```java
   public CollectionModel getCollectionModel()
   {
     if (_model == null)
     {
       FacesContext fc = FacesContext.getCurrentInstance();
       Application app = fc.getApplication();
       ExpressionFactory elFactory = app.getExpressionFactory();
       ELContext el = fc.getELContext();

       // This is EL to avoid typecasting to an Internal class.
       ValueExpression ve = elFactory.createValueExpression(el,
                 "#{bindings.DepartmentsView1.collectionModel}", Object.class);

       // Now GET the collectionModel
       _model = (CollectionModel)ve.getValue(el);
     }
     return _model;
   }
   
   3. Create an inner class that is your own implementation of an ActiveDataModel class, which the decorator can use to start and stop the active data and connect and disconnect from the data source. This class should also use the changeCount API to maintain data read consistency, as shown in the following example. For more information, see What You May Need to Know About Maintaining Read Consistency.
public class MyActiveDataModel extends BaseActiveDataModel
{
    protected void startActiveData(Collection<Object> rowKeys,
        int startChangeCount)
    {
        _listenerCount.incrementAndGet();
        if (_listenerCount.get() == 1)
        {
            System.out.println("start up");
            Runnable dataChanger = new Runnable()
            {
                public void run()
                {
                    System.out.println("MyThread starting.");
                    try
                    {
                        Thread.sleep(2000);
                        System.out.println("thread running");
                        triggerDataChange(MyActiveDataModel.this);
                    }
                    catch (Exception exc)
                    {
                        System.out.println("MyThread exceptioned out.");
                    }
                    System.out.println("MyThread terminating.");
                }
            };
            Thread newThrd = new Thread(dataChanger);
            newThrd.start();
        }
    }
    protected void stopActiveData(Collection<Object> rowKeys)
    {
        _listenerCount.decrementAndGet();
        if (_listenerCount.get() == 0)
        {
            System.out.println("tear down");
        }
    }
    public int getCurrentChangeCount()
    {
        return _currEventId.get();
    }
    public void bumpChangeCount()
    {
        _currEventId.incrementAndGet();
    }
    public void dataChanged(ActiveDataUpdateEvent event)
    {
        fireActiveDataUpdate(event);
    }
    private final AtomicInteger _listenerCount = new AtomicInteger(0);
    private final AtomicInteger _currEventId = new AtomicInteger();
}
4. Implement the method that will return the \texttt{ActiveDataModel} class, as shown in the following example.

```java
public ActiveDataModel getActiveDataModel()
{
    return _activeDataModel;
}
```

5. Create a method that creates application-specific events that can be used to insert or update data on the active model.

The following example shows the \texttt{triggerDataChange()} method, which uses the active model (an instance of \texttt{MyActiveDataModel}) to create \texttt{ActiveDataUpdateEvent} objects to insert and update data. You will need to import \texttt{oracle.adf.view.rich.activeData.ActiveDataEventUtil} and \texttt{oracle.adf.view.rich.activeData.JboActiveDataEventUtil} to implement this method.

```java
public void triggerDataChange(MyActiveDataModel l)
    throws Exception
{

    // do an update on dept 1
    1.bumpChangeCount();
    ActiveDataUpdateEvent event =
        ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.UPDATE,
            1.getCurrentChangeCount(),
            JboActiveDataEventUtil.convertKeyPath(new Key
                { new Object[] { new Long(1), new Integer(0) } }),
            null,
            new String[] { "name" },
            new Object[] { "Name Pushed" });

    l.dataChanged(event);

    try
    {
        Thread.sleep(2000);
    }
    catch (InterruptedException ie)
    {
        ie.printStackTrace();
    }

    // insert dept 99
    1.bumpChangeCount();
    event =
        ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.INSERT_AFTER,
            1.getCurrentChangeCount(),
            JboActiveDataEventUtil.convertKeyPath(new Key
                { new Object[] { new Long(99), new Integer(0) } }),
            JboActiveDataEventUtil.convertKeyPath(null),
            new String[] { "addr1", "name" },
            new Object[] { "Addr Inserted", "Name Inserted" });

    l.dataChanged(event);

    try
    {
        Thread.sleep(2000);
    }
    catch (InterruptedException ie)
    {
        ie.printStackTrace();
    }
}
```
```java
Thread.sleep(2000);
}
catch (InterruptedException ie)
{
    ie.printStackTrace();
}
// delete dept 10
l.bumpChangeCount();
event =
    ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REMOVE,
        l.getCurrentChangeCount(),
        JboActiveDataEventUtil.convertKeyPath(new Key{
            new Object[]{ new Long(9), new Integer(0) }},
            null, null, null);
    l.dataChanged(event);

try
{
    Thread.sleep(2000);
}
catch (InterruptedException ie)
{
    ie.printStackTrace();
}
// refresh the entire table
l.bumpChangeCount();
event =
    ActiveDataEventUtil.buildActiveDataUpdateEvent(ActiveDataEntry.ChangeType.REFRESH,
        l.getCurrentChangeCount(),
        null, null, null, null);
    l.dataChanged(event);
}
private MyActiveDataModel _activeDataModel = new MyActiveDataModel();
private CollectionModel _model = null;

53.5 What You May Need to Know About Maintaining Read Consistency

Using active data means that your component has two sources of data: the active data feed and the standard data fetch. Because of this, you must make sure your application maintains read consistency.

For example, say your page contains a table and that table has active data enabled. The table has two methods of delivery from which it updates its data: normal table data fetch and active data push. Say the back end data changes from foo to bar to fred. For each of these changes, an active data event is fired. If the table is refreshed before those events hit the browser, the table will display fred because standard data fetch will always get the latest data. But then, because the active data event might take
```
longer, some time after the refresh the data change event would cause foo to arrive at the browser, and so the table would update to display foo instead of fred for a period of time. Therefore, you must implement a way to maintain the read consistency.

To achieve read consistency, the ActiveDataModel has the concept of a change count, which effectively timestamps the data. Both data fetch and active data push need to maintain this changeCount object by monotonically increasing the count, so that if any data returned has a lower changeCount, the active data event can throw it away. For an example of an implementation of the ActiveDataModel class that maintains read consistency, see How to Use the Active Data Proxy.

53.6 Using the Active Data with a Scalar Model

ADF components that display collection-based data can be configured to work with ADS and require no extra setup in the view layer. However, imagine that your JSPX page uses an activeOutputText component to display new counts based on a Java timer. In this case, you will replace the model layer with scalar or "flat" data that you display from a Java Bean.

53.6.1 How to Use the Active Data with a Scalar Model

To implement the scalar model, follow these basic steps (as illustrated in the following example):

1. Use the ActiveModelContext API to register the bean with ADS so the bean (a scalar model) imitates an actual model.
   
   Add the registration code to the active attribute's getter method. Adding the registration code to the bean's constructor can cause ADS to fail.

2. Implement a custom mechanism to push the data to the view layer, as shown in the following example.

```java
package oracle.adfdemo.view.feature.rich;

import java.util.Collection;
import java.util.Timer;
import java.util.TimerTask;
import java.util.concurrent.atomic.AtomicInteger;
import oracle.adf.view.rich.activedata.ActiveModelContext;
import oracle.adf.view.rich.activedata.BaseActiveDataModel;
import oracle.adf.view.rich.activedata.ActiveDataEventUtil;
import oracle.adf.view.rich.event.ActiveDataEntry;
import oracle.adf.view.rich.event.ActiveDataUpdateEvent;

public class CounterBean extends BaseActiveDataModel
    // Example using a Java timer to create new counts
{
   public CounterBean()
   {
      timer.schedule(new UpdateTask(), 2000, 2000);
   }

   public String getState()
   {
      // 1. Use the ActiveModelContext API to register the scalar model key path for
      // the "state" attribute.
```
ActiveModelContext context = ActiveModelContext.getActiveModelContext();
Object[] keyPath = new String[0];
context.addActiveModelInfo(this, keyPath, "state");

return String.valueOf(counter);
}

// Not needed. We do not need to connect to a (real) active data source.
protected void startActiveData(Collection<Object> rowKeys, int startChangeCount) {}

// Not needed. We do not need to connect to a (real) active data source.
protected void stopActiveData(Collection<Object> rowKeys) {}

public int getCurrentChangeCount()
{
  return counter.get();
}

protected class UpdateTask extends TimerTask
{
  public void run()
  {
    counter.incrementAndGet();

    // 2. Use ActiveDataEventUtil to create an event object to update the model.
    ActiveDataUpdateEvent event =
      ActiveDataEventUtil.buildActiveDataUpdateEvent(
        ActiveDataEntry.ChangeType.UPDATE,
        counter.get(),
        new String[0],
        null,
        new String[] { "state" },
        new Object[] { counter.get() });
    fireActiveDataUpdate(event);
  }
}

private static final Timer timer = new Timer();
private final AtomicInteger counter = new AtomicInteger(0);

After you create the bean, register the bean as a managed bean in the faces-config.xml file, as the following example for counterBean illustrates:

...  
<managed-bean>
  <managed-bean-name>counterBean</managed-bean-name>
  <managed-bean-class>
    oracle.adfdemo.view.feature.rich.CounterBean
  </managed-bean-class>
  <managed-bean-scope>session</managed-bean-scope>
</managed-bean>

Once the bean is registered, you can use ADS to stream the data to the view layer. Your ADF Faces component use expression language to receive the pushed data, as illustrated by the activeOutputText component value attribute in the following example:
Using the Active Data with a Scalar Model
This chapter describes considerations for developing Fusion web applications that you intend to deploy to a high availability, clustered server environment. This chapter includes the following topics:

- About Oracle ADF High Availability
- Configuring Oracle ADF for High Availability
- Troubleshooting Fusion Web Applications for High Availability

54.1 About Oracle ADF High Availability

High availability for the Fusion web application is the ability of the application to be available when it is needed.

A high availability environment ensures that users can access the application without loss of service. Deploying the Fusion web application to a high availability environment minimizes the time when the application is down, or unavailable, and maximizes the time when it is running, or available.

High availability comes from redundant systems and components. You can categorize high availability solutions by their level of redundancy into active-active solutions and active-passive solutions.

An active-active solution deploys two or more active servers and can be used to improve scalability and provide high availability. In active-active deployments, all instances handle requests concurrently. Oracle recommends active-active solutions for all single-site middleware deployments. Active-passive solutions deploy an active instance that handles requests and a passive instance that is on standby.

For more information about high availability environments, see the High Availability Guide.

54.1.1 Oracle ADF Scope and Session State Considerations

At runtime, ADF objects such as the binding container and managed beans are instantiated. Each of these objects has a defined life span set by its scope attribute.

For more information about the life span of ADF objects, see About Object Scope Lifecycles.

54.1.2 Oracle ADF Failover and Expected Behavior Considerations

An Oracle WebLogic cluster provides application high availability. If one member of the cluster is unavailable, any other available member of the cluster is able to handle
the request. You should familiarize yourself with failover requirements and the expected behavior of an application in the event of a failover.

### 54.1.2.1 Session Failover Requirements

For seamless failover of a Fusion web application, the application must meet the following conditions:

- The application is in a cluster and at least one member of the application cluster is available to serve the request.
- For stateful applications, state replication is configured correctly, as described in Configuring Oracle ADF for High Availability.
- If you use Oracle HTTP Server, the server is configured with the WebLogicCluster directive to balance among all available application instances.
- If you use a hardware load balancer, the load balancer is:
  - Routing traffic to all available instances
  - Configured correctly with a health monitor to mark unavailable instances
  - Configured to support persistence of session state

### 54.1.2.2 Expected Behavior for Application Failover

If the environment is configured correctly, application users do not notice when an application instance in a cluster becomes unavailable. The sequence of events in an application failover is, for example, as follows:

1. A user makes a request and is routed by a hardware load balancer to Instance A of the application.
2. Instance A of the application becomes unavailable because of node failure, process failure, or network failure.
3. The hardware load balancer marks Instance A as unavailable.
4. The user makes a subsequent request. The request is routed to Instance B.
5. Instance B is configured as a replication partner of Instance A and has the user’s session state.
6. The application resumes using the session state on Instance B and the user continues working without interruption.

### 54.1.3 ADF Application Module for Oracle RAC Considerations

When you configure the ADF application module to access a highly available database system, such as redundant databases or Oracle Real Application Clusters (Oracle RAC) as the backend, the data source must be container-defined. In this scenario, you must use a GridLink data source or a multi data source. However, from the standpoint of the application module configuration, the naming convention for the multi data source or GridLink data source is the same as it is for a non-multi data source or GridLink data source. This naming convention ensures that the correct data source is used at runtime.
To more information about configuring GridLink data sources or multi data sources for high availability applications, see the "Database Considerations" chapter of the High Availability Guide.

For information about high availability considerations related to modifying the mdsDS data source URL post deployment of the Fusion web application, see the "Configuring High Availability for Other Components" chapter of the High Availability Guide.

54.2 Configuring Oracle ADF for High Availability

To support automatic replication and failover for web applications in a clustered environment, Oracle WebLogic Server supports mechanisms for replicating HTTP session state across clusters. You can configure Oracle ADF to ensure the Fusion web application’s state can be restored from any server in the cluster.

54.2.1 How to Configure Application Modules for High Availability

An application module is the transactional component that the Fusion web application uses to work with application data. It defines an updateable data model and top-level procedures and functions, called service methods, related to a logical unit of work related to an end-user task. An application module supports passivating, or storing, its transaction state as a snapshot in the database. It also supports the reverse operation of activating the transaction state from one of these saved snapshots.

For more information on application module state management, see About Fusion Web Application State Management.

To enable support for ADF Business Components failover, set the jbo.dofailover parameter to true so that the application module state is saved on release. This enables Oracle ADF to restore the application module state from a snapshot saved from a previous check in. By contrast, when the failover feature is disabled, which it is by default, then application module state is saved only when the application is reused by a subsequent user session and only when the application module pool cannot find an unused application module.

You can set this parameter in your application module configuration on the Pooling and Scalability tab of the overview editor for application module configurations (on the bc4j.xcfg file).

To configure application modules for high availability:

1. Launch JDeveloper and open the application.

2. In the Applications window, expand the project that contains the data model and double-click the application module.

3. In the overview editor for the application module, select the Configurations navigation tab and click the configuration hyperlink for the configuration you want to configure for high availability.

4. In the overview editor for application module configurations (on the bc4j.xcfg file), click the Database and Scalability tab.

5. Select the Failover Transaction State Upon Managed Release checkbox and save the change.
54.2.2 How to Enable Support for Replicating HTTP Session State

To enable support for replicating HTTP session state, you must assign a value to the persistent-store-type element in the Oracle WebLogic Server weblogic.xml file. The value replicated_if_clustered ensures that the in-effect persistent store type will be replicated so that sessions on the clustered environment are stored in accordance with the value set for the cluster of servers to which this server belongs.

Note:
Oracle ADF applications such as the Oracle WebCenter Portal Suite are preconfigured and do not need additional configuration.

To configure the weblogic.xml file for high availability:

1. Launch JDeveloper and open the application.
2. In the Applications window, expand the project that contains the web application and expand the WEB-INF folder.
3. Double-click the weblogic.xml file, and click the Source tab to edit the file.
4. In the file, add the persistent-store-type definition to the session-descriptor element:

```xml
<weblogic-web-app>
  <session-descriptor>
    <persistent-store-type>
      replicated_if_clustered
    </persistent-store-type>
  </session-descriptor>
</weblogic-web-app>
```

54.2.3 How to Ensure Oracle ADF Receives Notifications From Managed Bean Changes

When you design an application to run in a clustered environment, you must ensure that Oracle ADF is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

When a value within a managed bean in either view scope or page flow scope is modified, the application must notify Oracle ADF so that it can ensure the bean’s new value is replicated.

To enable ADF Controller to track changes to ADF memory scopes and replicate the page flow scope and view scope within the server cluster, you must set the ADF Controller parameter <adf-scope-ha-support> in the application’s adf-config.xml file to true. For example, when set to true for an application and that application adds or removes a bean from a page flow scope during a request, the change will automatically replicated within a cluster.

The adf-config.xml file is the central configuration file for all ADF components. The file contains sections to configure the runtime behavior for ADF components, including, ADF Controller.

Note:
If your application uses MDS and will use an Oracle database that supports failover, Oracle recommends enabling MDS retry on failover. To do this, add the following `retry-connection` entry to the MDS configuration section of `adf-config.xml`.

```xml
<persistence-config>
  <metadata-namespaces>...
  <metadata-store-usages>...
  <external-change-detection enabled="false" />
  <read-only-mode enabled="true"/>
  <retry-connection enabled="true"/>
</persistence-config>
```

To configure the `adf-config.xml` file for high availability:

1. In the Application window, expand the Application Resources.
2. Select Descriptors, and then select the ADF META-INF node.
3. Double-click the `adf-config.xml` file, and click the Source tab to edit the file.
4. Add the following to the file:

   ```xml
   <adf-controller-config xmlns="http://xmlns.example.com/adf/controller/config">
     <adf-scope-ha-support>true</adf-scope-ha-support>
   </adf-controller-config>
   
   For more information about using the `adf-config.xml` file to configure ADF, see `adfc-config.xml`.

54.2.4 What You May Need to Know About Using Application Scoped Managed Beans in a Clustered Environment

JSF Application Scope beans are backed by a servlet context which can only have one instance per cluster node. Therefore, for each design time configured bean, there will be a runtime instance of the bean for each node in a cluster. Because there is no synchronization across nodes, each instance of the application running on different nodes will have separate instances of that bean with separate values. Therefore, application scoped managed beans should not be used to carry application-wide values that can be updated to be shared across all nodes in a cluster. They can, however, be used to carry constants, read-only values, or values to reflect the state of a single node within the cluster (such as the number of users on a node).

54.2.5 How to Disable Design Time Optimizations

The `org.apache.myfaces.trinidad.CHECK_FILE_MODIFICATION` context parameter provides optimization for developing and testing the Fusion web application in the JDeveloper. Leaving this parameter set to `true` when the application runs in a high availability environment can lead to errors after failover occurs. Note that this limitation should not affect your work because you typically use this parameter in a development environment only, not a high availability environment.

To configure the `CHECK_FILE_MODIFICATION` parameter for high availability:

1. In the Applications window, expand the user interface project and expand the WEB-INF folder.
2. Double-click the web.xml file and click the Application navigation tab.

3. In the overview editor, expand the Context Initialization Parameters section and confirm that the org.apache.myfaces.trinidad.CHECK_MODIFICATION parameter definition is set to false.

   The web.xml file definition will be:

   ```xml
   <web-app>
   ...
   <context-param>
     <param-name>org.apache.myfaces.trinidad.CHECK_FILE_MODIFICATION</param-name>
     <param-value>false</param-value>
   </context-param>
   </web-app>
   ```

## 54.3 Troubleshooting Fusion Web Applications for High Availability

This section describes procedures for troubleshooting possible issues with Fusion web applications at design time and after deployment.

### 54.3.1 How to Test the Fusion Web Application With Failover Mode Enabled

When running or debugging an application that uses failover support (jbo.dofailover is enabled) within the JDeveloper environment, you are frequently starting and stopping the application server. The ADF failover mechanism has no way of knowing whether you stopped the server to simulate an application server failure, or whether you stopped it because you want to retest something from scratch in a fresh server instance. If you intend to do the latter, exit out of your browser before restarting the application on the server. This eliminates the chance that you will be confused by the correct functioning of the failover mechanism when you didn’t intend to be testing that aspect of your application.

### 54.3.2 How to Troubleshoot High Availability Issues at Design Time

When you develop the Fusion web application in Oracle JDeveloper, the integrated development environment provides support for detecting potential high availability issues. The warnings that JDeveloper provides are generated by the audit framework and are triggered to appear in the JDeveloper source editors. The warnings the editors show are based on the audit rules for high availability applications.

The high availability audit rules that JDeveloper enables by default are:

- **ADF Controller Configuration - High Availability for ADF Scopes is not Enabled** warns the developer that the adf-scope-ha-support flag in the adf-config.xml file is set is not set to true. This audit rule fires only when the `<adf-controller-config>` element is in the ADF application-level configuration file (adf-config.xml).

- **ADF Page Flows - Bean in Scope Map is Modified** warns the developer when some code calls a setter method on a bean to indicate that the code did not subsequently call the ControllerContext.markScopeDirty() method. This audit rule fire only when the adf-scope-ha-support flag in the adf-config.xml file is set to true.

- **ADF Page Flows - EL Bean is Modified** warns the developer when some code evaluates an EL expression that mutates a bean to indicate that the code did not
subsequently call the `ControllerContext.markScopeDirty()` method. This audit rule fire only when the `adf-scope-ha-support` flag in the `adf-config.xml` file is set to true.

- **ADF Page Flows - Managed Bean Class Not Serializable** warns the developer that a managed bean has a non-serializable class defined in `viewScope`, `pageFlowScope`, or `sessionScope`. This audit rule fire only when the `adf-scope-ha-support` flag in the `adf-config.xml` file is set to true.

You can modify the high availability audit rule settings using the Preference dialog in JDeveloper. From the JDeveloper toolbar, choose **Tools - Preferences**, under **Audit - Profiles** expand **ADF Controller Configuration** or **ADF Pages Flows** and make the desired audit rule selections.

You can also trigger the audit by choosing **Build - Audit project.jpr** from the JDeveloper toolbar.

### 54.3.3 How to Troubleshoot High Availability Issues After Deployment

There are two actions to take if you encounter Fusion web application deployment issues: verify the JRF Runtime and verify the status of application deployments.

#### 54.3.3.1 Verifying the JRF Runtime Installation

The first step to troubleshooting an Fusion web application deployment is to verify that the JRF Runtime is installed on the WebLogic Server domain. ADF applications require the JRF and ADF runtime. You cannot run ADF applications with a standalone WebLogic Server domain or just the WebLogic Server portion of the Application Development product; you must extend it with the JRF extension template.

For more information on the JRF Template, see "Oracle JRF and ADF Templates" in **Domain Template Reference**.

#### 54.3.3.2 Verifying the Success of All Application Deployments

Fusion web applications deploy when the Managed Server first starts. Use the Administration Console to check that all application deployments were successful:

1. Click **Deployments** in the left hand pane. The right hand pane shows the application deployments and their status. The state of all applications, assuming all the servers are running, should be **ACTIVE**.

2. If an application deployment has failed, the server logs may provide some indication of why the application was not deployed successfully. The server logs are located in the `DOMAIN_HOME/servers/server_name/logs` directory. Common issues include:
   - Unavailability of external resources, such as database resources. Examine the error, fix it, and attempt to redeploy the application.
   - The appropriate applications or libraries are not targeted correctly to the right Managed Server or Cluster.

### 54.3.4 How to Troubleshoot Oracle ADF Replication and Failover Issues

State Replication is most prominent in failover scenarios. A user working on one server may discover that, upon failover:

- Windows may close or the state might reset.
• Screens may require a reset.
• The application may redirect to the logon screen.

To diagnose and troubleshoot state replication issues.

1. Confirm that this is not a known replication issue.

   See Oracle ADF Failover and Expected Behavior Considerations for possible
   expected behaviors. Before proceeding to further diagnose the issue, first confirm
   that the failover behavior is not an expected behavior.

2. Check load balancer settings.

   For replication and failover to function correctly, the load balancer must be
   configured with the appropriate persistence settings. For more details on
   configuring Hardware Load Balancers for Oracle WebLogic Server, see
   Administering Clusters for Oracle WebLogic Server.

3. Check the cluster status.

   Replication occurs within the context of a cluster. For failover to be successful,
   there must be at least one other healthy member of the cluster available. You can
   check cluster status in one of two ways:

   • Check the cluster status using the Oracle WebLogic Server Administration
     Console - In the Left-hand pane, click on Servers. Verify the state of all servers
     in the cluster.

   • Check the cluster status using the weblogic.Admin utility. You can use the
     weblogic.Admin utility to query the state of all servers in a specific cluster.
     For example:

     $ java weblogic.Admin -url Adminhost:7001 -username <username> -password
     <password> CLUSTERSTATE -clustername Spaces_Cluster

     This example returns:

     There are 2 server(s) in cluster: Spaces_Cluster
     The alive servers and their respective states are listed below:
     Application Server---RUNNING
     Managed Server---RUNNING

4. Check cluster communications.

   Even if all cluster members are running, there may be communication issues which
   prevent them from communicating replication information to each other. There are
   two types of cluster communication configurations. Troubleshooting depends on
   the cluster type:

   • Checking Unicast cluster communications - For Unicast clusters, Managed
     Servers must be able to access each other’s hosts and each other’s default
     listening port.
     Ensure that all individual Managed Servers have their Listen Address set
     correctly. You can find this setting by selecting Configuration, General for each
     Managed Server.

   • Checking Multicast cluster communications - For multicast clusters, servers
     must be able to intercept the same multicast traffic. Ensure that multicast is
configured correctly by running the WebLogic utility `utils.MulticastTest` on each machine. For example:

```bash
$ java utils MulticastTest -H
```

5. **Confirm Oracle WebLogic Server application configuration.**

Oracle WebLogic Server is not configured by default for failover. In-memory replication takes place only with the proper setting in the `weblogic.xml` file:

```xml
<session-descriptor>
  <persistent-store-type>replicated_if_clustered</persistent-store-type>
</session-descriptor>
```

A persistent-store-type of replicated is also acceptable. This setting can be made in JDeveloper, as described in [How to Enable Support for Replicating HTTP Session State](#).

6. **Confirm Oracle ADF Business Components configuration.**

Oracle ADF is not configured by default for failover. Failover is supported only with the proper setting in the ADF Business Components configuration file (`bc4j.xcfg`):

```xml
<AppModuleConfig ...
  <AM-Pooling jbo.dofailover="true"/>
</AppModuleConfig>
```

This setting is made in JDeveloper through the Edit Business Components Configuration dialog, as described in [How to Configure Application Modules for High Availability](#).

7. **Confirm Oracle WebLogic Server connection pool parameter.**

Set an appropriate value for the `weblogic-application.xml` deployment descriptor parameter `inactive-connection-timeout-seconds` on the element `<connection-check-params> pool-params.`

When enabling application module state passivation, a failure can occur when Oracle WebLogic Server is configured to forcibly release connections back into the pool. The failure creates an exception "Connection has already been closed" that gets saved to the server log. The user interface does not show this exception.

Set `inactive-connection-timeout-seconds` to several minutes. In most cases, this setting avoids forcing the inactive connection timeout and passivation failure. Adjust the setting as needed for your environment.

8. **Confirm ADF Controller configuration.**

Oracle ADF is not configured by default to replicate changes to ADF objects in ADF memory scopes. ADF object replication is supported only with the proper setting in the ADF application-level configuration file (`adf-config.xml`):

```xml
<adf:adf-controller-config>
  <adf:adf-scope-ha-support>true</adf:adf-scope-ha-support>
</adf:adf-controller-config>
```

This setting is made in JDeveloper through the source editor. See [How to Configure Application Modules for High Availability](#).
9. Check default logger messages.

By default the ADF log shows high-level messages (INFO level). The default logging often reports problems with serialization and replication without the need to enable more detailed log messages.

10. Enable log messages for ADF high availability applications.

Configure the ADF logger to output runtime messages for high availability. By default the ADF log shows high-level messages (INFO level). You enable high availability diagnostics for ADF Controller by setting the logging level in Fusion Middleware Control to FINE.

When enabled, the logger outputs a warning if the adfc:adf-scope-ha-support setting in the adf-config.xml file is not set.

11. Enable debug.

Check the server logs for any unusual messages on Managed Server startup. In particular, if the Managed Server is unable to locate other members of the cluster. The server logs are located in the DOMAIN_HOME/servers/SERVER_NAME/logs directory.

For further debugging, enable the flags DebugCluster, DebugClusterAnnouncements, DebugFailOver, DebugReplication, and DebugReplicationDetails. You can enable each flag with the weblogic.Admin utility:

```
$ java weblogic.Admin -url Adminhost:7001 -username <username> -password <password> SET -type ServerDebug -property DebugCluster true
```

12. Enable component state serialization checking.

Enable server checking to ensure no unserializable state content on session attributes is detected. This check is disabled by default to reduce runtime overhead. Serialization checking is supported by the Java server system property org.apache.myfaces.trinidad.CHECK_STATE_SERIALIZATION.

Table 54-1 shows the options you can use with the property. Use commas to delimit the options.

Table 54-1 CHECK_STATE_SERIALIZATION Options

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>tree</td>
<td>Checks whether the entire component tree is serializable. This is the fastest component check. Most testing should be performed with this flag enabled.</td>
</tr>
<tr>
<td>component</td>
<td>Checks each component individually for serializability. This option is much slower than “tree.” It is typically turned on only after testing with “tree” reports an error. This option narrows down the problematic component.</td>
</tr>
<tr>
<td>property</td>
<td>Checks each component attribute individually for serializability. This is slower than “component” and narrows down the specific problematic component attribute after a failure has been detected in the “tree” or “component” modes.</td>
</tr>
<tr>
<td>session</td>
<td>Checks that all attributes in the JSF Session Map that are marked as Serializable are serializable.</td>
</tr>
</tbody>
</table>
### Table 54-1  (Cont.) CHECK_STATE_SERIALIZATION Options

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>application</td>
<td>Checks that all attributes in the JSF Application Map that are marked as Serializable are serializable.</td>
</tr>
<tr>
<td>beans</td>
<td>Checks that any serializable object in the appropriate map has been marked as dirty if the serializable content of the object changes during the request.</td>
</tr>
<tr>
<td>all</td>
<td>Checks everything.</td>
</tr>
</tbody>
</table>

For high availability testing, start off by validating that the Session and JSF state is serializable by launching the application server with the system property:

```
-Dorg.apache.myfaces.trinidad.CHECK_STATE_SERIALIZATION=session,tree
```

Add the `beans` option to check that any serializable object in the appropriate map has been marked as dirty if the serialized content of the object has changed during the request:

```
-Dorg.apache.myfaces.trinidad.CHECK_STATE_SERIALIZATION=session,tree,beans
```

If a JSF state serialization failure is detected, relaunch the application server with the system property to enable component and property flags and rerun the test:

```
-Dorg.apache.myfaces.trinidad.CHECK_STATE_SERIALIZATION=all
```

These are Java system properties and you must specify them when you start the application server.
This chapter describes how to deploy Oracle ADF applications to a target application server. It describes how to create deployment profiles, how to create deployment descriptors, and how to load ADF runtime libraries. It includes instructions for running an application in the Integrated WebLogic Server as well as deploying to a standalone Oracle WebLogic Server.

This chapter includes the following sections:

- About Deploying Fusion Web Applications
- Running a Fusion Web Application in Integrated WebLogic Server
- Preparing the Application
- Deploying the Application
- Postdeployment Configuration
- Testing the Application and Verifying Deployment

### 55.1 About Deploying Fusion Web Applications

Deployment is the process of packaging application files as an archive file and transferring that file to a target application server. You can use JDeveloper to deploy Oracle ADF applications directly to the application server (such as Oracle WebLogic Server), or indirectly to an archive file as the deployment target, and then install this archive file to the target server. For application development, you can also use JDeveloper to run an application in Integrated WebLogic Server. JDeveloper supports deploying to server clusters, but you cannot use JDeveloper to deploy to individual Managed Servers that are members of a cluster.

Figure 55-1 shows the flow diagram that describes the overall deployment process. Note that preparing the target application server for deployment by installing the ADF runtime is described in *Administering Oracle ADF Applications*. 
Note:

Normally, you use JDeveloper to deploy applications for development and testing purposes. If you are deploying Oracle ADF applications for production purposes, you can use Enterprise Manager or scripts to deploy to production-level application servers.

For more information about deployment to later-stage testing or production environments, see *Administering Oracle ADF Applications*.

ADF Java EE applications are based on standardized, modular components and can be deployed to the following application server:

- **Oracle WebLogic Server**
  
  Oracle WebLogic Server provides a complete set of services for those modules and handles many details of application behavior automatically, without requiring programming. For information about which versions of Oracle WebLogic Server are compatible with JDeveloper, see the certification information website at [http://www.oracle.com/technetwork/developer-tools/jdev/documentation/index.html](http://www.oracle.com/technetwork/developer-tools/jdev/documentation/index.html).

- **IBM WebSphere Application Server**
For information about which versions of IBM WebSphere are compatible, see the . Deploying a Fusion web application is slightly different from deploying a standard Java EE application. JSF applications that contain ADF Faces components have a few additional deployment requirements:

- ADF Faces requires Sun’s JSF Reference Implementation 1.2 and MyFaces 1.0.8 (or later).

You can use JDeveloper to:

- Run applications in Integrated WebLogic Server
  You can run and debug applications using Integrated WebLogic Server and then deploy to standalone WebLogic Server.

- Deploy directly to the standalone application server
  You can deploy applications directly to the standalone application server by creating a connection to the server and choosing the name of that server as the deployment target.

- Deploy to an archive file
  You can deploy applications indirectly by choosing an EAR file as the deployment target. The archive file can subsequently be installed on a target application server.

The Summit sample application for Oracle ADF demonstrates the use of the Fusion web application technology stack to create transaction-based web applications. You can run the Summit sample application in JDeveloper using Integrated WebLogic Server. For more information about the Summit ADF sample applications, see Introduction to the ADF Sample Application.

55.1.1 Developing Applications with Integrated WebLogic Server

If you are developing an application in JDeveloper and you want to run the application in Integrated WebLogic Server, you do not need to perform the tasks required for deploying directly to Oracle WebLogic Server or to an archive file. JDeveloper has a default connection to Integrated WebLogic Server and does not require any deployment profiles or descriptors. Integrated WebLogic Server has a preconfigured domain that includes the ADF libraries, as well as the -Djps.app.credential.overwrite.allowed=true setting, that are required to run Oracle ADF applications. You can run an application by choosing Run from the JDeveloper main menu.

You debug the application using the features described in Testing and Debugging ADF Components.

55.1.2 Developing Applications to Deploy to Standalone Application Server

Typically, for deployment to standalone application servers, you test and develop your application by running it in Integrated WebLogic Server. You can then test the application further by deploying it to standalone Oracle WebLogic Server in development mode to more closely simulate the production environment.

In general, you use JDeveloper to prepare the application or project for deployment by:

- Creating a connection to the target application server
• Creating deployment profiles (if necessary)
• Creating deployment descriptors (if necessary, and that are specific to the target application server)
• Updating application.xml and web.xml to be compatible with the application server (if required)
• Enabling the application for Real User Experience Insight (RUEI) in web.xml (if desired)
• Migrating application level security policy data to a domain-level security policy store
• Configuring the Oracle Single Sign-On (Oracle SSO) service and properties in the domain jps-config.xml file when you intend the web application to run using Oracle SSO

You must already have an installed application server. For Oracle WebLogic Server, you can use the Oracle 12c Installer or the Oracle Fusion Middleware 12c Application Developer Installer to install one. For other application servers, follow the instructions in the applications server documentation to obtain and install the server.

You must also prepare the application server for Fusion web application deployment. For more information, see the "Preparing the Standalone Application Server for Deployment" section of Administering Oracle ADF Applications.

• Extending Oracle WebLogic Server domains to be ADF-compatible using the ADF runtime
• For WebLogic, setting the Oracle WebLogic Server credential store overwrite setting as required (-Djps.app.credential.overwrite.allowed=true setting).
• Creating a global JDBC data source for applications that require a connection to a data source

After the application and application server have been prepared, you can:

• Use JDeveloper to:
  – Directly deploy to the application server using the deployment profile and the application server connection.
  – Deploy to an EAR file using the deployment profile. For Oracle ADF applications, WAR and MAR files can be deployed only as part of an EAR file.
• Use Enterprise Manager, scripts, or the application server's administration tools to deploy the EAR file created in JDeveloper. For more information, see Administering Oracle ADF Applications.

55.2 Running a Fusion Web Application in Integrated WebLogic Server

JDeveloper is installed with Integrated WebLogic Server which you can use to test and develop your application. For most development purposes, Integrated WebLogic Server will suffice. When your application is ready to be tested, you can select the run target and then choose the Run command from the main menu.
The first time you run an application in Integrated WebLogic Server, the Create Default Domain dialog appears for you to define an administrative password for the new domain.

When you run the application target, JDeveloper detects the type of Java EE module to deploy based on artifacts in the projects and workspace. JDeveloper then creates an in-memory deployment profile for deploying the application to Integrated WebLogic Server. JDeveloper copies project and application workspace files to an “exploded EAR” directory structure. This file structure closely resembles the EAR file structure that you would have if you were to deploy the application to an EAR file. JDeveloper then follows the standard deployment procedures to register and deploy the "exploded EAR" files into Integrated WebLogic Server. The "exploded EAR" strategy reduces the performance overhead of packaging and unpackaging an actual EAR file.

In summary, when you select the run target and run the application in Integrated WebLogic Server, JDeveloper:

- Detects the type of Java EE module to deploy based on the artifacts in the project and application
- Creates a deployment profile in memory
- Copies project and application files into a working directory with a file structure that would simulate the "exploded EAR" file of the application.
- Performs the deployment tasks to register and deploy the simulated EAR into Integrated WebLogic Server
- Automatically migrates identities, credentials, and policies

Later on, if you plan to deploy the application to a standalone WebLogic Server instance, you will need to migrate this security information. For more information, see How to Deploy Applications with ADF Security Enabled.

Note:
JDeveloper ignores the deployment profiles that were created for the application when you run the application in Integrated WebLogic Server.

The application will run in the base domain in Integrated WebLogic Server. This base domain has the same configuration as a base domain in a standalone WebLogic Server instance. In other words, this base domain will be the same as if you had used the Oracle Fusion Middleware Configuration Wizard to create a base domain with the default options in a standalone WebLogic Server instance.

JDeveloper will extend this base domain with the necessary domain extension templates, based on the JDeveloper technology extensions. For example, if you have installed JDeveloper Studio, JDeveloper will automatically configure the Integrated WebLogic Server environment with the ADF runtime template (JRF Fusion Middleware runtime domain extension template).

You can explicitly create a default domain for Integrated WebLogic Server. You can use the default domains to run and test your applications. Open the Application
Servers window, right-click IntegratedWebLogicServer and choose Create Default Domain.

55.2.1 How to Run an Application in Integrated WebLogic Server

You can test an application by running it in Integrated WebLogic Server. You can also set breakpoints and then run the application within the ADF Declarative Debugger.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you run an application in the Integrated WebLogic Server. For more information, see Running a Fusion Web Application in Integrated WebLogic Server.

To run an application in Integrated WebLogic Server:

1. In the Applications window, select the project, unbounded task flow, JSF page, or file as the run target.
2. Right-click the run target and choose Run or Debug.

The Create Default Domain dialog appears for the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

55.2.2 How to Run an Application with Metadata in Integrated WebLogic Server

When an application is running in Integrated WebLogic Server, the MAR (Metadata Archive) profile itself will not be deployed to a repository, but a simulated MDS repository will be configured for the application that reflects the metadata information contained in the MAR. This metadata information is simulated, and the application runs based on this location in source control.

Any customizations or documents created by the application that are not configured to be stored in other MDS repositories are written to this simulated MDS repository directory. For example, if you customize an object, the customization is written to the simulated MDS repository. If you execute code that creates a new metadata object, then this new metadata object is also written to the same location in the simulated MDS repository. You can keep the default location for this directory (ORACLE_HOME\jdeveloper\systemXX.XX\o.mds.dt\adr\Application\AutoGeneratedMar\mds_adrs_writedir), or you can set it to a different directory. You also have the option to preserve this directory across different application runs, or to delete this directory before each application run.

If your workspace has different working sets, only the metadata from the projects defined in the working set and their dependent projects will be included in the MAR. You can view and change a project’s dependencies by right-clicking the project in the Applications window, choosing Project Properties, and then selecting Dependencies. For instance, an application may have several projects but workingsetA is defined to be viewcontroller2 and viewcontroller5; and viewcontroller5 has a dependency on modelproject1. When you run or debug workingsetA, only the metadata for viewcontroller2, viewcontroller5, and modelproject1 will be included in the MAR for deployment.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you run an application with metadata in the Integrated WebLogic Server. For
more information, see Running a Fusion Web Application in Integrated WebLogic Server.

You will need to complete this task:

Created a MAR profile, either manually or automatically by JDeveloper.

To deploy the MAR profile to Integrated WebLogic Server:

1. In the Applications window, right-click the application and choose Application Properties.

2. In the Application Properties dialog, expand Run and choose MDS.

3. On the Run MDS page:
   - Select the MAR profile from the MAR Profile dropdown list
   - Enter a directory path in Override Location if you want to customize the location of the simulated MDS repository.
   - Select the Directory Content option. You can chose to preserve the customizations across application runs or delete customizations before each run.

Select the MAR profile from the MAR Profile dropdown list. Figure 55-2 shows Demometadata1 selected as the MAR profile.

Figure 55-2  Setting the Run MDS Options

55.3 Preparing the Application

Before you deploy a Fusion web application to a standalone application server, you must perform prerequisite tasks within JDeveloper to prepare the application for deployment.

Figure 55-3 show the process flow to prepare the application for deployment. After the application has been prepared and the application server has been prepared as
described in *Administering Oracle ADF Applications*, you can proceed to deploy the application as described in *Deploying the Application*.

Figure 55-3  Preparing the Application for Deployment Flow Diagram

55.3.1 How to Create a Connection to the Target Application Server

You can deploy applications to the application server via JDeveloper application server connections.

If your application involves customization using MDS, you should register your MDS repository with the application server:

- **WebLogic**: register the MDS into the WebLogic Domain
  
  For more information about registering MDS in WebLogic, see *Administering Oracle Fusion Middleware*.

- **WebSphere**: register the MDS into the WebSphere Cell
  
  For more information about registering MDS in WebSphere, see the .

For more information about registering MDS, see *Administering Oracle Fusion Middleware*.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you prepare an application for deployment. For more information, see *Preparing the Application*. 
You will need to complete this task:

Installed an application server.

To create a connection to an application server:

1. Launch the Application Server Connection wizard.

   You can:
   - In the Applications Servers window, right-click Application Servers and choose New Application Server.
   - In the New Gallery, expand General, select Connections and then Application Server Connection, and click OK.
   - In the Resources window, choose New > IDE Connections > Application Server.

2. In the Create Application Server Connection dialog, on the Usage page, select Standalone Server and click Next.

3. On the Name and Type page, enter a connection name.

4. In the Connection Type dropdown list, choose:
   - WebLogic to create a connection to Oracle WebLogic Server
   - WebSphere Server 7.x to create a connection to IBM WebSphere Server

5. Click Next.

6. On the Authentication page, enter a user name and password for the administrative user authorized to access the application server.

7. Click Next.

8. On the Configuration page, enter the information for your server:

   For WebLogic:
   - The Oracle WebLogic host name is the name of the WebLogic Server instance containing the TCP/IP DNS where your application (.jar,.war,.ear) will be deployed.
   - In the Port field, enter a port number for the WebLogic Server instance on which your application (.jar,.war,.ear) will be deployed. If you don’t specify a port, the port number defaults to 7001.
   - In the SSL Port field, enter an SSL port number for the WebLogic Server instance on which your application (.jar,.war,.ear) will be deployed. Specifying an SSL port is optional. It is required only if you want to ensure a secure connection for deployment. If you don’t specify an SSL port, the port number defaults to 7002.
   - Select Always Use SSL to connect to the WebLogic Server instance using the SSL port.
• Optionally enter a **WebLogic Domain** only if WebLogic Server is configured to distinguish non-administrative server nodes by name.

For WebSphere:

• In the **Host Name** field, enter the name of the WebSphere server containing the TCP/IP DNS where your Java EE applications (.jar,.war,.ear) are deployed. If no name is entered, the name defaults to localhost.

• In the **SOAP Connector Port** field, enter the port number. The host name and port are used to connect to the server for deployment. The default SOAP connector port is 8879.

• In the **Server Name** field, enter the name assigned to the target application server for this connection.

• In the **Target Node** field, enter the name of the target node for this connection. A node is a grouping of Managed Servers. The default is `machineNode01`, where `machine` is the name of the machine the node resides on.

• In the **Target Cell** field, enter the name of the target cell for this connection. A cell is a group of processes that host runtime components. The default is `machineNode01Cell`, where `machine` is the name of the machine the node resides on.

• In the **Wsadmin script location** field, enter, or browse to, the location of the `wsadmin` script file to be used to define the system login configuration for your IBM WebSphere application server connection. Note that you should not use the `wsadmin` files from the `ORACLE_HOME/oracle_common/common/bin` directory, which are not the correct version. The default location is `websphere-home/bin/wsadmin.sh` for Unix/Linux and `websphere-home/bin/wsadmin.bat` for Windows.

9. Click **Next**.

10. If you have chosen WebSphere, the JMX page appears. On the JMX page, enter the JMX information (optional):

    **Note:**
    JMX configuration is optional and is not required for connecting to the WebSphere Application Server. JMX is only needed for deploying SOA applications.

• Select **Enable JMX** for this connection to enable JMX.

• In the **RMI Port** field, enter the port number of the WebSphere RMI connector port. The default is 2809.

• In the **WebSphere Runtime Jars Location** field, enter or browse to the location of the WebSphere runtime JARs.

• In the **WebSphere Properties Location (for secure MBEAN access)** field, enter or browse to the location of the file that contains the properties for the security configuration and the mbeans that are enabled. This field is optional.

11. Click **Next**.
12. If the SSL Signer Exchange Prompt dialog appears, click Y.

13. On the Test page, click Test Connection to test the connection.

JDeveloper performs several types of connections tests. The JSR-88 test must pass for the application to be deployable. If the test fails, return to the previous pages of the wizard to fix the configuration.

14. Click Finish.

55.3.2 How to Create Deployment Profiles

A deployment profile defines the way the application is packaged into the archive that will be deployed to the target environment. The deployment profile:

- Specifies the format and contents of the archive file that will be created
- Lists the source files, deployment descriptors, and other auxiliary files that will be packaged
- Describes the type and name of the archive file to be created
- Highlights dependency information, platform-specific instructions, and other information

You need a WAR deployment profile for each web user interface project that you want to deploy in your application. If you want to package seeded customizations or place base metadata in the MDS repository, you need an application level metadata archive (MAR) deployment profile as well. For more information about seeded customizations, see Customizing Applications with MDS. If the application has customization classes, you need a JAR file for those classes and you need to add that JAR when you create the EAR file. Finally, you need an application level EAR deployment profile and you must select the projects (such as WAR and MAR profiles and customization classes JAR files) to include from a list. When the application is deployed, the EAR file will include all the projects that were selected in the deployment profile.

**Note:**

If you create your project or application using the ADF Fusion Web Application template, JDeveloper automatically creates default WAR, EAR, MAR, and JAR deployment profiles. Typically, you would not need to edit or create deployment profiles manually.

For Oracle ADF applications, you can deploy the application only as an EAR file. The WAR and MAR files that are part of the application should be included in the EAR file when you create the deployment profile.

**Note:**

If your Fusion web application has business services that you want to deploy, you will need to create a Business Component Service Interface deployment profile and deploy it. For more information about business services, see How to Deploy Web Services to Oracle WebLogic Server.
55.3.2.1 Creating a WAR Deployment Profile

You will need to create a WAR deployment profile for each web-based project you want to package into the application. Typically, the WAR profile will include the dependent data model projects it requires.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a WAR deployment profile. For more information, see Preparing the Application.

You will need to complete this task:

Create web-based projects. If you used the ADF Fusion Web Application template, you should already have a default WAR deployment profile.

To create WAR deployment profiles for an application:

1. In the Applications window, right-click the web project that you want to deploy and choose New > From Gallery.

   You will create a WAR profile for each web project.

2. In the New Gallery, expand General, select Deployment Profiles and then WAR File, and click OK.

   If you don't see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- WAR File dialog, enter a name for the project deployment profile and click OK.

4. In the Edit WAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

   • If you have customization classes in your application, they must be loaded from the EAR-level application class loader and not from the WAR. You will later add these customization classes to the EAR.

      By default, customization classes that are implemented in the data model project are added to the data model project's WAR class path. So for each WAR, you must exclude the customization classes.

      If you created your customization classes in an extension project of the application and included them using the Libraries and Classpath page of the Application Properties dialog, they will be packaged at the EAR level by default. No further action is necessary to remove them from the WAR profile.

      However, if you created your customization classes in the data model project of the application, they must be removed from the WAR profile. Deselect any customization classes in the Edit WAR Deployment Profiles Properties dialog Filters page for each user interface project. If you are using a customization.properties file, it should also be deselected.

   • You might also want to change the Java EE web context root setting. To do so, choose General in the left pane.

      By default, when Use Project's Java EE Web Context Root is selected, the associated value is set to the project name, for example, Application1-
Project1-context-root. You need to change this if you want users to use a different name to access the application.

If you are using custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

5. Click OK to exit the Deployment Profile Properties dialog.

6. Click OK again to exit the Project Properties dialog.

7. Repeat Steps 1 through 7 for all web projects that you want to deploy.

55.3.2.2 Creating a MAR Deployment Profile

If you have seeded customizations or base metadata that you want to place in the MDS repository, you need to create a MAR deployment profile.

The namespace configuration under `<mds-config>` for MAR content in the `adf-config.xml` file is generated based on your selections in the MAR Deployment Profile Properties dialog.

Although uncommon, an enterprise application (packaged in an EAR) can contain multiple web application projects (packaged in multiple WARs), but the metadata for all these web applications will be packaged into a single metadata archive (MAR). The metadata contributed by each of these individual web applications can be global (available for all the web applications) or local to that particular web application.

To avoid name conflicts for metadata with global scope, make sure that all metadata objects and elements have unique names across all the web application projects that forms part of the enterprise application.

JDeveloper creates an auto-generated MAR when the Enable User Customizations and Across Sessions using MDS options are selected in the ADF View page of the Project Properties dialog or when you explicitly specify the deployment target directory in the `adf-config.xml` file.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create a MAR deployment profile. For more information, see Preparing the Application.

You will need to complete this task:

Create an MDS repository for your customization requirements to deploy metadata using the MAR deployment profile. For more information, see the section about managing the MDS repository in Administering Oracle Fusion Middleware. If you used the ADF Fusion Web Application template, you should already have a default MAR deployment profile.

To create a MAR deployment profile:

1. In the Applications window, right-click the application in which you want to create a MAR profile and choose New > From Gallery.

   You will create a MAR profile if you want to include customizations.

2. In the New Gallery, expand General, select Deployment Profiles and then MAR File, and click OK.
If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- MAR File dialog, enter a name for the MAR deployment profile and click OK.

4. In the Edit MAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane.

Figure 55-4 shows a sample User Metadata directory tree.

Figure 55-4  Selecting Items for the MAR Deployment Profiles

Note the following important points:

- To include all customizations, you need only create a file group with the desired directories.

- ADF Model and ADF view directories are added by default. No further action is required to package the ADF Model and ADF view customizations into the MAR. ADF view content is added to HTML Root dir, while ADF Model and Business Components content is added to User Metadata.

- To include the base metadata in the MDS repository, you need to explicitly select these directories in the dialog.

  When you select the base document to be included in the MAR, you also select specific packages. When you select one package, all the documents (including subpackages) under that package will be used. When you select a package, you cannot deselect individual items under that package.

- To include files from other than ADF Model and ADF view, users should create a new file group under User Metadata with the desired directories and explicitly select the required content in the Directories page.
• If a dependent ADF library JAR for the project contains seeded customizations, they will automatically be added to the MAR during MAR packaging. They will not appear in the MAR profile.

• If ADF Library customizations were created in the context of the consuming project, those customizations would appear in the MAR profile dialog by default.

5. Click OK to exit the Deployment Profile Properties dialog.

6. Click OK again to exit the Application Properties dialog.

55.3.2.3 Creating an Application Level EAR Deployment Profile

The EAR file contains all the necessary application artifacts for the application to run in the application server. If you used the ADF Fusion Web Application template, you should already have a default EAR deployment profile. For more information about the EAR file, see What You May Need to Know About EAR Files and Packaging.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an EAR deployment profile. For more information, see Preparing the Application.

You will need to complete these tasks:

1. Add classes into a JAR file, as described in Adding Customization Classes into a JAR.

2. Create the WAR deployment profiles, as described in Creating a WAR Deployment Profile.

To create an EAR deployment profile for an application:

1. In the Applications window, right-click the application and choose New > From Gallery.

You will create an EAR profile for the application.

2. In the New Gallery, expand General, select Deployment Profiles and then EAR File, and click OK.

If you don't see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- EAR File dialog, enter a name for the application deployment profile and click OK.

4. In the Edit EAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

Be sure that you:

• Select Application Assembly and then in the Java EE Modules list, select all the project profiles that you want to include in the deployment, including any WAR or MAR profiles.

• Select Platform, select the application server you are deploying to, and then select the target application connection from the Target Connection dropdown list.
Note:
If you are using a custom JAAS LoginModule for authentication with JAZN, the context root name also defines the application name that is used to look up the JAAS LoginModule.

5. If you have customization classes in your application, configure these classes so that they load from the EAR-level application class loader.

Note:
If you created your customization classes in an extension project of the application and included them using the Libraries and Classpath page of the Application Properties dialog, this step is not necessary because they will be packaged at the EAR level by default.

a. In the Edit EAR Deployment Profile Properties dialog, select Application Assembly.

b. Select the JAR deployment profile that contains the customization classes, and enter lib in the Path in EAR field at the bottom of the dialog.

Note:
You should have created this JAR as described in Adding Customization Classes into a JAR.

The JAR file containing the customization classes is added to the EAR file's lib directory.

Note:
If you have customization classes in your application, you must also make sure they are not loaded from the WAR. By default, customization classes that are added to the data model project's libraries and class path are packaged to the WAR class path.

If you created your customization classes in the data model project of the consuming application, deselect any customization classes in the Edit WAR Deployment Profile Properties dialog Filters page.

6. Click OK again to exit the Edit EAR Deployment Profile Properties dialog.

7. Click OK again to exit the Application Properties dialog.

Note:
To verify that your customization classes are put correctly in the EAR class path, you can deploy the EAR profile to file system. Then you can examine the EAR to make sure that the customization class JAR is available in the EAR class path (the EAR/lib directory) and not available in the WAR class path (the WEB-INF/lib and WEB-INF/classes directories).
55.3.2.4 Adding Customization Classes into a JAR

If your application has customization classes, create a JAR that contains only these customization classes. When you create your EAR, you can add the JAR to the EAR assembly. And when you create WAR profiles for your web projects, you must make sure they don’t include the customization classes JAR.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you add customization classes. For more information, see Preparing the Application.

You will need to complete this task:

Make sure that your project has customization classes. You do not need to perform this procedure if the application does not have customization classes. For more information about customization classes, see How to Create Customization Classes.

To add customization classes into a JAR:

1. In the Applications window, right-click the data model project that contains the customization classes for which you want to create a JAR, and choose New > From Gallery.

2. In the New Gallery, expand General, select Deployment Profiles and then JAR File, and click OK.

Alternatively, if you want to create a shared library, select Shared Library JAR File from the list of profile types, and click OK.

Note:

If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- JAR File dialog, enter a name for the project deployment profile (for example, CCArchive) and click OK.

4. In the Edit JAR Deployment Profile Properties dialog, select JAR Options.

5. Enter the location for the JAR file.

6. Expand Files Groups > Project Output > Filters to list the files that can be selected to be included in the JAR.

7. In Filters page, in the Files tab, select the customization classes you want to add to the JAR file.

   If you are using a customization.properties file, it needs to be in the same class loader as the JAR file. You can select the customization.properties file to package it along with the customization classes in the same JAR.

8. Click OK to exit the Edit JAR Deployment Profile Properties dialog.

9. Click OK again to exit the Project Properties dialog.

10. In the Applications window, right-click the project containing the JAR deployment profile, and choose Deploy > deployment profile > to JAR file.
Note:
If this is the first time you deploy to a JAR from this deployment profile, you choose Deploy > deployment profile and select Deploy to JAR in the wizard.

55.3.2.5 Delivering Customization Classes as a Shared Library
As an alternative to adding your customization classes to the EAR, as described in Creating an Application Level EAR Deployment Profile, you can also include the customization classes in the consuming application as a shared library.

Note:
This procedure describes how to create and use a shared library if you are deploying to Oracle Weblogic Server.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create and use a shared library for customization classes. For more information, see Preparing the Application.

You will need to complete this task:
- Add customization classes into a JAR using JDeveloper in Studio Developer role.
- Follow the procedure described in Adding Customization Classes into a JAR, and make sure that you select Shared Library JAR File as the type of archive to create.

To create and use a shared library for your customization classes:

1. In the Applications window, right-click the customization classes project, and choose Deploy > deployment-profile.
2. In the Deploy wizard, select Deploy to Application Server and click Next.
3. Select the appropriate application server, and click Finish.

   This makes the shared library available on the application server. You must now add a reference to the shared library from the consuming application.
4. Open the application you want to customize in JDeveloper in the Studio Developer role.
5. In the Application Resources panel of the Applications window, double-click the weblogic-application.xml file.
6. In the overview editor, click the Libraries navigation tab.
7. On the Libraries page, in the Shared Library References section, click the Add icon.
8. In the Library Name field of the newly created row in the Shared Library References table, enter the name of the customization classes shared library you deployed, and save your changes.

55.3.2.6 Viewing andChanging Deployment Profile Properties
After you have created a deployment profile, you can view and change its properties.
Before you begin:

It may be helpful to have an understanding of the options that are available to you when you view deployment profiles. For more information, see Preparing the Application.

To view, edit, or delete a project’s deployment profile:

1. In the Applications window, right-click the project which you want to view or edit and choose Project Properties.

2. In the Project Properties dialog, click Deployment.

   The Deployment Profiles list displays all profiles currently defined for the project.

3. In the Deployment Profiles section, select a deployment profile.

4. To edit or delete a deployment profile, click Edit or Delete.

55.3.3 How to Create and Edit Deployment Descriptors

Deployment descriptors are server configuration files that define the configuration of an application for deployment and that are deployed with the Java EE application as needed. The deployment descriptors that a project requires depend on the technologies the project uses and on the type of the target application server. Deployment descriptors are XML files that can be created and edited as source files, but for most descriptor types, JDeveloper provides dialogs or an overview editor that you can use to view and set properties. If you cannot edit these files declaratively, the XML file opens in the source editor for you to edit its contents.

In addition to the standard Java EE deployment descriptors (for example, application.xml and web.xml), you can also have deployment descriptors that are specific to your target application server. For example, if you are deploying to Oracle WebLogic Server, you can also have weblogic.xml, weblogic-application.xml, and weblogic-ejb-jar.xml.

For WebLogic Server, make sure that the application EAR file includes a weblogic-application.xml file that contains a reference to adf.oracle.domain, and that it includes an ADFApplicationStateListener to clean up application resources between deployment and undeployment actions. The following example shows a sample weblogic-application.xml file:

```xml
  <listener>
    <listener-class>oracle.adf.share.weblogic.listeners.ADFApplicationStateListener</listener-class>
  </listener>
  <listener>
    <listener-class>oracle.mds.lcm.weblogic.WLLifecycleListener</listener-class>
  </listener>
  <library-ref>
    <library-name>adf.oracle.domain</library-name>
  </library-ref>
</weblogic-application>
```

If you are deploying web services, you may need to modify your weblogic-application.xml and web.xml files as described in How to Deploy Web Services to Oracle WebLogic Server.
If you want to enable the application for Real User Experience Insight (RUEI) monitoring, you must add a parameter to the web.xml file, as described in Enabling the Application for RUEI and Click History.

During deployment, the application's security properties are written to the weblogic-application.xml file to be deployed with the application in the EAR file. For more information, see What Happens When You Configure Security Deployment Options.

Because Oracle WebLogic Server runs on the Java EE Platform, you may need to modify the application.xml and web.xml files to be compatible with the application server.

For IBM WebSphere, the deployment descriptors are created at runtime and cannot be edited. Some of the relevant descriptors are shown in Table 55-1.

Table 55-1 IBM WebSphere Deployment Descriptors

<table>
<thead>
<tr>
<th>WebSphere</th>
<th>Action</th>
</tr>
</thead>
<tbody>
<tr>
<td>ibm-application-bnd.xml</td>
<td>References the security role just mapped in application.xml and maps it to the well-known name</td>
</tr>
<tr>
<td></td>
<td>AllAuthenticatedUsers. Similar to weblogic.xml for WebLogic Server. Maps the valid-users JEE security role to the well-known name Users.</td>
</tr>
<tr>
<td>application.xml</td>
<td>A standard Java EE deployment description. Also used to populate a security mapping for the &quot;valid-users&quot; role (which is defined in web.xml when using ADF Security).</td>
</tr>
<tr>
<td>&lt;EAR_ROOT&gt;/META-INF/manifest.mf</td>
<td>References application shared libraries such as adf.oracle.domain</td>
</tr>
<tr>
<td>&lt;EAR_ROOT&gt;/META-INF/deployment.xml</td>
<td>References WAR shared libraries such as adf.oracle.domain.webapp</td>
</tr>
</tbody>
</table>

55.3.3.1 Creating Deployment Descriptors

JDeveloper automatically creates many of the required deployment descriptors for you. If they are not present, or if you need to create additional descriptors, you can use JDeveloper to create them.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create deployment descriptors. For more information, see Preparing the Application.

You will need to complete this task:

Check to see whether JDeveloper has already generated deployment descriptors.

To create a deployment descriptor:

1. In the Applications window, right-click the project for which you want to create a descriptor and choose New > From Gallery.
2. In the New Gallery, expand General, select Deployment Descriptors and then a descriptor type, and click OK.

If you can’t find the item you want, make sure that you chose the correct project, and then choose the All Features tab or use the Search field to find the descriptor. If the item is not enabled, check to make sure that the project does not already have a descriptor of that type. A project is allowed only one instance of a descriptor.

JDeveloper starts the Create Deployment Descriptor wizard and then opens the file in the overview or source editor, depending on the type of deployment descriptor you choose.

**Note:**

For EAR files, do not create more than one deployment descriptor file of the same type per application or workspace. These files can be assigned to projects, but have application workspace scope. If multiple projects in an application have the same deployment descriptor, the one belonging to the launched project will supersede the others. This restriction applies to application.xml, weblogic-jdbc.xml, jazn-data.xml, and weblogic.xml.

The best place to create an application level descriptor is in the Descriptors node of the Application Resources panel in the Applications window. This ensures that the application is created with the correct descriptors.

Application level descriptors created in the project will be ignored at runtime. Only the application resources descriptors or descriptors generated at the EAR level will be used by the runtime.

### 55.3.3.2 Viewing or Modifying Deployment Descriptor Properties

After you have created a deployment descriptor, you can change its properties by using JDeveloper dialogs or by editing the file in the source editor. The deployment descriptor is an XML file (for example, application.xml) typically located under the Application Sources node.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you view deployment descriptors. For more information, see Preparing the Application.

To view or change deployment descriptor properties:

1. In the Applications window or in the Application Resources panel, double-click the deployment descriptor.

2. In the editor window, select either the Overview tab or the Source tab, and configure the descriptor by setting property values.

   If the overview editor is not available, the file opens in the source editor.

### 55.3.3.3 Configuring the application.xml File for Application Server Compatibility

You may need to configure your application.xml file to be compliant with your Java EE version.
Preparing the Application

Note:
Typically, your project has an application.xml file that is compatible and you would not need to perform this procedure.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you configure application.xml. For more information, see Preparing the Application.

To configure the application.xml file:

1. In the Applications window, right-click the application and choose New > From Gallery.
2. In the New Gallery, expand General, select Deployment Descriptors and then Java EE Deployment Descriptor Wizard, and click OK.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select application.xml and click Next.
4. On the Select Version page, select 5.0 to be compatible with Java EE 5.0 or higher, and click Next.
5. On the Summary page, click Finish.
6. Edit the application.xml file with the appropriate values.

55.3.3.4 Configuring the web.xml File for Application Server Compatibility
You may need to configure your web.xml file to be compliant with your Java EE version. For more information, see web.xml.

Note:
Typically, your project has a web.xml file that is compatible and you would not need to perform this procedure. JDeveloper creates a starter web.xml file when you create a project.

If the application uses ADF Security and will be deployed to WebSphere, you need to manually edit the web.xml file. For more information, see Editing the web.xml File to Protect the Application Root for WebSphere.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you configure web.xml. For more information, see Preparing the Application.

To configure the web.xml file:

1. In the Applications window, right-click the project in which you want to configure a web.xml file and choose New > From Gallery.
2. In the New Gallery, expand General, select Deployment Descriptors and then Java EE Deployment Descriptor, and click OK.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select **web.xml** and click **Next**.

4. On the Select Version page, select the version you want to use and click **Next**.

   Version 3.0 is compatible with Java EE 6.0 or higher, and version 2.5 is compatible with Java EE 5.0.

5. On the Summary page, click **Finish**.

55.3.3.5 Enabling the Application for RUEI and Click History

Real User Experience Insight (RUEI) is a web-based utility to report on real-user traffic requested by, and generated from, your network. It measures the response times of pages and transactions at the most critical points in the network infrastructure. Session diagnostics allow you to perform root-cause analysis.

RUEI enables you to view server and network times based on the real-user experience, to monitor your Key Performance Indicators (KPIs) and Service Level Agreements (SLAs), and to trigger alert notifications on incidents that violate their defined targets. You can implement checks on page content, site errors, and the functional requirements of transactions. Using this information, you can verify your business and technical operations. You can also set custom alerts on the availability, throughput, and traffic of all items identified in RUEI.

For more information about RUEI, see the Oracle Real User Experience Insight documentation at [http://www.oracle.com/technetwork/documentation/realuserei-091455.html](http://www.oracle.com/technetwork/documentation/realuserei-091455.html).

Click History is a feature that is built into ADF that reports user actions on UI components such as button clicks and mouse scrolling. Click History needs to be enabled on the WebLogic server as well as within the application using the **web.xml** and **weblogic.xml** files.

For more information about Click History and how to enable it in WebLogic server, see the "Click History" section of Administering Oracle ADF Applications.

To enable RUEI and Click History in the **web.xml** file:

1. In the Applications window, expand **WEB-INF** and double-click **web.xml**.

2. In the overview editor, add the **context-param** tag to the **web.xml** file, as shown in the following example.

   ```xml
   <context-param>
   <description>This parameter notifies ADF Faces that the
   ExecutionContextProvider service provider is enabled.
   When enabled, this will start monitoring and aggregating
   user activity information for the client initiated
   requests. By default this param is not set or is false.
   </description>
   <param-name>oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER</param-name>
   <param-value>true</param-value>
   </context-param>
   
   For Click History, in addition to adding the parameter to the **web.xml** file, you also need to define the **odl.clickhistory.webapp** library in the **weblogic.xml** file.

   To finish enabling Click History using the **weblogic.xml** file:
1. In the Applications window, expand WEB-INF and double-click weblogic.xml.

2. In the overview editor, add the library entry to the weblogic.xml file, as shown in the following example.

   `<library-ref>
   <library-name>odl.clickhistory.webapp</library-name>
   </library-ref>`

If there is an `EndUserMonitoringService` service provider available, you can use it to log performance metrics and data by registering it in your application. The service provider should have been implemented by extending the `EndUserMonitoringService` class. For more information about this class, see the Javadoc.

Note that the context-parameter `oracle.adf.view.faces.context.ENABLE_ADF_EXECUTION_CONTEXT_PROVIDER` needs to be set when an `EndUserMonitoringService` provider is used within an ADF application.

To enable End User Monitoring in an application:

1. Verify that an `EndUserMonitoringService` service provider has been implemented.

2. Navigate to the application's `<application_home>/src/META-INF/services` folder using your operating system tools.

   If the `services` folder does not exist, create one.

3. In the `<application_home>/src/META-INF/services` folder, create a file named `oracle.adf.view.rich.monitoring.EndUserMonitoringService` where `EndUserMonitoringService` is the name of the service interface.

4. Open the file in an editor and add this entry:

   `<package>.MyEndUserMonitoringService`

   where `package` is the Java package name where the service provider resides and `MyEndUserMonitoringService` is the name of the `EndUserMonitoringService` service provider.

### 55.3.4 How to Deploy Applications with ADF Security Enabled

If you are developing an application in JDeveloper using Integrated WebLogic Server, application security deployment properties are configured by default, which means that the application and security credentials and policies will be overwritten each time you redeploy for development purposes. However, the application security deployment properties are the same for Integrated WebLogic Server and the standalone WebLogic Server.

You can change the default behavior in the Application Properties dialog, as described in *How to Configure, Deploy, and Run a Secure Application in JDeveloper*.

#### 55.3.4.1 Applications That Will Run Using Oracle Single Sign-On (SSO)

Before you can deploy and run the web application with ADF Security enabled on the application server, the administrator of the target server must configure the domain-level `jps-config.xml` file for the Oracle Access Manager (OAM) security provider. To complete this configuration task, you can use Oracle WebLogic Scripting Tool (WLST) provided with the JDeveloper install. For details about running WLST (with

Running the `addOAMSSOProvider()` command ensures that the ADF Security framework defers to the OAM service provider to clear the ObSSOCookie token. OAM uses this token to save the identity of authenticated users and, unless it is cleared during logout, the user will be unable to log out.

After the system administrator runs the command on the target server, the domain `jps-config.xml` file will contain the following security provider definition that is specific for ADF Security:

```xml
<propertySet name="props.auth.uri">
    <property name="login.url.FORM" value="/${app.context}/adfAuthentication"/>
    <property name="logout.url" value=""/>
</propertySet>
```

Additionally, the authentication type required by SSO is CLIENT-CERT. The `web.xml` authentication configuration for the deployed application must specify the `<auth-method>` element as one of the following CLIENT-CERT types.

WebLogic supports two types of authentication methods:

- For FORM-type authentication method, specify the elements like this:

  ```xml
  <login-config>
  <auth-method>CLIENT-CERT,FORM</auth-method>
  <realm-name>myrealm</realm-name>
  <form-login-config>
    <form-login-page>/login.html</form-login-page>
    <form-error-page>/error.html</form-error-page>
  </form-login-config>
</login-config>
```

- For BASIC-type authentication method, specify the elements like this:

  ```xml
  <login-config>
  <auth-method>CLIENT-CERT,BASIC</auth-method>
  <realm-name>myrealm</realm-name>
</login-config>
```

WebSphere supports a single authentication method. Specify the elements like this:

```xml
<login-config>
  <auth-method>CLIENT-CERT</auth-method>
  <realm-name>myrealm</realm-name>
  <form-login-config>
    <form-login-page>/login.html</form-login-page>
    <form-error-page>/error.html</form-error-page>
  </form-login-config>
</login-config>
```

You can configure the `web.xml` file either before or after deploying the web application. For further details about setting up the authentication method for Single Sign-On, see Part IV, “Managing Access Manager SSO, Policies, and Testing” of the Administrator’s Guide for Oracle Access Management.
55.3.4.2 Configuring Security for Weblogic Server

In a development environment, JDeveloper will automatically migrate application level credentials, identities, and policies to the standalone WebLogic Server instance only if the server is set up to be in development mode. Integrated WebLogic Server is set up in development mode by default. You can set up a standalone WebLogic Server to be in development mode during Oracle WebLogic Server domain creation using the Oracle Fusion Middleware Configuration Wizard. For more information about configuring Oracle WebLogic Server domains, see Creating WebLogic Domains Using the Configuration Wizard.

JDeveloper will not migrate application level security credentials to WebLogic Server set up in production mode. Typically, in a production environment, administrators will use Enterprise Manager or WLST to deploy an application, including its security requirements.

When you deploy an application to WebLogic Server, credentials (in the cwallet.sso file) and security policies (in the jazn-data.xml file) will either overwrite or merge with the WebLogic Server's domain-level credential store, depending on whether an option in weblogic-application.xml is set to OVERWRITE or MERGE. In production-mode WebLogic Server, to avoid security risks, only MERGE is allowed. For development-mode WebLogic Server, you can set to OVERWRITE to test user names and passwords. You can also set the option by running setDomainEnv.cmd or setDomainEnv.sh with the following option added to the command (usually located in ORACLE_HOME/user_projects/domains/MyDomain/bin).

For setDomainEnv.cmd:

```bash
set EXTRA_JAVA_PROPERTIES=-Djps.app.credential.overwrite.allowed=true
%EXTRA_JAVA_PROPERTIES%
```

For setDomainEnv.sh:

```bash
EXTRA_JAVA_PROPERTIES="-Djps.app.credential.overwrite.allowed=true
${EXTRA_JAVA_PROPERTIES}"
export EXTRA_JAVA_PROPERTIES
```

If the Administration Server is already running, you must restart it for this setting to take effect.

You can check to see whether WebLogic Server is in production mode by using the Oracle WebLogic Server Administration Console or by verifying the following line in WebLogic Server's config.xml file:

```xml
<production-mode-enabled>true</production-mode-enabled>
```

By default, JDeveloper sets the application's credential, identities, and policies to OVERWRITE mode. That is, the Application Policies, Credentials, and Users and Groups options are selected by default in the Application Properties dialog Deployment page. However, an application's credentials will be migrated only if the target WebLogic Server instance is set to development mode with -Djps.app.credential.overwrite.allowed=true

Policy migration only works in development-mode. Identity migration only works when using JDeveloper to directly deploy to WebLogic Server regardless of whether it is in development or production-mode.

When your application is ready for deployment to a production environment, you should remove the identities from the jazn-data.xml file or disable the migration of
identities by deselecting Users and Groups from the Application Properties dialog. Application credentials must be manually migrated outside of JDeveloper.

Note:
Before you migrate the jazn-data.xml file to a production environment, check that the policy store does not contain duplicate permissions for a grant. If a duplicate permission (one that has the same name and class) appears in the file, the administrator migrating the policy store will receive an error and the migration of the policies will be halted. You should manually edit the jazn-data.xml file to remove any duplicate permissions from a grant definition.

For more information about migrating application credentials and other jazn-data user credentials, see the "Configuring the OPSS Security Store" chapter in Securing Applications with Oracle Platform Security Services.

55.3.4.2.1 Applications with JDBC URL for WebLogic
If your application has components that use JDBC URL connections, the connection user names and passwords are also stored in the application level credential and policy stores. For the deployed application to be able to connect to the database using the JDBC URL, these credentials and policies must be migrated. That is, if WebLogic Server is in production mode, system administrators must migrate this security information. If WebLogic Server is in development mode, it must have domain-level credential and policy stores set to OVERWRITE to allow the migration of security information.

55.3.4.2.2 Applications with JDBC Data Source for WebLogic
If your application uses application level JDBC data sources with password indirection for database connections, you may need to create credential maps in WebLogic Server to enable the database connection. For more information, see Administering Oracle ADF Applications.

55.3.4.3 Configuring Security for Websphere Application Server
Applications with credentials (in the cwallet.sso file) and security policies (in the jazn-data.xml file) can be migrated to WebSphere. You will need to perform additional tasks in WebSphere. Be aware that the opss-application.xml file is not included in the application EAR file if it is intended for WebSphere Application Server.

Note:
Before you migrate the jazn-data.xml file to a production environment, check that the policy store does not contain duplicate permissions for a grant. If a duplicate permission (one that has the same name and class) appears in the file, the administrator migrating the policy store will receive an error and the migration of the policies will be halted. You should manually edit the jazn-data.xml file to remove any duplicate permissions from a grant definition.
For more information about setting up WebSphere to accept credentials and policies, see the.

55.3.4.3.1 Applications with JDBC URL for WebSphere

If your application has components that use JDBC URL connections, the connection user names and passwords are also stored in the application level credential and policy stores. For the deployed application to be able to connect to the database using the JDBC URL, OPSS migration must be enabled.

55.3.4.3.2 Applications with JDBC Data Source for WebSphere

If your application uses application level JDBC data sources with password indirection for database connections, you will need to create a JDBC data source in WebSphere. For more information, see IBM WebSphere documentation.

55.3.4.3.3 Editing the web.xml File to Protect the Application Root for WebSphere

When you enable ADF Security for your web application, the web.xml file includes the Java EE security constraint allPages to protect the Java EE application root. By default, to support deploying to Oracle WebLogic Server, JDeveloper specifies the URL pattern for the security constraint as / (backslash). If you intend to deploy the application to IBM WebSphere, the correct URL pattern is /* (backslash-asterisk).

Before you deploy the application to WebSphere, manually edit the web.xml file for your application to change the allPages security constraint as follows:

```xml
<security-constraint>
  <web-resource-collection>
    <web-resource-name>allPages</web-resource-name>
    <url-pattern>/*</url-pattern>
  </web-resource-collection>
</security-constraint>
```

55.3.5 How to Replicate Memory Scopes in a Clustered Environment

If you are deploying an application that is intended to run in a clustered environment, you need to ensure that all managed beans with a lifespan longer than one request are serializable, and that Oracle ADF is aware of changes to managed beans stored in ADF scopes (view scope and page flow scope).

For more information, see How to Set Managed Bean Memory Scopes in a Server-Cluster Environment.

55.3.6 How to Enable the Application for ADF MBeans

A Fusion web application uses many XML files for setting configuration information. Three of these configuration files have ADF MBean counterparts that are deployed with the application. After the application has been deployed, you can change configuration properties by accessing the ADF MBeans using the Enterprise Manager Fusion Middleware Control MBean browser.

To enable ADF MBeans, register them in the web.xml file. The following example shows a web.xml file with listener entries for connections, configuration, and business components.

```xml
<listener>
  <listener-class>
    oracle.adf.mbean.share.connection.ADFConnectionLifeCycleCallBack
  </listener-class>
</listener>
```
Additionally, you must configure a writable MDS repository to enable post-deployment configuration of connections.xml using ADF Connections MBeans and bc4j.xcfg using ADF Business Components MBeans.

MDS configuration entries in the adf-config.xml file for a database-based MDS are shown in the example below. For more information about configuring MDS, see Administering Oracle Fusion Middleware.

```
<adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
  <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
    <persistence-config>
      <metadata-store-usages>
        <metadata-store-usage
          default-cust-store="true" deploy-target="true" id="myStore">
        </metadata-store-usage>
      </metadata-store-usages>
    </persistence-config>
  </mds-config>
</adf-mds-config>
```

In a production environment, an MDS repository that uses a database is required. You can use JDeveloper, Enterprise Manager Fusion Middleware Control or scripts to switch from a file-based repository to a database MDS repository.

Additionally, if several applications are sharing the same MDS configuration, each application can achieve distinct customization layers by defining a adf:adf-properties-child property in the adf-config.xml file. JDeveloper automatically generates this entry when creating applications. If your adf-config.xml file does not have this entry, add it to the file with code similar to this one:

```
<adf:adf-properties-child xmlns="http://xmlns.oracle.com/adf/config/properties">
  <adf-property name="adfAppUID" value="Application3-4434"/>
  <adf-property name="partition_customizations_by_application_id" value="true"/>
</adf:adf-properties-child>
```

The value attribute is either generated by JDeveloper or you can set it to any unique identifier within the server farm where the application is deployed. This value can be set to the value attribute of the adfAppUID property.

When adf-property name is set to adfAppUid, then the corresponding value property should be set to the name of the application. By default, JDeveloper generates the value property using the application’s package name. If the package name is not specified, JDeveloper generates the value property by using the workspace name and a four digit random number.

For more information about configuring ADF applications using ADF MBeans, see Administering Oracle ADF Applications.
55.3.7 What You May Need to Know About JDBC Data Source for Oracle WebLogic Server

ADF applications can use either a JDBC data source or a JDBC URL for database connections. You use the Oracle WebLogic Server Administration Console to configure a JDBC data source. For more information about database access, see Configuring Your Application Module Database Connection.

Note:

Fusion web applications are not compatible with data sources defined with the JDBC XA driver. When creating a data source on Oracle WebLogic Server, be sure to change the Fusion web application data source’s JDBC driver from “Oracle’s Driver (Thin XA)” to “Oracle’s Driver (Thin)”. Because XA data sources close all cursors upon commit, random JBO-27122 and closed statement errors may result when running the Fusion web application with an XA data source.

The application module in the data model project of a Fusion web application can be configured to use a JDBC URL connection type, a JDBC data source connection type, or a combination of both types. By default, Fusion web application modules use a JDBC URL connection. A component that uses a JDBC URL will attempt to connect directly to the database using the JDBC URL, and it will ignore any JDBC data sources (global or application level) that are available in WebLogic Server. For more information about migrating JDBC URL security information (user names and passwords) from the application to WebLogic Server, see How to Deploy Applications with ADF Security Enabled.

A Fusion web application can use a JDBC data source to connect to the database. A JDBC data source has three types: global, application level, and application level with password indirection. You generally set up a global JDBC data source in WebLogic Server. Any application that requires access to that database can use that JDBC data source. An application can also include application level JDBC data sources. When the application is packaged for deployment, if the Auto Generate and Synchronize weblogic-jdbc.xml Descriptor During Deployment option is selected, JDeveloper creates a connection_name-jdbc.xml file for each connection that was defined. Each connection’s information is written to the corresponding connection_name-jdbc.xml file (entries are also changed in weblogic-application.xml and web.xml). When the application is deployed to WebLogic Server, the server looks for application level data source information before it looks for the global data source.

If the application is deployed with password indirection set to true, WebLogic Server will look for the connection_name-jdbc.xml file for user name information and it will then attempt to locate application level credential maps for these user names to obtain the password. If you are using JDeveloper to directly deploy the application to WebLogic Server, JDeveloper automatically creates the credential map and populates the map to the server using an MBean call.

However, if you are deploying to an EAR file, JDeveloper will not be able to make the MBean call to WebLogic Server. You must set up the credential maps using the Oracle WebLogic Administration Console. Even if you have a global JDBC data source set up, if you do not also have credential mapping set up, WebLogic Server will not be able to map the credentials with passwords and the connection will fail.
Once the data source has been created in Oracle WebLogic Server, it can be used by an application module. For more information, see the "Preparing the Standalone Application Server for Deployment" section of Administering Oracle ADF Applications.

55.4 Deploying the Application

You can use JDeveloper to deploy ADF applications directly to the standalone application server or you can create an archive file and use other tools to deploy to the application server.

**Note:**

Before you begin to deploy applications that use Oracle ADF to the standalone application server, you need to prepare the application server environment by performing tasks such as installing the ADF runtime and creating and extending domains or cells. For more information, see the "Preparing the Standalone Application Server for Deployment" section of Administering Oracle ADF Applications.

Figure 55-5 show the process flow for deploying an application and also for deploying customizations to the target standalone application server.
Table 55-2 describes some common deployment techniques that you can use during the application development and deployment cycle. The deployment techniques are listed in order from deploying on development environments to deploying on production environments. It is likely that in the production environment, the system administrators deploy applications by using Enterprise Manager Fusion Middleware Control or scripts.
Table 55-2 Deployment Techniques for Development or Production Environments

<table>
<thead>
<tr>
<th>Deployment Technique</th>
<th>Environment</th>
<th>When to Use</th>

</table>

Any necessary MDS repositories must be registered with the application server. If the MDS repository is a database, the repository maps to a data source with MDS-specific requirements.

If you are deploying the application to Oracle WebLogic Server, make sure to target this data source to the WebLogic Administration Server and to all Managed Servers to which you are deploying the application. For more information about registering MDS, see *Administering Oracle Fusion Middleware*.

If you are using the application server’s administrative console or scripts to deploy an application packaged as an EAR file that requires MDS repository configuration in *adf-config.xml*, you must run the `getMDSArchiveConfig` command to configure MDS before deploying the EAR file. MDS configuration is required if the EAR file contains a MAR file or if the application is enabled for DT@RT (Design Time At RunTime).

For more information about WLST commands, see the *WLST Command Reference for Infrastructure Components*.

For more information about `wsadmin` commands, see the *and the*.
Note:

For IBM WebSphere Application Server, after you have deployed the application, you need to perform additional tasks such as starting the server. For more information about IBM WebSphere Application Server, wsadmin commands, and using the WebSphere Administrative Console, see the . For more information about wsadmin commands specific to Oracle ADF and installing the ADF runtime into the IBM WebSphere Application Server, see Administering Oracle ADF Applications.

If you plan to configure ADF connection information, ADF Business Components information, or adf-config.xml using ADF MBeans after the application has been deployed, make sure that the application is configured with MDS and have the MBean listeners enabled in the web.xml file. For more information, see How to Enable the Application for ADF MBeans.

Note:

If your Fusion web application has business services that you want to deploy to WebLogic Server, see How to Deploy Web Services to Oracle WebLogic Server.

55.4.1 How to Deploy to the Application Server from JDeveloper

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you deploy an application. For more information, see Deploying the Application.

You will need to complete this task:

Create an application level deployment profile that deploys to an EAR file as described in Creating an Application Level EAR Deployment Profile.

Note:

When you are deploying to Oracle WebLogic Server from JDeveloper, ensure that the HTTP Tunneling property is enabled in the Oracle WebLogic Server Administration Console. This property is located under Servers > ServerName > Protocols. ServerName refers to the name of Oracle WebLogic Server.

Note:

JDeveloper does not support deploying applications to individual Managed Servers that are members of a cluster. You may be able to target one or more Managed Servers within a cluster using the Oracle WebLogic Server Administration Console or other Oracle WebLogic tools; however, the cluster can be negatively affected. For more information about deploying to Oracle WebLogic Server clusters, see Administering Oracle Fusion Middleware.
To deploy to the target application server from JDeveloper:

1. In the Applications window, right-click the application and choose **Deploy > deployment profile**.

2. In the Deploy wizard, on the Deployment Action page, select **Deploy to Application Server** and click **Next**.

3. On the Select Server page, select the application server connection, and click **Next**.

4. If you are deploying to a WebLogic Server instance, the WebLogic Options page appears. Select a deployment option and click **Next**.

---

**Note:**

If you are deploying an ADF application, do not use the **Deploy to all instances in the domain** option.

---

5. Click **Finish**.

During deployment, you can see the process steps displayed in the deployment Log window. You can inspect the contents of the modules (archives or exploded EAR) being created by clicking on the links that are provided in the log window. The archive or exploded EAR file will open in the appropriate editor or directory window for inspection.

If the adf-config.xml file in the EAR file requires MDS repository configuration, the Deployment Configuration dialog appears for you to choose the target metadata repository or shared metadata repositories, as shown in **Figure 55-6**. The **Repository Name** dropdown list allows you to choose a target metadata repository from a list of metadata repositories registered with the Administration Server. The **Partition Name** dropdown list allows you to choose the metadata repository partition to which the application's metadata will be imported during deployment. You can use Oracle WebLogic Scripting Tool (WLST) and Oracle WebLogic Server Administration Tool to configure and register MDS. For more information about managing the MDS Repository, see *Administering Oracle Fusion Middleware*.
Note:

If you are deploying a Java EE application, click the application menu next to the Java EE application in the Applications window.

For more information on creating application server connections, see How to Create a Connection to the Target Application Server.

55.4.2 How to Create an EAR File for Deployment

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using Enterprise Manager, Oracle WebLogic Scripting Tool (WLST), or Oracle WebLogic Server Administration Console.

Although a Fusion web application is encapsulated in an EAR file (which usually includes WAR, MAR, and JAR components), it may have parts that are not deployed with the EAR. For instance, ADF Business Services can be deployed as a JAR. For more information about business services, see How to Deploy Web Services to Oracle WebLogic Server.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an EAR file for deployment. For more information, see Deploying the Application.

You will need to complete this task:
Create an application level deployment profile that deploys to an EAR file as described in Creating an Application Level EAR Deployment Profile.

To create an EAR archive file:

1. In the Applications window, right-click the application containing the deployment profile, and choose Deploy > deployment profile.

2. In the Deploy wizard, on the Deployment Action page, select Deploy to EAR and click Finish.

If an EAR file is deployed at the application level, and it has dependencies on a JAR file in the data model project and dependencies on a WAR file in the user interface project, then the files will be located in the following directories by default:

- `ApplicationDirectory/deploy/EARdeploymentprofile.EAR`
- `ApplicationDirectory/ModelProject/deploy/JARdeploymentprofile.JAR`
- `ApplicationDirectory/ViewControllerProject/deploy/WARdeploymentprofile.WAR`

**Tip:**

Choose View > Log to see messages generated during creation of the archive file.

### 55.4.3 How to Deploy New Customizations Applied to ADF Library

If you have created new customizations for an ADF Library, you can use the MAR profile to deploy these customizations to any deployed application that consumes that ADF Library. For instance, suppose `applicationA`, which consumes `ADFLibraryB`, is deployed to a standalone application server. Later on, when new customizations are added to `ADFLibraryB`, you only need to deploy the updated customizations into `applicationA`. You do not need to repackage and redeploy the whole application nor do you need to manually patch the MDS repository.

**Note:**

This procedure is for applying ADF Library customizations changes to an application that has already been deployed to a standalone application server. It is not for the initial packaging of customizations into a MAR that will eventually be a part of an EAR. For information about initial packaging of the customization using a MAR, see Creating a MAR Deployment Profile.

To deploy ADF Library customizations, create a new MAR profile and only include the customizations to be deployed and then use JDeveloper to:

- Deploy the customizations directly into the MDS repository in the standalone application server.

- Deploy the customizations to a JAR. And then import the JAR into the MDS repository using tools such as the Fusion Middleware Control.
55.4.3.1 Exporting Customization to a Deployed Application

You can export the customizations directly from JDeveloper into the MDS repository for the deployed application on the standalone application server.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you export customizations directly into the application server. For more information, see Deploying the Application.

You will need to complete this task:

Create new customizations to the ADF Library. For more information on customizations, see How to Customize ADF Library Artifacts in JDeveloper.

To export the customizations directly into the application server:

1. In the Applications window, right-click the application and choose Deploy > metadata.

2. In the Deploy metadata dialog, on the Deployment Action page, select Export to a Deployed Application and click Next.

   If the MAR profile is included in the EAR profile of any application, Export to a Deployed Application will be dimmed and disabled.

3. On the Application Server page, select the application server connection and click Next.

4. For WebLogic Server, the Server Instance page appears. In this page, select the server instance where the deployed application is located and click Next.

5. On the Deployed Application page, select the application you want to apply the customizations to and click Next.

6. On the Sandbox Instance page, if you want to deploy to a sandbox, select Deploy to an associated sandbox, choose the sandbox instance, and click Next.

7. On the Summary page, verify the information and click Finish.

55.4.3.2 Deploying Customizations to a JAR

When you deploy the ADF Library customizations to a JAR, you are packaging the contents as defined by the MAR profile.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you deploy customizations as a JAR. For more information, see Deploying the Application.

You will need to complete this task:

Create new customizations to the ADF Library. For more information on customizations, see How to Customize ADF Library Artifacts in JDeveloper.

To deploy the customizations as a JAR:

1. In the Applications window, right-click the application and choose Deploy > metadata.
2. In the Deploy Metadata dialog, on the Deployment Action page, select **Deploy to MAR**.

3. On the Summary page, click **Finish**.

4. Use Enterprise Manager Fusion Middleware Control or the application server’s administration tool to import the JAR into the MDS repository. For more information about Fusion Middleware Control, see *Administering Oracle Fusion Middleware*.

**55.4.4 What You May Need to Know About ADF Libraries**

An ADF Library is a JAR file that contains JAR services registered for ADF components such as ADF task flows, pages, or application modules. If you want the ADF components in a project to be reusable, you create an ADF Library deployment profile for the project and then create an ADF Library JAR based on that profile.

An application or project can consume the ADF Library JAR when you add it using the Resources window or manually by adding it to the library classpath. When the ADF Library JAR is added to a project, it will be included in the project’s WAR file if the **Deployed by Default** option is selected.

For more information, see *Reusing Application Components*.

**55.4.5 What You May Need to Know About EAR Files and Packaging**

When you package a Fusion web application into an EAR file, it can contain the following:

- **WAR files**: Each web-based view controller project should be packaged into a WAR file.
- **MAR file**: If the application has customizations that are deployed with the application, it should be packaged into a MAR.
- **ADF Library JAR files**: If the application consumes ADF Library JARs, these JAR files may be packaged within the EAR.
- **Other JAR files**: The application may have other dependent JAR files that are required. They can be packaged within the EAR.

**55.4.6 How to Deploy the Application Using Scripts and Ant**

You can deploy the application using commands and automate the process by putting those commands in scripts. The *ojdeploy* command can be used to deploy an application without JDeveloper. You can also use Ant scripts to deploy the application. JDeveloper has a feature to help you build Ant scripts. Depending on your requirements, you may be able to integrate regular scripts with Ant scripts.

For more information about commands, scripts, and Ant, see *Administering Oracle ADF Applications*.

**55.4.7 How to Deploy ADF Faces Library JARs with the Application**

You can develop applications that only use ADF Faces without using ADF Model. In that case, you can deploy the ADF Faces JARs with the application into the application server.

Before you begin:
Create an application with a web-based project. If you used the Fusion Web Application (ADF) template, you should already have a default WAR deployment profile.

To deploy ADF Faces JARs as part of the application:

1. In the Applications window, right-click the web project that you want to deploy and choose Project Properties.

2. In the Project Properties dialog, select Deployment and then the deployment profile and click Edit.

   If your project does not have a WAR deployment profile, follow Steps 1 to 3 in Creating a WAR Deployment Profile, to create a new WAR deployment profile.

4. Click OK to exit the Deployment Profile Properties dialog.

5. Click OK again to exit the Project Properties dialog.

6. Deploy your application as described in this chapter either directly using JDeveloper or by creating a EAR and deploying it using the Enterprise Manager Fusion Middleware Control, the Oracle WebLogic Server Administration Console, or other methods.

   Make sure your application-level EAR contains the WAR file as described in Creating an Application Level EAR Deployment Profile.

55.4.8 What You May Need to Know About JDeveloper Runtime Libraries

When an application is deployed, it includes some of its required libraries with the application. The application may also require shared libraries that have already been loaded to WebLogic Server as JDeveloper runtime libraries. It may be useful to know which JDeveloper libraries are packaged within which WebLogic Server shared library. For a listing of the contents of the JDeveloper runtime libraries, see Administering Oracle ADF Applications.

55.5 Postdeployment Configuration

After you have deployed your application to WebLogic Server, you can perform configuration tasks.

55.5.1 How to Migrate an Application

If you want to migrate a Fusion web application from one WebLogic Server to another WebLogic Server, you may need to perform some of the same steps you did for a first time deployment.

In general, to migrate an application, you would:

- Load the ADF runtime (if it is not already installed) to the target application server.
  For more information, see the "Preparing the Standalone Application Server for Deployment" section of Administering Oracle ADF Applications.

- Configure the target application server with the correct database or URL connection information.
• Migrate security information from the source to the target.
  For instructions, see How to Deploy Applications with ADF Security Enabled.

• Deploy the application using Enterprise Manager, administration console, or
  scripts.
  For more information, see Administering Oracle ADF Applications.

55.5.2 How to Configure the Application Using ADF MBeans

If ADF MBeans were enabled and packaged with the deployed application, you can
configure ADF properties using the Enterprise Manager MBean Browser. For
instructions on how to enable an application for MBeans, see How to Enable the
Application for ADF MBeans.

For information on how to configure ADF applications using ADF MBeans, see
Administering Oracle ADF Applications.

55.5.3 How to Configure WebSphere for Result Set Reuse

ADF applications deployed to WebSphere Application Server use shared database
connections. You need to set the non-transactional datasource and
DisableMultiThreadedServletConnectionMgmt properties in WebSphere to
allow the application to reuse result sets across requests.

If you do not set these properties, WebSphere will close the result sets between
requests.

For more information, see the "Configuring WebSphere Application Server" section in
Administering Oracle ADF Applications

55.6 Testing the Application and Verifying Deployment

After you deploy the application, you can test it from the application server. To test-
run your ADF application, open a browser window and enter a URL:

• For non-Faces pages: http://<host>:port/<context root>/<page>

• For Faces pages: http://<host>:port/<context root>/faces/<view_id>
  where <view_id> is the view ID of the ADF task flow view activity.

  Tip:
  The context root for an application is specified in the user interface project
  settings by default as ApplicationName/ProjectName/context-root. You
can shorten this name by specifying a name that is unique across the
target application server. Right-click the user interface project, and choose
Project Properties. In the Project Properties dialog, select Java EE Application
  and enter a unique name for the context root.

  Note:
  /faces has to be in the URL for Faces pages. This is because JDeveloper
configures your web.xml file to use the URL pattern of /faces in order to be
associated with the Faces Servlet. The Faces Servlet does its per-request
  processing, strips out /faces part in the URL, then forwards the URL to the
JSP. If you do not include the /faces in the URL, then the Faces Servlet is not
engaged (since the URL pattern doesn't match). Your JSP is run without the necessary JSF per-request processing.
This chapter describes the Fusion web application state management facilities for ADF application modules to support stateful applications on the web.

This chapter includes the following sections:

- About Fusion Web Application State Management
- Managing When Passivation and Activation Occurs
- Testing to Ensure Your Application Module is Activation-Safe
- Controlling Where Model State Is Saved
- Cleaning Up the Model State
- Managing the HttpSession in Fusion Web Applications
- Managing Custom User-Specific Information During Passivation
- Managing the State of View Objects During Passivation

56.1 About Fusion Web Application State Management

Most real-world business applications need to support multi-step user tasks. Transactional web sites tend to use a step-by-step style user interface to guide the end user through a logical sequence of pages to complete these tasks. When the task is done, the user can save or cancel everything as a unit. However, the HTTP protocol is built on the concept of individual, stateless requests, so the responsibility of grouping a sequence of user actions into a logical, stateful unit of work falls to the application developer.

The limitations of the HTTP protocol have led developers to invent solutions involving a "shadow" set of database tables with no constraints and with all of the column types defined as character-based. Using such a solution becomes very complex very quickly. Ultimately, some kind of generic application state management facility is needed to address these issues in a more generic and workable way. The solution comes in the form of ADF Business Components, which implements this for you out of the box.

State management enables you to easily create web applications that support multi-step use cases without falling prey to the memory, reliability, or implementation complexity problems. Oracle ADF simplifies the process of implementing and maintaining session state through the use of application module pools, which are configurable resource managers that release application module caches safely. By default, the ADF Business Components project enables one application module pool for each application module definition in your application.
In Fusion web applications, state management is provided at these levels:

- **Save For Later** feature in the ADF Controller layer implemented in task flows, as described in [Using Save Points in Task Flows](#).

  Save For Later is activated at the ADF Controller layer and automatically saves a "snapshot" of the current UI and controller states, and delegates to the ADF Model layer to save its state as well. Save for Later saves an incomplete transaction without enforcing validation rules or submitting the data. You can use it to save data and state information about a region, view port, or portlet. Later, you can restore application state and data associated with a save point that supports both explicit saves (initiated by the user) or implicit saves (without user action). The end user can resume working on the same transaction with the same data that was originally saved when the application was exited.

- **Application state management facility** in the ADF Model layer implemented in application modules.

  Through the application state management facility, the ADF runtime automatically manages the application state of each user session and supports highly scalable applications. An application module supports passivating (storing) its pending transaction state to an XML document, which is stored either in-memory or in the database in a single, generic table, keyed by a unique passivation snapshot ID. It also supports the reverse operation of activating pending transaction state from one of these saved XML snapshots. This passivation and activation is performed automatically by the **application module pool** when needed, and is controlled by configuration properties that you can specify. Understanding what happens behind the scenes is essential to make the most efficient use of this important feature, as explained in [Managing When Passivation and Activation Occurs](#).

- **Application state management support** for a server farm, or clustered server environment with failover.

  If you deploy in a multiple application server environment with failover enabled, then subsequent end-user requests may be handled by any server in your server farm or cluster. To support this scenario, the application state management facility passivates the application module at the end of every request. In the event failover occurs, where the user session is redirected to another server node, the session cookie can reactivate the pending application state from the database-backed XML snapshot, regardless of which server handles the request. Thus application module passivation and activation provides built-in support for cluster failover without additional configuration. For more information about ADF support for failover, see [Configuring High Availability for Fusion Web Applications](#).

The ADF Business Components application module lets you implement completely stateless applications or support a unit of work that spans multiple browser pages. Figure 56-1 illustrates the basic architecture of the state management facility to support these multi-step scenarios.
The ADF binding context is the one object that lives in the HttpSession for each end user. It holds references to lightweight application module data control objects that manage acquiring an application module instance from the pool during the request (when the data control is accessed) and releasing it to the pool at the end of each request. The data control holds a reference to the application module handle that identifies the user session. In particular, serialized session objects of the application module state created or modified in the pending transaction are not saved in the HttpSession using this approach. This minimizes both the session memory required per user and eliminates the network traffic related to session replication if the servers are configured in a cluster.

56.1.1 What You May Need to Know About Multi-Step Tasks

In a typical search-then-edit scenario, the end user searches to find an appropriate row to update, then may open several different pages of related master-detail information to make edits before deciding to save or cancel work. Consider another scenario where the end user wants to book a vacation online. The process may involve the end user’s entering details about:

- One or more flight segments that comprise the journey
- One or more passengers taking the trip
- Seat selections and meal preferences
- One or more hotel rooms in different cities
- Car they will rent

Along the way, the user might decide to complete the transaction, save the reservation for finishing later, or abandon the transaction before saving.
It’s clear these scenarios involve a logical unit of work that spans multiple web pages. You’ve seen in previous chapters how to use JDeveloper’s JSF page navigation diagram to design the page flow for these use cases, but that is only part of the puzzle. The pending changes the end user makes to business domain objects along the way — Trip, Flight, Passenger, Seat, HotelRoom, Auto, etc. — represent the in-progress state of the application for each end user. Along with this, other types of "bookkeeping" information about selections made in previous steps comprise the complete picture of the application state.

56.1.2 What You May Need to Know About the Stateless HTTP Protocol

While it may be easy to imagine the multi-step application scenarios, implementing them in web applications is complicated by the stateless nature of HTTP, the hypertext transfer protocol. Figure 56-2 illustrates how an end user’s visit to a site comprises a series of HTTP request/response pairs. However, HTTP affords a web server no way to distinguish one user’s request from another user’s, or to differentiate between a single user’s first request and any subsequent requests that user makes while interacting with the site. The server gets each request from any user always as if it were the first (and only) one they make.

Figure 56-2  Web Applications Use the Stateless HTTP Protocol

56.1.3 What You May Need to Know About Session Cookies

As shown in Figure 56-3, the technique used to recognize an ongoing sequence of requests from the same end user over the stateless HTTP protocol involves a unique identifier called a cookie. A cookie is a name/value pair that is sent in the header information of each HTTP request the user makes to a site. On the initial request made by a user, the cookie is not part of the request. The server uses the absence of the cookie to detect the start of a user’s session of interactions with the site, and it returns a unique identifier to the browser that represents this session for this user. In practice, the cookie value is a long string of letters and numbers, but for the simplicity of the illustration, assume that the unique identifier is a letter like "A" or "Z" that corresponds to different users using the site.

Web browsers support a standard way of recognizing the cookie returned by the server that allows the browser to identify the following:

- the site that sent the cookie
- how long it should remember the cookie value

On each subsequent request made by that user, until the cookie expires, the browser sends the cookie along in the header of the request. The server uses the value of the cookie to distinguish between requests made by different users.
Cookies can be set to live beyond a single browser session so that they might expire in a week, a month, or a year from when they were first created, while a session cookie expires when the user closes the browser.

**Figure 56-3  Tracking State Using a Session Cookies and Server-Side Session**

Java EE-compliant web servers provide a standard server-side facility called the HttpSession that allows a web application to store Java objects related to a particular user's session as named attribute/value pairs. An object placed in this session Map on one request can be retrieved by the application while handling a subsequent request during the same session.

The session remains active while the user continues to send new requests within the timeframe specified by the `<session-timeout>` element in the web.xml file. The default session length is typically around 30 minutes, depending on the container.

### 56.1.4 What You May Need to Know About Using HttpSession

The HttpSession facility is an ingredient in most application state management strategies, but it can present performance and reliability problems if not used judiciously. First, because the session-scope Java objects the application creates are held in the memory of the Java EE web server, the objects in the HTTP session are lost if the server should fail.

As shown in **Figure 56-4**, one way to improve the reliability is to configure multiple Java EE servers in a cluster. By doing this, the Java EE application server replicates the objects in the HTTP session for each user across multiple servers in the cluster so that if one server goes down, the objects exist in the memory of the other servers in the cluster that can continue to handle the users requests. Since the cluster comprises separate servers, replicating the HTTP session contents among them involves broadcasting the changes made to HTTP session objects over the network.
You can begin to see some of the performance implications of overusing the HTTP session:

- The more active users, the more HTTP sessions will be created on the server.
- The more objects stored in each HTTP session, the more memory you will need. Note that the memory is not reclaimed when the user becomes inactive; this only happens with a session timeout or an explicit session invalidation. Session invalidations don’t always happen because users don’t always logout.
- In a cluster, the more objects in each HTTP session that change, the more network traffic will be generated to replicate the changed objects to other servers in the cluster.

At the outset, it would seem that keeping the number of objects stored in the session to a minimum addresses the problem. However, this implies leveraging an alternative mechanism for temporary storage for each user’s pending application state. The solution comes in the form of ADF Business Components, which implements this for you out of the box.

56.2 Managing When Passivation and Activation Occurs

The passivation/activation cycle supports application module pooling and was designed originally to maintain a reasonable number of caches in memory, as well as to support failover in high-availability, clustered server environments. This process however requires the application module state to be written to and read from the database, and is itself an expensive operation. In legacy systems, comprised of 32-bit platforms, where generally smaller amounts of memory were available than on today’s middle-tier servers, the passivation of application module instances helped compensate for memory limitations.

In today’s systems, where RAM generally is not a limitation, passivation/activation provides little benefit by reducing middle-tier server memory usage. Today the best use of the passivation/activation cycle built into application module pooling is to support failure conditions in a clustered server environment.
The following scenario depicts when the automatic passivation and activation of application module state occurs. This background may help you to understand later how application module pooling can be tuned to limit the use of passivation/activation.

1. At the beginning of an HTTP request, the application module data control handles the `beginrequest` event by checking out an application module instance from the pool.

   The application module pool returns an *unreferenced* instance. An unreferenced application module is one that is not currently managing the pending state for any other user session.

2. At the end of the request, the application module data control handles the `endrequest` event by checking the application module instance back into the pool in "managed state" mode.

   That application module instance is now *referenced* by the data control that just used it. And the application module instance is an object that still contains pending transaction state made by the data control (that is, *entity object* and *view object* caches; updates made but not committed; and cursor states), stored in memory. As you’ll see below, the instance is not *dedicated* to this data control, just referenced by it.

3. On a subsequent request, the same data control — identified by its application module handle — checks out an application module instance again.

   Due to the "stateless with user affinity" algorithm the pool uses, the pool returns the exact same application module instance, with the state still there in memory.

The default configuration of application module pooling dictates, at peak usage times, with a high number of users simultaneously accessing the site, application module instances must be sequentially reused by different user sessions. In this case, the application pool will *recycle* a currently referenced application module instance for use by another session, as follows:

1. The application module data control for User A's session checks an application module instance into the application pool at the end of a request. Assume this instance is named *AM1*.

2. The application module data control for User Z's new session requests an application module instance from the pool for the first time, but there are no unreferenced instances available. The application module pool then:
   
   • Passivates the state of instance *AM1* to the database.
   
   • Resets the state of *AM1* in preparation to be used by another session.
   
   • Returns the *AM1* instance to User Z's data control.

3. On a subsequent request, the application module data control for User A's session requests an application module instance from the pool. The application module pool then:

   • Obtains an unreferenced instance.

   This could be instance *AM1*, obtained by following the same tasks as in Step 2, or another *AM2* instance if it had become unreferenced in the meantime.

   • Activates the appropriate pending state for User A from the database.
• Returns the application module instance to User A's data control.

In summary, the process of passivation, activation, and recycling preserves the state referenced by the data control across requests without requiring a dedicated application module instance for each data control. Both browser users in the above scenario are carrying on an application transaction that spans multiple HTTP requests, but the end users are unaware whether the passivation and activation is occurring in the background. They just continue to see the pending changes. While the pending changes never need to be saved into the underlying application database tables until the end user is ready to commit the logical unit of work. The application module pool makes a best effort to keep an application module instance "sticky" to the current data control whose pending state it is managing. This is known as maintaining user session affinity.

The best performance is achieved by minimizing the need for passivation/activation cycle in the deployed Fusion web application. You can control this by changing the default configuration parameters that specify the size of the application module pool, control the resource cleanup behavior of the pool manager, and tune the JDBC connection disconnect behavior used by application module instance at the end of a user request. For more information about design time configuration parameters that let you tune application module pools to reduce passivation, see What You May Need to Know About Application Module Pooling Configuration Parameters.

56.2.1 How to Confirm That Fusion Web Applications Use Optimistic Locking

Oracle recommends using optimistic locking, the default mode for web applications. Pessimistic locking should not be used for web applications as it creates pending transactional state in the database in the form of row-level locks. If pessimistic locking is set, state management will work, but the locking mode will not perform as expected. Behind the scenes, every time an application module is recycled, a rollback is issued in the JDBC connection. This releases all the locks that pessimistic locking had created.

Performance Tip:

Always use the default mode optimistic locking for web applications. Only optimistic locking is compatible with the application module unmanaged release level mode, which allows the application module instance to be immediately released when a web page terminates. This provides the best level of performance for web applications that expect many users to access the application simultaneously.

To ensure your configuration uses optimistic locking, open the Business Components page of the adf-config.xml overview editor and confirm that Locking Mode (corresponding to the jbo.locking.mode property) is set to optimistic or optupdate. To open the adf-config.xml editor, in the Application Resources window, expand Descriptors and ADF META-INF folders and double-click the file node.

Optimistic locking (optimistic) issues a SELECT FOR UPDATE statement to lock the row, then detects whether the row has been changed by another user by comparing the change indicator attribute — or, if no change indicator is specified, the values of all the persistent attributes of the current entity as they existed when the entity object was fetched into the cache.

Optimistic update locking (optupdate) does not perform any locking. The UPDATE statement determines whether the row was updated by another user by including a
WHERE clause that will match the existing row to update only if the attribute values are unchanged since the current entity object was fetched.

56.2.2 What You May Need to Know About Pending Changes Across HTTP Requests

The ADF state management mechanism relies on passivation and activation to manage the state of an application module instance. Implementing this feature in a robust way is only possible if all pending changes are managed by the application module transaction in the middle tier. The most scalable strategy is to keep pending changes in middle-tier objects and not perform operations that cause pending database state to exist across HTTP requests. This allows the highest leverage of the performance optimizations offered by the application module pool and the most robust runtime behavior for your application.

Caution:

When the jbo.doconnectionpooling configuration parameter is set to true — typically in order to share a common pool of database connections across multiple application module pools — upon releasing your application module to the application module pool, its JDBC connection is released back to the database connection pool and a ROLLBACK will be issued on that connection. This implies that all changes which were posted but not committed will be lost. On the next request, when the application module is used, it will receive a JDBC connection from the pool, which may be a different JDBC connection instance from the one it used previously. Those changes that were posted to the database but not committed during the previous request are lost.

The jbo.doconnectionpooling configuration parameter is set by checking the Disconnect Application Module Upon Release property on the Database and Scalability tab of the overview editor for application module configurations (on the bc4j.xcfg file).

56.2.3 What You May Need to Know About Release Levels and postChanges() Method

The transaction-level postChanges() method exists to force the transaction to post unvalidated changes without committing them. This method is not recommended for use in web applications unless you can guarantee that the transaction will definitely be committed or rolled back during the same HTTP request. Failure to heed this advice can lead to strange results in an environment where both application modules and database connections can be pooled and shared serially by multiple different clients.

If for some reason you need to create a transactional state in the database in a particular request by invoking the postChanges() method or by calling a PL/SQL stored procedure, but you cannot issue a commit or rollback by the end of that same request, then you must release the application module instance with the reserved level from that request until a subsequent request when you either commit or rollback.

Note:

Use as short a period of time as possible between creation of transactional state in the database and performing the concluding commit or rollback. This ensures that reserved level doesn’t have to be used for a long time, as it has adverse effects on application’s scalability and reliability.
Once an application module has been released with reserved level, it remains at that release level for all subsequent requests until release level is explicitly changed back to managed or unmanaged level. So, it is your responsibility to set release level back to managed level once commit or rollback has been issued.

56.3 Testing to Ensure Your Application Module is Activation-Safe

If you have not explicitly tested that your application module functions when its pending state gets activated from a passivation snapshot, then you may encounter an unpleasant surprise in your production environment when heavy system load tests this aspect of your system for the first time.

56.3.1 How To Disable Application Module Pooling to Test Activation

As part of your overall testing plan, you should adopt the practice of testing your application modules with the `jbo.ampool.doampooling` configuration parameter set to `false`. This setting completely disables application module pooling and forces the system to activate your application module's pending state from a passivation snapshot on each page request. It is an excellent way to detect problems that might occur in your production environment due to assumptions made in your custom application code.

**Note:**

It is important to re-enable application module pooling after you conclude testing and are ready to deploy the application to a production environment. The configuration property `jbo.ampool.doampooling` set to `false` is not a supported configuration for production applications and must be set to `true` before deploying the application.

For example, if you have transient view object attributes you believe **should** be getting passivated, this technique allows you to test that they are working as you expect. In addition, consider situations where you might have introduced:

- Private member fields in application modules, view objects, or entity objects
- Custom user session state in the `Session` user data hashtable

Your custom code likely assumes that this custom state will be maintained across HTTP requests. As long as you test with a single user on the JDeveloper Integrated WebLogic Server, or test with a small number of users, things will appear to work fine. This is due to the 'stateless with affinity' optimization of the ADF application module pool. If system load allows, the pool will continue to return the same application module instance to a user on subsequent requests. However, under heavier load, during real-world use, it may not be able to achieve this optimization and will need to resort to grabbing any available application module instance and reactivating its pending state from a passivation snapshot. If you have not correctly overridden `passivateState()` and `activateState()` (as described in Managing Custom User-Specific Information During Passivation) to save and reload your custom component state to the passivation snapshot, then your custom state will be missing (i.e. null or back to your default values) after this reactivation step. Testing with `jbo.ampool.doampooling` set to false allows you to quickly isolate these kinds of situations in your code.
For more information about configuring Business Component configuration properties, How to Set Configuration Properties Declaratively.

56.3.2 What You May Need to Know About the jbo.ampool.doampooling Configuration Parameter

The jbo.ampool.doampooling configuration property corresponds to the Enable Application Module Pooling option in the Database and Scalability tab of the overview editor for application module configurations (on the bc4j.xcfg file). By default, this checkbox is checked so that application module pooling is enabled. Whenever you deploy your application in a production environment the default setting of jbo.ampool.doampooling=true is the way you will run your application. But, as long as you run your application in a test environment, setting the property to false can play an important role in your testing. When this property is false, there is effectively no application pool. When the application module instance is released at the end of a request it is immediately removed. On subsequent requests made by the same user session, a new application module instance must be created to handle it and the pending state of the application module must be reactivated from the passivation store.

For more information about configuring Business Component properties, How to Set Configuration Properties Declaratively.

56.3.3 What You May Need to Know About State Management and Data Consistency

When an entity object is updated concurrently by more than one user and one of those users loses affinity with their application module during the update, it is possible to experience data corruption if a change indicator has not been defined for the entity object.

Consider a scenario where two users (User A and User B) access the same entity object at the same time.

- After querying, User B changes the value of an attribute (for example, changing the Dept attribute value from Accounting to Research) and then commits.
- Meanwhile, User A has also queried and sees the same record where the value of the Dept attribute is Accounting.
- User A loses affinity with the application module that was used to query, resulting in passivation.
- User A then changes the Dept attribute value from Accounting to Sales and commits, resulting in activation.
- When activation occurs, the new value of the Dept attribute is activated but the browser is unaware of the data change, and the commit proceeds without issue.

To avoid this type of scenario, define a change indicator attribute for all entity objects. For more information, see How to Protect Against Losing Simultaneously Updated Data.

56.3.4 What You May Need to Know About State Management and Subclassed Entity Objects

If your application employs subclassed entity objects, the key attribute of new entities must be prepopulated. If the key is not prepopulated, passivation and activation will
fail. You can prepopulate the key attribute by overriding the create() method or by using the DBSequence type that will assign a temporary negative value to the key before the real value is fetched from the database after commit. For more information, see How to Get Trigger-Assigned Primary Key Values from a Database Sequence.

56.4 Controlling Where Model State Is Saved

By default, passivation snapshots are saved in the database, but you can configure it to use the file system as an alternative.

When saving to the database, the passivated XML snapshot is written to a BLOB column in a table named PS_TXN, using a connection specified by the jbo.server.internal_connection property. Each time a passivation record is saved, it is assigned a unique passivation snapshot ID based on the sequence number taken from the PS_TXN_SEQ sequence. The application module handle held by the application module data control in the ADF binding context remembers the latest passivation snapshot ID that was created on its behalf and remembers the previous ID that was used.

56.4.1 How to Control the Schema Where the State Management Table Resides

The ADF runtime recognizes a configuration property named jbo.server.internal_connection that controls which database connection and schema should be used for the creation of the PS_TXN table and the PS_TXN_SEQ sequence. If you don’t set the value of this configuration parameter explicitly, then the state management facility creates the temporary tables using the credentials of the current application database connection.

To keep the temporary information separate, the state management facility uses a different connection instance from the database connection pool, but the database credentials are the same as the current user. Since the framework creates temporary tables, and possibly a sequence if they don’t already exist, the implication of not setting a value for the jbo.server.internal_connection is that the current database user must have CREATE TABLE, CREATE INDEX and CREATE SEQUENCE privileges. Since this is often not desirable, Oracle recommends always supplying an appropriate value for the jbo.server.internal_connection property, providing the credentials for a state management schema where table and schema be created. Valid values for the jbo.server.internal_connection property in your configuration are:

- A fully qualified JDBC connection URL like:
  
  jdbc:oracle:thin:username/password@host:port:SID

- A JDBC datasource name like:

  java:/comp/env/jdbc/YourJavaEEDataSourceName

Performance Tip:

When creating the PS_TXN table, use securefiles to store LOB data (the content column), and create a primary column index on the PS_TXN table as global, partitioned reverse key index. The securefile configuration delivers superior performance over the basicfile configuration when working with LOB data. The reverse key index helps by reducing contention that can happen when the rate of inserts is high.
56.4.2 How to Configure the Passivation Store

Passivated information can be stored in several places. You can control it by configuring an option in the application module configuration. The choices are database or a file stored on local file system:

- **File**
  
  This choice may be the fastest available, because access to the file is faster than access to the database. This choice is good if the entire middle tier is either installed on the same machine or has access to a commonly shared file system, so passivated information is accessible to all. Usually, this choice may be good for a small middle tier where one Oracle WebLogic Server domain is used. In other words, this is a very suitable choice for a small middle tier such as one Oracle WebLogic Server instance with all its components installed on one physical machine. The location and name of the persistent snapshot files are determined by the `jbo.tmpdir` property if specified. It follows usual rules of ADF property precedence for a configuration property. If nothing else is specified, then the location is determined by `user.dir` if specified. This is a default property and the property is OS specific.

- **Database**
  
  This is the default choice. While it may be a little slower than passivating to file, it is by far the most reliable choice. With passivation to file, the common problem might be that it is not accessible to Oracle WebLogic Server instances that are remotely installed. In this case, in a cluster environment, if one node goes down the other may not be able to access passivated information and then failover will not work. Another possible problem is that even if file is accessible to the remote node, the access time for the local and remote node may be very different and performance will be inconsistent. With database access, time should be about the same for all nodes.

To set the value of your choice in design time, set the property `jbo.passivationstore` to `database` or `file`. The value `null` will indicate that a connection-type-specific default should be used. This will use database passivation for Oracle or DB2, and file serialization for any others.

56.4.3 What Happens at Runtime: What Model State Is Saved and When It Is Cleaned Up

The information saved by application model passivation is divided in two parts: transactional and nontransactional state. Transactional state is the set of updates made to entity object data – performed either directly on entity objects or on entities through view object rows – that are intended to be saved into the database. Nontransactional state comprises view object runtime settings, such as the current row index, `WHERE` clause, and `ORDER BY` clause.

The information saved as part of the application module passivation snapshot includes the following.

**Transactional State**

- New, modified, and deleted entities in the entity caches of the root application module for this user session's (including old/new values for modified ones).
Nontransactional State

- For each active view object (both statically and dynamically created):
  - Current row indicator for each row set (typically one)
  - New rows and their positions. (New rows are treated differently then updated ones. Their index in the view object is traced as well.)
  - ViewCriteria and all related parameters such as view criteria row, etc.
  - Flag indicating whether or not a row set has been executed
  - Range start and Range size
  - Access mode
  - Fetch mode and fetch size
  - Any view object-level custom data

Note:
Transient view object attributes can be saved if they are selected for passivation at design time. However, use this feature judiciously because this results in a snapshot that will grow in size with the number of rows that have been retrieved. See How to Manage the State of View Objects for information on enable the passivation of transient attributes.

- SELECT, FROM, WHERE, and ORDER BY clause if created dynamically or changed from the View definition

Note:
If you enable ADF Business Components runtime diagnostics, the contents of each XML state snapshot are also saved. See How to Enable ADF Business Components Debug Diagnostics for information on how to enable diagnostics.

Other information, such as user-specific information or instant variables in ADF Business Components objects, is not saved as part of the passivation snapshot. To save this type of information, use the techniques described in Managing Custom User-Specific Information During Passivation.

56.5 Cleaning Up the Model State

Under normal circumstances, the ADF state management facility provides automatic cleanup of the passivation snapshot records.

56.5.1 How to Clean Up Temporary Storage Tables Resulting from Passivation

JDeveloper supplies the adfbc_purge_statesnapshots.sql script to help with periodically cleaning up the application module state management table. You can find this file in the oracle_common subdirectory of your Oracle Middleware installation directory (for example, ORACLE_HOME\oracle_common\common\sql).
Persistent snapshot records can accumulate over time if the server has been shutdown in an abnormal way, such as might occur during development or due to a server failure. Running the script in SQL*Plus will create the BC4J_CLEANUP PL/SQL package. The two relevant procedures in this package are:

- **PROCEDURE Session_State(olderThan DATE)**
  This procedure cleans up application module session state storage for sessions older than a given date.

- **PROCEDURE Session_State(olderThan_minutes INTEGER)**
  This procedure cleans up application module session state storage for sessions older than a given number of minutes.

You can schedule periodic cleanup of your ADF temporary persistence storage by submitting an invocation of the appropriate procedure in this package as a database job.

You can use an anonymous PL/SQL block like the one shown in the following example to schedule the execution of bc4j_cleanup.session_state() to run starting tomorrow at 2:00 am and each day thereafter to cleanup sessions whose state is over 1 day (1440 minutes) old.

```
SET SERVEROUTPUT ON
DECLARE
  jobId    BINARY_INTEGER;
  firstRun DATE;
BEGIN
  -- Start the job tomorrow at 2am
  firstRun := TO_DATE(TO_CHAR(SYSDATE+1,'DD-MON-YYYY')||' 02:00',
                        'DD-MON-YYYY HH24:MI');
  -- Submit the job, indicating it should repeat once a day
  dbms_job.submit(job       => jobId,
                   what      => 'bc4j_cleanup.session_state(1440);',
                   next_date => firstRun,
                   interval  => 'SYSDATE + 1');
  dbms_output.put_line('Successfully submitted job. Job Id is '||jobId);
END;
```

**56.5.2 What Happens at Runtime: When a Passivation Record Is Updated**

When a passivation record is saved to the database on behalf of a session cookie, this passivation record gets a new, unique snapshot ID. The passivation record with the previous snapshot ID used by that same session cookie is deleted as part of the same transaction. In this way, assuming no server failures, there will only ever be a single passivation snapshot record per active end-user session.
56.5.3 What Happens at Runtime: When a Passivation Snapshot is Removed on Unmanaged Release

The passivation snapshot record related to a session cookie is removed when the application module is checked into the pool with the unmanaged state level. This can occur when:

- Your code specifically calls `resetState()` on the application module data control.

- Your code explicitly invalidates the `HttpSession`, for example, as part of implementing an explicit "Logout" functionality.

- The `HttpSession` times out due to exceeding the session timeout threshold for idle time and failover mode is disabled (which is the default).

In each of these cases, the application module pool also resets the application module referenced by the session cookie to be "unreferenced" again. Since no changes were ever saved into the underlying database tables, once the pending session state snapshots are removed, there remains no trace of the unfinished work the user session had completed up to that point.

56.5.4 What Happens at Runtime: Passivation Snapshot Retained in Failover Mode

When the failover mode is enabled, if the `HttpSession` times out due to session inactivity, then the passivation snapshot is retained so that the end user can resume work upon returning to the browser.

After a break in the action, when the end user returns to the browser and continues to use the application, it continues working as if nothing had changed. The session cookie is used to reactivate any available application module instance with the user's last pending state snapshot before handling the request. So, even though the users next request will be processed in the context of a new `HttpSession` (perhaps even in a different application server instance), the user is unaware that this has occurred.

**Note:**

If an application module was released with Reserved level then when the `HttpSession` times out, the user will have to go through an authentication process, and all unsaved changes are lost.

56.6 Managing the HttpSession in Fusion Web Applications

Since HTTP is a stateless protocol, the server receives no implicit notice that a client has closed the browser or gone away for the weekend. Therefore any Java EE-compliant server provides a standard, configurable session timeout mechanism to allow resources tied to the HTTP session to be freed when the user has stopped performing requests. You can also programmatically force a timeout.

56.6.1 How to Configure the Implicit Timeout Due to User Inactivity

You configure the session timeout threshold using the `<session-timeout>` tag in the `web.xml` file. The default value is typically around 30 minutes, depending on the container.
56.6.2 How to Code an Explicit HttpSession Timeout

To end a user's session before the session timeout expires, you can call the `invalidate()` method on the `HttpSession` object from a backing bean in response to the user's click on a Logout button or link. This cleans up the `HttpSession` in the same way as if the session time had expired. Using JSF and ADF, after invalidating the session, you must perform a redirect to the next page you want to display, rather than just doing a forward. The following example shows sample code to perform this task from a Logout button.

```java
public String logoutButton_action() throws IOException {
    ExternalContext ectx = FacesContext.getCurrentInstance().getExternalContext();
    HttpServletResponse response = (HttpServletResponse) ectx.getResponse();
    HttpSession session = (HttpSession) ectx.getSession(false);
    session.invalidate();
    response.sendRedirect("Welcome.jspx");
    return null;
}
```

As with the implicit timeouts, when the HTTP session is cleaned up this way, it ends up causing any referenced application modules to be marked unreferenced.

56.6.3 What Happens at Runtime: How Application Modules are Handled When the HTTP Times Out

When the `HttpSession` times out, the `BindingContext` goes out of scope, and along with it, any data controls that might have referenced application modules released to the pool in the managed state level. The application module pool resets any of these referenced application modules and marks the instances unreferenced again.

56.7 Managing Custom User-Specific Information During Passivation

It is fairly common practice to add custom user-defined information in the application module in the form of member variables or some custom information stored in `oracle.jbo.Session` user data hashtable. The ADF state management facility provides a mechanism to save this custom information to the passivation snapshot as well, by overriding the `passivateState()` method and the `activateState()` methods in the `ApplicationModuleImpl` class.

**Note:**

Similar methods are available on the `ViewObjectImpl` class and the `EntityObjectImpl` class to save custom state for those objects to the passivation snapshot as well.

56.7.1 How to Passivate Custom User-Specific Information

You can override `passivateState()` and `activateState()` to ensure that custom application module state information is included in the passivation/activation cycle. The following example shows how this is done.

In the example, `jbo.counter` contains custom values you want to preserve across passivation and activation of the application module state. Each application module has an `oracle.jbo.Session` object associated with it that stores application module-specific session-level state. The session contains a user data hashtable where
you can store transient information. For the user-specific data to "survive" across application module passivation and reactivation, you need to write code to save and restore this custom value into the application module state passivation snapshot.

```java
/**
 * Overridden framework method to passivate custom XML elements
 * into the pending state snapshot document
 */
public void passivateState(Document doc, Element parent) {
    // 1. Retrieve the value of the value to save
    int counterValue = getCounterValue();
    // 2. Create an XML element to contain the value
    Node node = doc.createElement(COUNTER);
    // 3. Create an XML text node to represent the value
    Node cNode = doc.createTextNode(Integer.toString(counterValue));
    // 4. Append the text node as a child of the element
    node.appendChild(cNode);
    // 5. Append the element to the parent element passed in
    parent.appendChild(node);
}
/**
 * Overridden framework method to activate custom XML elements
 * into the pending state snapshot document
 */
public void activateState(Element elem) {
    super.activateState(elem);
    if (elem != null) {
        // 1. Search the element for any <jbo.counter> elements
        NodeList nl = elem.getElementsByTagName(COUNTER);
        if (nl != null) {
            // 2. If any found, loop over the nodes found
            for (int i=0, length = nl.getLength(); i < length; i++) {
                // 3. Get first child node of the <jbo.counter> element
                Node child = nl.item(i).getFirstChild();
                if (child != null) {
                    // 4. Set the counter value to the activated value
                    setCounterValue(new Integer(child.getNodeValue()).intValue()+1);
                    break;
                }
            }
        }
    }
}

/* Helper Methods */
private int getCounterValue() {
    String counterValue = (String)getSession().getUserData().get(COUNTER);
    return counterValue == null ? 0 : Integer.parseInt(counterValue);
}
private void setCounterValue(int i) {
    getSession().getUserData().put(COUNTER, Integer.toString(i));
}
private static final String COUNTER = "jbo.counter";
```

### 56.7.2 What Happens When You Passivate Custom Information

As the example in How to Passivate Custom User-Specific Information illustrates, when `activateState()` is overridden, the following steps are performed:

1. Search the element for any `jbo.counter` elements.
2. If any are found, loop over the nodes found in the node list.

3. Get first child node of the \texttt{jbo.counter} element.
   It should be a DOM Text node whose value is the string you saved when your \texttt{passivateState()} method above got called, representing the value of the \texttt{jbo.counter} attribute.

4. Set the counter value to the activated value from the snapshot.

When \texttt{passivateState()} is overridden, it performs the reverse job by doing the following:

1. Retrieve the value of the value to save.
2. Create an XML element to contain the value.
3. Create an XML text node to represent the value.
4. Append the text node as a child of the element.
5. Append the element to the parent element passed in.

---

\textbf{Note:}

The API's used to manipulate nodes in an XML document are provided by the Document Object Model (DOM) interfaces in the \texttt{org.w3c.dom} package. These are part of the Java API for XML Processing (JAXP). See the Javadoc for the \texttt{Node, Element, Text, Document, and NodeList} interfaces in this package for more details.

---

\textbf{56.7.3 What You May Need to Know About Activating Custom Information}

The \texttt{activateState()} method is called at the end of the activation process after the view objects have been activated. Most of the time this is where you want to place the application module state activation logic. However, if your application module activation logic needs to set up custom state information before the ADF state management facility activates the view objects (for example, you might need to write custom code to allow the view objects to internally reference custom values at execution time), then the \texttt{prepareForActivation()} method in the \texttt{ApplicationModuleImpl} class would be the right place because it fires at the beginning of the activation process.

\textbf{56.8 Managing the State of View Objects During Passivation}

By default, all view objects are marked as passivation-enabled, so their state will be saved. However, view objects that have transient attributes do not have those attributes passivated by default. You can change how a view object is passivated, and even which attributes are passivated, using the Tuning page of the view object overview editor.

\textbf{56.8.1 How to Manage the State of View Objects}

Each view object can be declaratively configured to be passivation-enabled or not. If a view object is not passivation enabled, then no information about it gets written in the application module passivation snapshot.
Performance Tip:

There is no need to passivate read-only view objects that are not used to display values in the UI but are simply used in re-entrant methods for calculation or derivation of values. This eliminates the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

Before you begin:

It may be helpful to have an understanding of passivation in view objects. For more information, see Managing the State of View Objects During Passivation.

To set the passivation state of a view object:

1. In the Applications window, double-click the view object for which you want to set the passivation state.
2. In the overview editor, click the General navigation tab.
3. On the General page, expand the Tuning section and select Passivate State to make sure the view object data is saved.
4. Optionally, you can select Including All Transient Attributes to passivate all transient attributes at this time, but see What You May Need to Know About Passivating Transient View Objects for additional information.

56.8.2 What You May Need to Know About Passivating View Objects

The activation mechanism is designed to return your view object to the state it was in when the last passivation occurred. To ensure that, Oracle ADF stores in the state snapshot the values of any bind variables that were used for the last query execution. These bind variables are in addition to those that are set on the row set at the time of passivation. The passivated state also stores the user-supplied WHERE clause on the view object related to the row set at the time of passivation.

56.8.3 How to Manage the State of Transient View Objects and Attributes

Because view objects are marked as passivated by default, a transient view object — one that contains only transient attributes — is marked to be passivation enabled, but only passivates its information related to the current row and other nontransactional state.

Performance Tip:

Transient view object attributes are not passivated by default. Due to their nature, they are usually intended to be read-only and are easily re-created. So, it often doesn’t make sense to passivate their values as part of the XML snapshot. This also avoids the performance overhead associated with passivation and activation and reduces the CPU usage needed to maintain the application module pool.

Before you begin:

It may be helpful to have an understanding of passivation in view objects. For more information, see Managing the State of View Objects During Passivation.
You will also need to perform the following task:

- Open the application in JDeveloper.

To individually set the passivation state for transient view object attributes:

1. In the Applications window, double-click the view object that contains the transient attributes for which you want to specify the passivation state.

2. In the overview editor, click the Attributes navigation tab.

3. On the Attributes page, select the transient attribute you want to passivate and click the Details tab.

4. In the Details page, select the Passivate checkbox.

### 56.8.4 What You May Need to Know About Passivating Transient View Objects

Passivating transient view object attributes is more costly resource-wise and performance-wise, because transactional functionality is usually managed on the entity object level. Since transient view objects are not based on an entity object, this means that all updates are managed in the view object row cache and not in the entity cache. Therefore, passivating transient view objects or transient view object attributes requires special runtime handling.

Usually passivation only saves the values that have been changed, but with transient view objects passivation has to save entire row. The row will include only the view object attributes marked for passivation.

**Note:**

The ADF passivation and activation logic will take care of restoring transient attribute values in the entity object and view object only as long as the entity object is in an unposted state. Once the user Saves their changes to the database, the entity object is posted to the database and in the next activation cycle, the view row is restored using the database query. Since the attribute is transient, its value will remain null. If you want your entity object or view object-based transient attribute values to survive failover, you need to define the transient attribute value using an expression and the expression should point to a getter method that can supply the value.

### 56.8.5 How to Use Transient View Objects to Store Session-level Global Variables

Using passivation, you can use a view object to store one or more global variables, each on a different transient attribute. When you mark a transient attribute as passivated, the ADF Business Components framework will remember the transient values across passivation and activation in high-throughput and failover scenarios. Therefore, it is an easy way to implement a session-level global value that is backed up by the state management mechanism, instead of the less-efficient HTTP Session replication. This also makes it easy to bind to controls in the UI if necessary.

There are two basic approaches to store values between invocations of different screens, one is controller-centric, and the other is model-centric.

To implement this task in the ADF Controller layer using the controller-centric approach involves storing and referencing values using attributes in the pageFlow scope. This approach might be appropriate if the global values do not need to be
referenced internally by any implementations of ADF Business Components. For more information about pageFlow scope, see What You May Need to Know About Memory Scope for Task Flows.

The model-centric approach involves creating a transient view object, which is conceptually equivalent to a nondatabase block in Oracle Forms.

Before you begin:

It may be helpful to have an understanding of passivation in view objects. For more information, see Managing the State of View Objects During Passivation.

You will also need to perform the following tasks:

1. Open the application in JDeveloper.
2. Create a new view object using the View Object wizard, as described in How to Create an Entity-Based View Object.
   a. On Page 1 of the wizard, select the option for Data Source: Programmatic.
   b. On Page 2, click New to define the transient attribute names and types the view object should contain.
   c. On Page 3, set the Updatable option to Always for each attribute.
   d. Click Finish and the newly created view object appears in the overview editor.
3. Add an instance of the view object with transient attributes to your application module's data model, as described in Adding Master-Detail View Object Instances to an Application Module.

To store session-level global variables using the model-centric approach:

1. Disable any entries from being performed in the view object:
   a. In the overview editor, on the General page, expand the Tuning section.
   b. In the Retrieve from the Database group, select the No Rows option.
2. Make sure data in the view object is not cleared out during a rollback operation. To implement this, you enable a custom Java class for the view object and override two rollback methods.
   a. In the overview editor, click the Java navigation tab, and click the Edit icon for the Java Classes section.
   b. In the Select Java Options dialog, select Generate View Object Class and click OK.
   c. In the overview editor, click the link next to View Object Class in the Java Classes section.
   d. From the main menu, choose Source > Override Methods.
   e. In the Override Methods dialog, select the beforeRollback() and afterRollback() methods to override, and click then OK.
   f. In both the beforeRollback() and afterRollback() methods, comment out the call to super in the Java code.
3. Create an empty row in the view object when a new user begins using the application module:

   a. In the Applications window, double-click the application module.

   b. Generate an application module Java class if you don't have one yet, as described in How to Generate a Custom Class for an Application Module.

   c. Override the `prepareSession()` method of the application module, as described in How to Override a Built-in Framework Method.

   d. After the call to `super.prepareSession()`, add code to create a new row in the transient view object and insert it into the view object.

Now you can bind read-only and updatable UI elements to the "global" view object attributes just as with any other view object using the Data Controls panel.
This chapter describes how ADF Business Components application module pools work and how you can tune application module pools to optimize application performance.

This chapter includes the following sections:

- About Application Module Pooling
- Setting Pool Configuration Parameters
- Initializing Database State and Pooling Considerations

57.1 About Application Module Pooling

An application module pool is a collection of application module runtime instances of the same type. To provision a number of users visiting it, the Fusion web application can be configured to provide one or more application module instances from the pool to service users at runtime.

Each application module instance in a pool is shared by multiple browser clients whose typical "think time" between submitting web pages allows optimizing the number of application module components to be effectively smaller than the total number of active users working on the system. For example, twenty users visiting the website from their browser might be able to be serviced by 5 or 10 application module instances instead of having as many application module instances as you have browser users. Therefore, not only can the pool service more users than the number of application modules available, but in addition the middle tier requires less memory to service this smaller set of application modules allowing ADF applications to scale further on limited hardware resources.

Through your design-time configuration, application modules can be used to support Fusion web application scenarios that are completely stateless, or they can be used to support a unit of work that spans multiple browser pages. As a performance optimization, when an instance of an application module is returned to the pool in "managed state" mode, the pool tracks session references to the application module. The application module instance is still in the pool and available for use, but it would prefer to be used by the same session that was using it the last time because maintaining this "session affinity" improves performance.

So, at any one moment in time, the instances of application modules in the pool are logically partitioned into three groups, reflecting their state:

- Checked into the pool and unconditionally available for use
- Checked into the pool and available for use, but referenced for session affinity reuse by an active user session
• Checked out of the pool and unavailable, inasmuch as it's currently in use (at that very moment) by some thread in the web container

Understanding what happens behind the scenes is essential to make the most efficient use of application module pooling. For details about session state management of application modules, see Managing When Passivation and Activation Occurs.

For details about the configuration parameters that can be set at design time to affect the behavior of the application module pool, see What You May Need to Know About Application Module Pool Configuration Parameters.

57.1.1 Application Module Pools

Application Module components can be used at runtime in two ways:

• As an application module the client accesses directly

• As a reusable component aggregated (or "nested") inside of another application module instance

When a client accesses it directly, an application module is called a root application module. Clients access nested application modules indirectly as a part of their containing application module instance. It’s possible, but not common, to use the same application module at runtime in both ways. The important point is that ADF Business Components only creates an application module pool for a root application module.

The basic rule is that one application module pool is created for each root application module used by a Fusion web application in each Java VM where a root application module of that type is used by the ADF Controller layer. For advanced topics related to the number of application module pools your application may need, see Deployment Environment Scenarios and Pooling.

57.1.2 Deployment Environment Scenarios and Pooling

The number of pools and the type of pools that your application will utilize will depend upon how the target platform is configured. For example, will there be more than one Java Virtual Machine (JVM) available to service the web requests coming from your application users and will there be more than one Oracle WebLogic Server domain? To understand how many pools of which kinds are created for an application in both a single-JVM scenario and a multiple-JVM runtime scenario, review the following assumptions:

• Your Fusion web application makes use of two application modules HRModule and PayablesModule.

• You have a CommonLOVModule containing a set of commonly used view objects to support list of values in your application, and that both HRModule and PayablesModule aggregate a nested instance of CommonLOVModule to access the common LOV view objects it contains.

• You have configured both HRModule and PayablesModule to use the same JDeveloper connection definition named appuser.
57.1.2.1 Single Oracle WebLogic Server Domain, Single Oracle WebLogic Server Instance, Single JVM

If you deploy this application to a single Oracle WebLogic Server domain, configured with a single Oracle WebLogic Server instance, there is only a single Java VM available to service the web requests coming from your application users.

Assuming that all the users are making use of web pages that access both the HRModule and the PayablesModule, this will give:

- One application module pool for the HRModule root application module
- One application module pool for the PayablesModule root application module

This gives a total of two application module pools in this single Java VM.

**Note:**
There is no separate application module pool for the nested instances of the reusable CommonLOVModule. Instances of CommonLOVModule are wrapped by instances of HRModule and PayablesModule in their respective application module pools.

57.1.2.2 Multiple Oracle WebLogic Server Domains, Multiple Oracle WebLogic Server Instance, Multiple JVMs

Next consider a deployment environment involving multiple Java VMs. Assume that you have configured four different physical machines as two Oracle WebLogic Server domains, with a hardware load-balancer in front. On these four machines, each Oracle WebLogic Server instance will have a single JVM. As users of your application access the application, their requests are shared across these two Oracle WebLogic Server domains, and within each domain, across the two JVMs that its Oracle WebLogic Server instances have available.

Again assuming that all the users are making use of web pages that access both the HRModule and the PayablesModule, this will give:

- Four application module pools for HRModule, one in each of four JVMs.
  
  \((1 \text{HRModule root application module}) \times (2 \text{Oracle WebLogic Server domains}) \times (2 \text{Oracle WebLogic Server JVMs each})\)

- Four application module pools for PayablesModule, one in each of four JVMs.
  
  \((1 \text{PayablesModule root application module}) \times (2 \text{Oracle WebLogic Server domains}) \times (2 \text{Oracle WebLogic Server JVMs each})\)

This gives a total of eight application module pools spread across four JVMs.

As you begin to explore the configuration parameters for the application module pools in What You May Need to Know About Application Module Pool Configuration Parameters, keep in mind that the parameters apply to a given application module pool for a given application module in a single JVM.

As the load balancing spreads user requests across the multiple JVMs where Oracle ADF is running, each individual application module pool in each JVM will have to support one \(n^{th}\) of the user load — where \(n\) is the number of JVMs available to service those user requests. The appropriate values of the application module pools need to be
set with the number of Java VMs in mind. The basic approach is to base sizing parameters on load testing and the results of the application module pooling statistics, then divide that total number by the number of pools you will have based on your use of multiple application server domains and multiple Oracle WebLogic Server instances. For example, if you decide to set the minimum number of application modules in the pool to ten and you end up with five pools due to having five Oracle WebLogic Server instances servicing this application, then you would want to configure the parameter to 2 (ten divided by five), not 10 (which would only serve a given application module in a single JVM).

For details about available sizing parameters, see Pool Sizing Parameters.

57.2 Setting Pool Configuration Parameters

You control the runtime behavior of an application module pool by setting appropriate configuration parameters. You can set these declaratively in an application module configuration, supply them as Java System parameters, or set them programmatically at runtime.

57.2.1 How to Set Configuration Properties Declaratively

You use the Database and Scalability tab of the overview editor for application module configurations shown in Figure 57-1 for viewing and setting runtime configuration properties of individual application modules.
Before you begin:

It may be helpful to have an understanding of application module pooling. For more information, see Setting Pool Configuration Parameters.

Familiarize yourself with the application module configuration parameters. For more information about configuration parameters for application module pool tuning, see What You May Need to Know About Application Module Pool Configuration Parameters.
For best practice guidelines that may help you to tune the Fusion web application for an expected level of usage, see the “Tuning Oracle Application Development Framework” chapter of Tuning Performance.

Note that if your application defines a JDBC URL connection type (legacy only), refer to the 11g release version of this guide to obtain documentation on the ADF database connection pool configuration parameters.

To edit your application module’s pooling configuration:

1. In the Applications window, double-click the application module.
2. In the overview editor, click the Configurations navigation tab.
3. In the Configurations page, click the configuration hyperlink for the configuration you want to edit.
4. In the overview editor for application module configurations, click the Database and Scalability tab and edit the desired runtime properties and click OK to save the changes for your configuration.

### 57.2.2 What Happens When You Set Configuration Properties Declaratively

The values that you supply through the overview editor for application module configurations are saved in an XML file named bc4j.xcfg in the ./common subdirectory relative to the application module’s XML definition. All of the configurations for all of the application modules in a single Java package are saved in that same file. Typically, you do not modify the bc4j.xcfg file directly and use the overview editor to change configuration settings for specific application modules. To display the application module configuration overview editor, double-click the application module in the Applications window and, in the overview editor, select the Configurations navigation tab. Then, in the Configurations page of the overview editor, click the configuration hyperlink.

For example, if you look at the overview editor for application module configurations for the BackOfficeAppModule application module in the SummitADF application (on the bc4j.xcfg file in the ./src/oracle/summit/model/services/common directory), you will see the two named configurations for the BackOfficeAppModule application module. In this case, as the following example shows, the BackOfficeAppModuleLocal and the BackOfficeAppModuleShared configurations specify JDBC URL connections for use by the Oracle ADF Model Tester. The connection details for the JDBC connections appear in the connections.xml file located in the ./adf/META-INF subdirectory relative to the project directory.

```xml
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
  ...
  <AppModuleConfigBag
    ApplicationName="oracle.summit.model.services.BackOfficeAppModule">
    <AppModuleConfig
      name="BackOfficeAppModuleLocal"
      jbo.project="oracle.summit.model.Model"
      ApplicationName="oracle.summit.model.services.BackOfficeAppModule"
      DeployPlatform="LOCAL" JDBCName="summit_adf">
      <Database jbo.TypeMapEntries="Java"/>
      <Security
        AppModuleJndiName="oracle.summit.model.services.BackOfficeAppModule"/>
    </AppModuleConfig>
    <AppModuleConfig
      name="BackOfficeAppModuleShared"
      jbo.project="oracle.summit.model.Model"
```
Note that attributes of child elements of the `<AppModuleConfig>` tag have names beginning with `jbo` that match the names of their ADF Business Components properties (for example, the `<AM-Pooling>` tag defines the attribute `jbo.ampool.maxpoolsize` that corresponds to the property `jbo.ampool.maxpoolsize`). It's also important to understand that if a property is currently set to its runtime `default` value in the application module configurations editor, then JDeveloper does `not` write the entry to the `bc4j.xcfg` file.

### 57.2.3 How to Programmatically Set Configuration Properties

When your application requires control over application module configuration properties at runtime, you can dynamically set these properties using ADF Business Components API. For example, in a typical ADF application, your application module may configure a static JDBC data source. However, when the application needs to display data, depending upon the user, from various databases, you might set the data source name and application module pool parameters at runtime.

You can set configuration properties programmatically by creating a Java class that implements the `EnvInfoProvider` interface in the `oracle.jbo.common.ampool` package. In your class, you override the `getInfo()` method and call `put()` to put values into the environment Hashtable passed in as shown in the following example.

```java
package devguide.advanced.customenv.view;
import java.util.Hashtable;
import oracle.jbo.common.ampool.EnvInfoProvider;
/**
 * Custom EnvInfoProvider implementation to set
 * environment properties programmatically
 */
public class CustomEnvInfoProvider implements EnvInfoProvider {
    /**
     * Overridden framework method to set custom values in the
     * environment hashtable.
     * @param string - ignore
     * @param environment Hashtable of config parameters
     * @return null - not used
     */
    public Object getInfo(String string, Object environment) {
        Hashtable envHashtable = (Hashtable)environment;
        envHashtable.put("some.property.name","some value");
        return null;
    }
    /* Required to implement EnvInfoProvider */
    public void modifyInitialContext(Object object) {} 
    /* Required to implement EnvInfoProvider */
    public int getNumOfRetries() {return 0;}
}
```
When creating an application module for a stateless or command-line-client, with the `createRootApplicationModule()` method of the `Configuration` class, you can pass the custom `EnvInfoProvider` as the optional second argument. In order to use a custom `EnvInfoProvider` in an ADF web-based application, you need to implement a custom session cookie factory class as shown in the following example. To use your custom session cookie factory, set the `jbo.ampool.sessioncookiefactoryclass` configuration property to the fully qualified name of your custom session cookie factory class.

```java
package devguide.advanced.customenv.view;
import java.util.Properties;
import oracle.jbo.common.ampool.ApplicationPool;
import oracle.jbo.common.ampool.EnvInfoProvider;
import oracle.jbo.common.ampool.SessionCookie;
import oracle.jbo.http.HttpSessionCookieFactory;
/**
 * Example of custom http session cookie factory
 * to install a custom EnvInfoProvider implementation
 * for an ADF web-based application.
 */
public class CustomHttpSessionCookieFactory
    extends HttpSessionCookieFactory {
    public SessionCookie createSessionCookie(String appId,
        String sessionId,
        ApplicationPool pool,
        Properties props) {
        SessionCookie cookie =
            super.createSessionCookie(appId, sessionId, pool, props);
        EnvInfoProvider envInfoProv = new CustomEnvInfoProvider();
        cookie.setEnvInfoProvider(envInfoProv);
        return cookie;
    }
}
```

### 57.2.4 What You May Need to Know About Configuration Property Scopes

Each runtime configuration property used by ADF Business Components has a scope. The scope of each property indicates when the property's value is evaluated and whether its value is effectively shared (i.e. static) in a single Java VM, or not. The ADF Business Components `PropertyManager` class is the registry of all supported properties. It defines the property names, their default values, and their scope. This class contains a `main()` method so that you can run the class from the command line to see a list of all the configuration property information.

Assuming `JDEVHOME` is the JDeveloper installation directory, to see this list of settings for reference, do the following:

```
$ java -cp JDEVHOME/BC4J/lib/bc4jmt.jar oracle.jbo.common.PropertyManager
```

Issuing this command will send all of the ADF Business Components configuration properties to the console. It also lists a handy reference about the different levels at which you can set configuration property values and remind you of the precedence order these levels have:

```
Properties loaded from following sources, in order:
1. Client environment [Provided programatically
   or declaratively in bc4j.xcfg]
2. Applet tags
3. -D flags (appear in System.properties)
```
You’ll see each property is listed with one of the following scopes:

- **MetaObjectManager**
  Properties at this scope are initialized once per Java VM when the ADF PropertyManager is first initialized.

- **SessionImpl**
  Properties at this scope are initialized once per invocation of ApplicationModule.prepareSession().

- **Configuration**
  Properties at this scope are initialized when the application module pool is first created and the application module's configuration is read the first time.

- **Diagnostic**
  Properties at this scope are specific to the built-in ADF Business Components diagnostic facility.

At each of these scopes, the layered value resolution described above is performed when the properties are initialized. Whenever property values are initialized, if you have specified them in the Client Environment (level 1 in the resolution order) the values will take precedence over values specified as System parameters (level 3 in the resolution order).

The Client Environment is a hashtable of name/value pairs that you can either programmatically populate, or which will be automatically populated for you by the Configuration object when loaded, with the name/value pairs it contains in its entry in the bc4j.xcfg file. The implication of this is that for any properties scoped at MetaObjectManager level, the most reliable way to ensure that all of your application modules use the same default value for those properties is to do both of the following:

1. Make sure the property value does not appear in any of your application module's bc4j.xcfg file configuration name/value pair entries.
2. Set the property value using a Java system property in your runtime environment.

If, instead, you leave any MetaObjectManager-scoped properties in your bc4j.xcfg files, you will have the undesirable behavior that they will take on the value specified in the configuration of the first application module whose pool gets created after the Java VM starts up.

### 57.2.5 What You May Need to Know About Application Module Pool Configuration Parameters

The application module pool configuration parameters fall into three logical categories relating to pool behavior, pool sizing, and pool cleanup behavior. By default Fusion web applications enable application module pooling.
57.2.5.1 Pool Behavior Parameters

The application module defines configuration parameters that affect the behavior of
the application module pool and whether application module instances holds onto
JDBC connection that they obtain from the connection pool after an instance is
removed from the application module pool.

How ADF application module pools use the database connection pool depends on the
setting of the Disconnect Application Module Upon Release configuration parameter
jbo.doconnectionpooling. As shown in Figure 57-1, by default the setting is
disabled and the parameter has the setting jbo.doconnectionpooling=false.

---

Note:

The setting jbo.doconnectionpooling=false does not mean that there is
no database connection pooling happening. What it means is that the
application module is not disconnected from its JDBC connection upon check
in back to the application module pool.

---

When an application module instance is created in the application module pool it
acquires a JDBC connection. By default, ADF favors maintaining session affinity so
that across the request of a single user, ADF will try and reuse the same application
module instance (including its associated memory and JDBC connection and state),
with the goal of speeding up performance for such users. The default setting of
jbo.doconnectionpooling=false enables this behavior which enforces
application module instances keep their JDBC PreparedStatement objects cached
and reusable across subsequent requests by clients.

However, as the number of users who access the Fusion web application increases, so
does the memory requirement on the server to hold onto the JDBC connection,
prepare statement, and result sets. When the application module pool is configured to
support several thousand users, the demands of not releasing JDBC connections after
each request can place demands on server load with a fraction of the supported
managed user sessions. This situation is particularly notable in a deployment
environment configured to use database drivers that optimize performance over
memory consumption, as has been the case for Oracle JDBC drivers since Oracle
Database 10g.

To avoid the situation where server memory can be rapidly consumed by the JDBC
driver, you can override the default application module instance connection behavior
by setting jbo.doconnectionpooling=true, then each time a user session finishes
using an application module (typically at the end of each HTTP request), the
application module instance disassociates itself with the JDBC connection it was using
on that request and it returns the connection to the JDBC connection pool. The next
time that application module instance is used by a user session, it will reacquire a
JDBC connection from the JDBC connection pool and use it for the span of time that
application module is checked out of the application module pool (again, typically the
span of one HTTP request). Since the application module instance “unplugs” itself
from the JDBC connection object used to create each PreparedStatement, in this
situation it follows that the prepareSession() method will fire each time the
application module is checked out of the pool to reinitialize the database state. So,
when releasing JDBC connections is enabled for sessions, the trade-off is slightly more
JDBC overhead setup each time, in return for holding onto a smaller number of overall database connections.

The key difference is seen when many application module pools are all using the same underlying database user for their application connection.

- If 50 different application module pools each have even just a single application module instance in them, with `jbo.doconnectionpooling=false` there will be 50 JDBC application connections in use. If the application module pooling size parameters are set such that the application module pools are allowed to shrink to 0 instances after an appropriate instance idle timeout by setting the **Minimum Available Size** configuration parameter `jbo.ampool.minavailablesize=0`, then when the application module is removed from its pool, it will put back the connection it's holding onto. This situation is optimal when the number of managed application module instances remains low, outside of peak demand times or when the application needs to support a low number of simultaneous users.

- In contrast, if 50 different application module pools each have a single application module instance and `jbo.doconnectionpooling=true`, then the amount of JDBC connections in use will depend on how many of those application modules are *simultaneously* being used by different clients. If an application module instance is in the pool and is not currently being used by a user session, then with `jbo.doconnectionpooling=true` it will have released its JDBC connection back to the connection pool and while the application module instance is sitting there waiting for either another user to need it again, or to eventually be cleaned up by the application module pool monitor, it will not be "hanging on" to a JDBC connection. This situation is optimal in ensuring the scalability of the Fusion web application during peak demand times or when the number of simultaneous users is expected to increase.

When you set `jbo.doconnectionpooling` to `true`, the default setting 1 for the **Transaction Disconnect Level** configuration parameter `jbo.txn.disconnect_level` ensures that all application modules, view objects and row sets remain in memory and stay valid after their corresponding references to JDBC connections are dropped. This configuration reduces the memory requirement associated with this situation where application module passivation is normally performed upon release. Instead, upon activation, the framework only needs to reexecute and synchronize the cursor positions.

Alternatively, you may be able to achieve a balance between conserving JDBC connections and holding onto connections by configuring the **Connection Threshold** configuration parameter `jbo.ampool.connection_threshold`. This parameter specifies the maximum number of connections that application modules in all application module pools combined may hold onto without releasing back to the connection pool during application module pool cleanup. Note that setting the `jbo.ampool.connection_threshold` parameter to a maximum number of connections (greater than 0) implies disconnecting application modules during pool cleanup is desired and therefore the configuration parameter `jbo.doconnectionpooling` must not be enabled. For more details about how the `jbo.ampool.connection_threshold` parameter affects application module pooling, see What You May Need to Know About Optimizing Application Module Pooling.

### 57.2.5.2 Pool Sizing Parameters

The application module defines configuration parameters that affect the sizing of the application module pool. When the pool monitor performs one of its resource cleanup
passes, it will try to bring the number of application module instances into the range specified by the maximum and minimum available size parameters.

When the pool monitor cannot reduce the pool size below the maximum size by removing unused and idle application module instance, it will then remove active instances that have not timed out and passivate the state of these active application modules. The **Referenced Pool Size** configuration parameter `jbo.recyclethreshold` determines how many active application modules will remain in the pool monitor when passivation occurs. By default, the threshold over which the pool monitor will begin passivating is 10 application module instances.

You can use the **Maximum Available Pool Size** configuration parameter `jbo.ampool.maxavailablesize` to specify the upper range of the pool size after resource cleanup by the pool monitor. Typically, you override the default maximum available size 25 based on the number of concurrent users and how frequently the users need to access the services of the application module. However, when server memory is not the limiting factor for application performance, the maximum available size may be set to an arbitrarily large value to minimize the affect of passivation and activation of application module instances that are still tied to active user sessions.

**Note:**

Specifying a sufficiently large maximum pool size is especially important when configuring pool cleanup not to reclaim unused application module instances and to allow idle times of 30 minutes for a typical HTTP session timeout. For more information about configuring pool cleanup, see **Pool Behavior Parameters**.

Similarly, you can use the **Minimum Available Pool Size** configuration parameter `jbo.ampool.minavailablesize` to specify the lower range of the pool size, when the default of 5 instances is not sufficient to ensure a baseline of available application module instance. Typically, consider setting this value equal to the number of concurrent users at non-peak usage. Setting this value too low results in needless instantiation of application module instances that can affect performance.

### 57.2.5.3 Pool Cleanup Parameters

The application module defines configuration parameters that affect how resources are reclaimed when the pool monitor does one of its resource cleanup passes.

A single application module pool monitor per Java VM runs in a background thread and wakes up to scan through the pool to perform cleanup at the interval of 600000 milliseconds (10 minutes) by default. To change the default Pool Polling Interval, you can configure the **Pool Polling Interval** parameter `jbo.ampool.monitorsleepinterval`.

The pool monitor uses the following two, independent strategies to identify which application module instances are candidates to be removed from the pool and reclaimed as a potential new resource.

1. The application module pool monitor removes application module instances from the pool that have not been used for more than 3600000 milliseconds (which is the default value and is exactly one hour). These unused application module instances will be reclaimed regardless of the minimum available size configured for the pool. To override the maximum time to live for an application module, you can set the **Maximum Instance Time to Live** configuration parameter.
jbo.ampool.timetolive. However, for most Fusion web applications, you will not need to reclaim unused application module instance and can set this parameter value to -1.

2. The application module pool monitor removes application module instances that have remained idle for 600000 milliseconds (which is the default value and is exactly 10 minutes). This cleanup stops when the number of instances in the pool reaches the minimum available size. You can override the idle timeout for application module instances using the Idle Instance Timeout configuration parameter jbo.ampool.maxinactiveage when you want to allow idle user sessions of more than 10 minutes.

Best Practice:

When you specify the length of time between application module pool cleanup passes, set the same value for Pool Polling Interval configuration parameter jbo.ampool.monitorsleepinterval for all application modules. Since there is only a single application monitor pool monitor per Java VM, the value that will effectively be used for the application module pool monitor polling interval will be the value found in the application module configuration read by the first application module pool that gets created. Setting all application modules to use the same value ensures that this value is set in a predictable way.

57.2.6 What You May Need to Know About Optimizing Application Module Pooling

You may be able to achieve a balance between conserving JDBC connections and holding onto connections by configuring the Connection Threshold configuration parameter jbo.ampool.connection_threshold. This parameter specifies the maximum number of connections that application modules in all application module pools combined may hold onto without releasing back to the connection pool upon the next pool cleanup cycle.

When the Connection Threshold parameter jbo.ampool.connection_threshold is enabled (value greater than 0), application module connections are released during pool cleanup, not during checkin. The cleanup monitor makes a best effort to disconnect least recently-used application modules until the total number of JDBC connections falls below the specified threshold limit. Since enabling the jbo.ampool.connection_threshold parameter changes when application module pool cleanup is performed, this implies setting the parameter jbo.ampool.connection_threshold=true is not compatible.

Note:

When configuring a threshold value for disconnecting application modules during the pool cleanup cycle, be sure to disable jbo.doconnectionpoolling so the value is false (default). The Connection Threshold parameter is not compatible with the setting jbo.doconnectionpoolling=true since this setting causes JDBC connections to release back to the connection pool upon checkin of the application module, and the setting works in combination with the jbo.txn.disconnect_level parameter to ensure business components
remain in memory. For more information about the
jbo.doconnectionpooling parameter, see Pool Behavior Parameters.

For example, assume the **Connection Threshold** parameter is set to 10 for two
application module pools, where application module pool 1 has seven application
modules and pool 2 has eight application modules for a total of 15 JDBC connections.
When the application module pool cleanup monitor runs, the monitor will make a best
effort to reclaim five connections (15 connection resources - 10 connection threshold).
The monitor disconnects application modules proportional to the total number of
connected application modules for each pool. In this case, one third of the application
modules connections (5/15) from each pool will be disconnected. So pool 1 will loose
two connections (7/3) and pool 2 will release three connections (8/3), where the
fraction of the pool size will be rounded up.

The cleanup monitor makes a best effort to disconnect application modules until the
connected resource number falls below the specified limit but note that it may not be
able to do so if there are not enough application modules in an available state. To
ensure JDBC connections are released efficiently, you can configure the **Pool Polling
Interval** parameter jbo.ampool.monitorsleepinterval to shorten the monitor
sleep period.

### 57.3 Initializing Database State and Pooling Considerations

Sometimes you may need to invoke stored procedures to initialize database state
related to the current user's session. The correct place to perform this initialization is in
an overridden *prepareSession()* method of your application module.

#### 57.3.1 How to Set Database State Per User

The Fusion web application can set database state on a per-user basis. You typically
create a database CONTEXT namespace, associate a PL/SQL procedure with it, and
then use the *SYS_CONTEXT()* SQL function to reference values from the context.

For example, you can use the PL/SQL package to set and get a package-level variable
that holds the name of the currently authenticated Fusion web application user as
shown in the following example.

```sql
create or replace package context_pkg as
    procedure set_app_user_name(username varchar2);
    function app_user_name return varchar2;
end context_pkg;
```

Then your application can define the WHERE clause of a view object to reference the
`context_pkg.app_user_name` function and query the per-user state.

To set the database state, the application module framework extension class
(*AppModuleImpl.java*) defines a *callStoredProcedure()* helper method
similar to the ones in *How to Invoke Stored Procedure with Only IN Arguments*. The
custom application module class then extends this framework extension class and
defines the *setCurrentUserInPLSQLPackage()* helper method shown in
the following example. The helper method uses the *callStoredProcedure()* method
to invoke the `context_pkg.set_app_user_name()` stored procedure, passing the
value of the currently authenticated user as a parameter value.

```java
// In CustomAppModuleImpl.java
public void setCurrentUserInPLSQLPackage() {
    String user = getUserPrincipalName();
```
With this helper method in place, the custom application module class then overrides the `prepareSession()` method as shown in the following example.

```java
// In CustomAppModuleImpl.java
protected void prepareSession(Session session) {
    super.prepareSession(session);
    getLoggedInUser().retrieveUserInfoForAuthenticatedUser();
    setUserIdIntoUserDataHashtable();
    setCurrentUserInPLSQLPackage();
}
```
This part provides information that developers may need to know when building Fusion web applications with Oracle ADF.

Specifically, it contains the following appendixes:

- Oracle ADF XML Files
- Oracle ADF Binding Properties
- ADF Security Permission Grants
- Most Commonly Used ADF Business Components Methods
- ADF Business Components Java EE Design Pattern Catalog
- ADF Equivalents of Common Oracle Forms Triggers
- Performing Common Oracle Forms Tasks in Oracle ADF
- Deploying ADF Applications to GlassFish
This appendix provides a reference for the Oracle ADF metadata files that you create in your data model and user interface projects. You may use this information when you want to edit the contents of the metadata these files define.

This appendix includes the following sections:

- About ADF Metadata Files
- ADF File Overview Diagram
- ADF File Syntax Diagram
- adfm.xml
- modelProjectName.jpx
- bc4j.xcfg
- DataBindings.cpx
- pageNamePageDef.xml
- adfc-config.xml
- task-flow-definition.xml
- adf-config.xml
- adf-settings.xml
- web.xml
- logging.xml

**A.1 About ADF Metadata Files**

Metadata files in a Fusion web application are structured XML files used by the application to:

- Specify the parameters, methods, and return values available to your application's Oracle ADF data control usages
- Create objects in the Oracle ADF binding context and define the runtime behavior of those objects
- Define configuration information about the UI components in JSF and ADF Faces
- Define application configuration information for the Java EE application server
In the case of ADF bindings, you can use the binding-specific editors to customize the runtime properties of the binding objects. You can open a binding editor when you display the Structure window for a page definition file and choose Go to Properties from the context menu.

Additionally, you can view and edit the contents of any metadata file in JDeveloper’s XML editor. The easiest way to work with these files is through the Structure window and Properties window. In the Structure window, you can choose an element and in the Properties window, you can define attribute values for the element, often by choosing among dropdown menu choices. Use this appendix to learn the choices you can choose in the case of the Oracle ADF-specific elements.

**A.2 ADF File Overview Diagram**

The relationship between the Oracle ADF metadata files defines dependencies between the model data and the user interface projects. The dependencies are defined as file references within XML elements of the files.

Figure A-1 illustrates the hierarchical relationship of the XML metadata files that you might work with in a Fusion web application that uses an ADF Business Components application module as a service interface to JSF web pages.

**Figure A-1  Oracle ADF File Hierarchy Overview for the Fusion Web Application**

A.2.1 Oracle ADF Data Control Files

In a Fusion web application containing ADF Business Components, the data control implementation files are contained within the application. The application module and view object XML component descriptor files provide the references for the data
control. These files, with the bc4j.xcfg file, provide the necessary information for the data control.

An application that uses ADF Business Components in one project and a non-ADF Business Components data control in another project may have a DataControls.dcx file, as well as supporting <sessionbeanname>.xml and <beanname>.xml files.

A.2.2 Oracle ADF Data Binding Files

These standard XML configuration files for a Fusion web application appear in your user interface project:

- adfm.xml: This file lists the DataBindings.cpx file that is available in the current project.
  See adfm.xml for more information.

- DataBindings.cpx: This file contains the page map, page definitions references, and data control references. The file is created the first time you create a data binding for a UI component (either from the Structure window or from the Data Controls panel). The DataBindings.cpx file defines the Oracle ADF binding context for the entire application. The binding context provides access to the bindings and data controls across the entire application. The DataBindings.cpx file also contains references to the <pagename>PageDef.xml files that define the metadata for the Oracle ADF bindings in each web page.
  For more information, see DataBindings.cpx.

- <pagename>PageDef.xml: This is the page definition XML file. It associates web page UI components with data, or data controls. JDeveloper creates this file each time you design a new web page using the Data Controls panel or Structure window. These XML files contain the metadata used to create the bindings that populate the data in the web page's UI components. For every web page that refers to an ADF binding, there must be a corresponding page definition file with binding definitions.
  For more information, see pageNamePageDef.xml.

A.2.3 Web Configuration Files

These standard XML configuration files required for a JSF application appear in your user interface project:

- web.xml: Part of the application's configuration is determined by the contents of its Java EE application deployment descriptor, web.xml. The web.xml file defines everything about your application that a server needs to know. The file plays a role in configuring the Oracle ADF data binding by setting up the ADFBindingFilter. Additional runtime settings include servlet runtime and initialization parameters, custom tag library location, and security settings.
  For more information about ADF data binding and JSF configuration options, see web.xml.

  An ADF Faces application typically uses its own set of configuration files in addition to web.xml. For more information, see the "Configuration in trinidad-config.xml" section in Developing Web User Interfaces with Oracle ADF Faces.

- adfc-config.xml: The configuration file for an ADF unbounded task flow. The configuration file contains metadata about the activities and control flows
contained in the unbounded task flow. The default name for this file is adfc-config.xml, but an end user can change the name.

For more information, see adfc-config.xml.

- task-flow-definition.xml: The configuration file for an ADF bounded task flow. The configuration file contains metadata about the activities and control flows contained in the bounded task flow. The default name for this file can be task-flow-definition.xml or whatever an end user specifies in the Create ADF Task Flow dialog. The same application can contain multiple task flow definition files.

For more information, see task-flow-definition.xml.

A.3 ADF File Syntax Diagram

Figure A-2 illustrates the hierarchical relationship of the XML metadata files that you might work with in a web application that uses an ADF application module as a service interface to ADF Business Components. At runtime, the objects created from these files interact in this sequence:

1. When the first request for an ADF databound web page occurs, the servlet registers the Oracle ADF servlet filter ADFBindingFilter named in the web.xml file.

2. The binding filter creates an empty binding context.

3. When a page is rendered, the binding filter asks the binding context to load a corresponding PageDef.xml for the page.

4. The binding context creates the binding container by loading the <page> file as referenced by the <pagemap> element in the DataBindings.cpx file.

5. The adfm.xml file loads the DataBindings.cpx contents and finds the right PageDef.xml based on the <pagemap> element reference to the <pageDefinitionUsage> element.

6. The binding container's prepareModel phase prepares and refreshes all relevant executables (most are marked deferred by default).

7. An iterator binding gets executed by referencing the named method on the data control found through the data control factory named in the case of ADF Business Components in the bc4j.xcfg file.

8. The binding container also creates the bindings defined in the <bindings> section of the pagenamePageDef.xml file for the mapped web page.

9. The web page references to ADF bindings through EL using the expression #{bindings} are resolved by accessing the binding container of the page.

10. The page pulls the available data from the bindings in the binding container.
A.4 adfm.xml

The adfm.xml file contains the classpath-relative paths for the .cpx, .dcx, .jpx, and .xcfg files in each design time project that is included in the runtime deployed application. The adfm.xml file operates as a dynamically maintained "Registry of Registries" that is used to quickly find all .cpx, .dcx, .jpx, and .xcfg files (which are themselves registries of metadata).

The file registry is used extensively by the ADF Library resource catalog browsing implementations, by ADF Model layer design time, and at runtime during merge and discovery.

When a developer creates a binding on a page, JDeveloper adds metadata files (for example, page definitions) in the project source tree. The adfm.xml file then notes the location of each.

When a project is built, the adfm.xml file is put in project-root/adfmsrc/META-INF/adfm.xml. The project-level archive deployment profiles locate the file at META-INF/adfm.xml.

At runtime, the application classpath is scanned to build the list of .cpx files that comprise the application. The application then loads each .cpx as needed to create the...
binding context. For details about ADF Model layer usage, see What Happens When You Use the Data Controls Panel.

Four types of sub registries are recorded by the adfm.xml file:

- DataBindingRegistry (.cpx)
- DataControlRegistry (.dcx)
- BusinessComponentServiceRegistry (.xcfg)
- BusinessComponentProjectRegistry (.jpx)

A.5 modelProjectName.jpx

The .jpx file contains configuration information that JDeveloper uses in the design time to allow you to create the data model project with ADF Business Components. It also contains metadata that defines how a shared application module is used at runtime. Because the shared application module can be accessed by any data model project in the same Fusion web application, JDeveloper maintains the scope of the shared application module in the ADF Business Components project configuration file.

This file is saved in the src directory of the project. For example, the Summit sample application for Oracle ADF stores the Model.jpx file in the .src/oracle/summit/model subdirectory of the Model project.

The following example displays a sample default .jpx file.

```xml
<jboProject
 xmlns="http://xmlns.oracle.com/bc4j"
 Name="Model"
 Version="12.1.2.66.11"
 SeparateXMLFiles="true"
 PackageName="oracle.summit.model">
 <DesignTime>
   <Attr Name="_appModuleNames2" Value="oracle.summit.model.services.BackOfficeAppModule"/>
   <Attr Name="_jprName" Value="../../../../Model.jpr"/>
   <Attr Name="_appModuleNames1" Value="oracle.summit.model.services.CustomerSelfServiceAppModule"/>
   <Attr Name="_appModuleNames0" Value="oracle.summit.model.services.SummitAppModule"/>
   <Attr Name="_jbo.TypeMapEntries" Value="Java"/>
   <Attr Name="_NamedConnection" Value="summit_adf"/>
 </DesignTime>
 <Containee
   Name="assoc"
   PackageName="oracle.summit.model.entities.assoc"
   ObjectType="JboPackage">
   <DesignTime>
     <Attr Name="_AS" Value="true"/>
   </DesignTime>
 </Containee>
 <Containee
   Name="entities"
   PackageName="oracle.summit.model.entities"
   ObjectType="JboPackage">
   <DesignTime>
     <Attr Name="_EO" Value="true"/>
   </DesignTime>
 </Containee>
</jboProject>
```
The `bc4j.xcfg` file contains metadata information about application module names, the database connection used by the application module, and the runtime parameters the user has configured for the application module.

The `bc4j.xcfg` file is located in the `.common` subdirectory relative to the application module’s XML component definition. All of the configurations for all of the application modules in a single Java package are saved in that same file. For example, if you look at the `bc4j.xcfg` file in the `/Model/src/oracle/summit/model/services/common` directory of the Summit ADF sample application's `Model` project, you see the configurations for its application modules. For details about editing the configurations, see How to Change Your Application Module's Runtime Configuration and Setting Pool Configuration Parameters.

Example A-1 displays a sample `bc4j.xcfg` file from the Summit ADF sample application.

**Example A-1   Sample bc4j.xcfg File**

```xml
<?xml version = '1.0' encoding = 'UTF-8'?>
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
  < AppModuleConfigBag
    ApplicationName="oracle.summit.model.services.SummitAppModule">
    < AppModuleConfig name="SummitAppModuleLocal" DeployPlatform="LOCAL" >
    </ AppModuleConfig>
  </ AppModuleConfigBag>
</BC4JConfig>
```
A-8 Developing Fusion Web Applications with Oracle Application Development Framework
The `DataBindings.cpx` file is created in the user interface project the first time you drop a data control usage onto a web page in the visual editor. The `DataBindings.cpx` file defines the Oracle ADF binding context for the entire application and provides the metadata from which the Oracle ADF binding objects are created at runtime. It is used extensively by the ADF Library resource catalog browsing implementations, and also by the `.cpx` and `.dcx` design time and runtime merge and discovery. When you insert a databound UI component into your document, the page will contain binding expressions that access the Oracle ADF binding objects at runtime.

The `DataBindings.cpx` file appears in the `/src` directory of the user interface project. When you double-click the file node, the binding context description appears in the XML source editor. (To edit the binding context parameters, use the Properties window and choose the desired parameter in the Structure window.)

### A.7.1 DataBindings.cpx Syntax

The top level element of the `DataBindings.cpx` file is `<Application>`. For example:

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<Application xmlns="http://xmlns.oracle.com/adfm/application"
    version="11.1.1.56.60" id="DataBindings" SeparateXMLFiles="false"
    Package="oracle.summit.view" ClientType="Generic">
```

Figure A-3 shows the structure definition of the `DataBindings.cpx` file in the Summit standalone sample applications for Oracle ADF.

The child elements have the following usages:

- `<definitionFactories>` registers a factory class to create the ADF binding objects associated with a particular namespace at runtime. The factory class is specific to the namespace associated with the type of ADF binding (for instance, a task flow binding).
• `<pageMap>` maps all user interface URLs and the corresponding page definition usage name. This map is used at runtime to map a URL to its page definition.

• `<pageDefinitionUsages>` maps a page definition usage (BindingContainer instance) name to the corresponding page definition. The `id` attribute represents the usage ID. The `path` attribute represents the full path to the page definition.

• `<dataControlUsages>` declares a list of data control usages (shortnames) and corresponding path to the data control definition entries in the `.dcx` or `.xcfg` file.

Table A-1 describes the attributes of the `DataBindings.cpx` elements.

<table>
<thead>
<tr>
<th>Element Syntax</th>
<th>Attributes</th>
<th>Attribute Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>&lt;definitionFactories&gt;</code></td>
<td><code>nameSpace</code></td>
<td>A URI. Identifies the location of the executable elements in the page definition usage.</td>
</tr>
<tr>
<td><code>&lt;factory&gt; &lt;/definitionFactories&gt;</code></td>
<td><code>className</code></td>
<td>The fully qualified class name. Identifies the location of the factory class that creates the page definition usage objects.</td>
</tr>
<tr>
<td><code>&lt;pageMap&gt;</code> <code>&lt;page /&gt; &lt;/pageMap&gt;</code></td>
<td><code>path</code></td>
<td>The full directory path. Identifies the location of the user interface page.</td>
</tr>
<tr>
<td></td>
<td><code>usageId</code></td>
<td>A unique qualifier. Names the page definition ID that appears in the ADF page definition file. The ADF binding servlet looks at the incoming URL requests and checks that the <code>bindings</code> variable is pointing to the ADF page definition associated with the URL of the incoming HTTP request.</td>
</tr>
<tr>
<td><code>&lt;pageDefinitionUsages&gt;</code></td>
<td><code>id</code></td>
<td>A unique qualifier. References the page definition ID that appears in the ADF page definition file.</td>
</tr>
<tr>
<td><code>&lt;page /&gt; &lt;/pageDefinitionUsages&gt;</code></td>
<td><code>path</code></td>
<td>The fully qualified package name. Identifies the location of the user interface page's ADF page definition file.</td>
</tr>
<tr>
<td><code>&lt;dataControlUsages&gt;</code></td>
<td><code>id</code></td>
<td>A unique qualifier. Identifies the data control usage as is defined in the <code>DataControls.dcx</code> file.</td>
</tr>
<tr>
<td><code>&lt;dc... /&gt; &lt;/dataControlUsages&gt;</code></td>
<td><code>path</code></td>
<td>The fully qualified package name. Identifies the location of the data control.</td>
</tr>
</tbody>
</table>

A.7.2 DataBindings.cpx Sample

Example A-2 shows the syntax for the `DataBindings.cpx` file in the Summit ADF sample application.

The ADF executable definition factory (factory element) is named by a `className` attribute and is associated with a `nameSpace`. At runtime, the factory class creates the executable definition objects that leads to the creation of the binding objects for the ADF binding container associated with a particular page definition. The factory locates the page definition through two `DataBindings.cpx` file elements: the `pageMap` element that maps the page URL to the page definition ID (`usageId` attribute) assigned at design time and the `pageDefinitionUsages` element that maps the ID to the location of the page definition from the project or project classpath.
Additionally, the ADF Business Components data control (BC4JDataControl element) is named by the id attribute. The combination of the Package attribute and the Configuration attribute is used to locate the bc4j.xcfg file in the ./.common subdirectory of the indicated package. The configuration contains the information of the application module name and all the runtime parameters the user has configured.

**Example A-2 Sample DataBindings.cpx File**

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<Application xmlns="http://xmlns.oracle.com/adfm/application"
    version="11.1.1.56.60" id="DataBindings" SeparateXMLFiles="false"
    Package="oracle.summit.view" ClientType="Generic">
    <definitionFactories>
        <factory nameSpace="http://xmlns.oracle.com/adf/controller/binding"
            className="oracle.adf.controller.internal.binding.TaskFlowBindingDefFactoryImpl"/>
        <dtfactory className="oracle.adf.controller.internal.dtrt.binding.BindingDTObjectFactory"/>
        <factory nameSpace="http://xmlns.oracle.com/adfm/dvt"
            className="oracle.adfinternal.view.faces.dvt.model.binding.FacesBindingFactory"/>
    </definitionFactories>
    <pageMap>
        <page path="/index.jsf" usageId="oracle_summit_view_indexPageDef"/>
        <page path="/Customers.jsff" usageId="oracle_summit_view_CustomersPageDef"/>
        <page path="/orders/Orders.jsff" usageId="oracle_summit_view_OrdersPageDef"/>
        <page path="/carousel/InventoryControl.jsff" usageId="oracle_summit_view_InventoryControlTestPageDef"/>
    </pageMap>
    <pageDefinitionUsages>
        <page id="oracle_summit_view_CustomersPageDef"
            path="oracle.summit.view.pageDefs.CustomersPageDef"/>
        <page id="oracle_summit_view_indexPageDef"
            path="oracle.summit.view.pageDefs.indexPageDef"/>
        <page id="oracle_summit_view_OrdersPageDef"
            path="oracle.summit.view.pageDefs.OrdersPageDef"/>
        <page id="oracle_summit_view_InventoryControlTestPageDef"
            path="oracle.summit.view.pageDefs.InventoryControlPageDef"/>
    </pageDefinitionUsages>
    <dataControlUsages>
        <BC4JDataControl id="BackOfficeAppModuleDataControl"
            Package="oracle.summit.model.services"
            FactoryClass="oracle.adf.model.bc4j.DataControlFactoryImpl"
            SupportsTransactions="true" SupportsFindMode="true"
            SupportsRangesize="true" SupportsResetState="true"
            SupportsSortCollection="true"
            Configuration="BackOfficeAppModuleLocal"
            syncMode="Immediate"
            xmlns="http://xmlns.oracle.com/adfm/datacontrol"/>
    </dataControlUsages>
</Application>
```

**A.8 pageNamePageDef.xml**

The pageNamePageDef.xml files are created each time you insert a databound component into a web page using the Data Controls panel or Structure window. These XML files define the Oracle ADF binding container for each web page in the application. The binding container provides access to the bindings within the page. You will have one XML file for each databound web page.
Caution:

The `DataBindings.cpx` file maps JSF pages to their corresponding page definition files. If you change the name of a page definition file or a JSF page, JDeveloper does not automatically refactor the `DataBindings.cpx` file. You must manually update the page mapping in the `DataBindings.cpx` file.

The `PageDef.xml` file appears in the `/src/view` directory of the user interface project. The Applications window displays the file in the view package of the Application Sources node. When you double-click the file node, the page description appears in the XML source editor. To edit the page description parameters, use the Properties window and choose the desired parameter in the Structure window.

For more information, see Working with Page Definition Files.

There are important differences in how the page definitions are generated for methods that return a single value and a collection.

### A.8.1 PageDef.xml Syntax

The top-level element of the `PageDef.xml` file is `<pageDefinition>`:

```
<pageDefinition xmlns="http://xmlns.oracle.com/adfm/uimodel"
    version="11.1.1.59.23" id="pagename" Package="oracle.summit.view.pageDefs">
```

where the XML namespace attribute (`xmlns`) specifies the URI to which the ADF binding container binds at runtime. Only the package name is editable; all other attributes should have the values shown.

The following example displays the child element hierarchy of the `<pageDefinition>` element. Note that each business service for which you have created a data control will have its own `<AdapterDataControl>` definition.

```xml
<?xml version="1.0" encoding="UTF-8" ?>
<pageDefinition>
    <parameters>
        ...
    </parameters>
    <executables>
        ...
    </executables>
    <bindings>
        ...
    </bindings>
</pageDefinition>
```

The child elements have the following usages:

- `<parameters>` defines page-level parameters that are EL accessible. These parameters store information local to the web page request and may be accessed in the binding expressions.

- `<executables>` defines the list of items (methods, view objects, and accessors) to execute during the `prepareModel` phase of the ADF page lifecycle. Methods to be executed are defined by `<methodIterator>`. The lifecycle performs the execute in the sequence listed in the `<executables>` section. Whether or not the method or operation is executed depends on its `Refresh` or `RefreshCondition` attribute value. Built-in operations on the data control are defined by:
- `<page>`: definition for a nested page definition (binding container)
- `<iterator>`: definition to a named collection in DataControls
- `<accessorIterator>`: definition to get an accessor in a data control hierarchy
- `<methodIterator>`: definition to get to an iterator returned by an invoked method defined by a `methodAction` in the same file
- `<variableIterator>`: internal iterator that contains variables declared for the binding container
- `<invokeAction>`: definition of which method to invoke as an executable

**Note:**
Only use `invokeAction` when your application does not use the ADF Controller module from the Fusion web application technology stack. If your application uses the ADF Controller module, Oracle recommends that you use a task flow method call activity, as described in Using Method Call Activities.

- `<bindings>` refers to an entry in `<executables>` to get to the collection from which bindings extract/submit attribute level data.

Table A-2 describes the attributes of the top-level `<pageDefinition>` element.
<table>
<thead>
<tr>
<th>Element Syntax</th>
<th>Attributes</th>
<th>Attribute Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;pageDefinition&gt;</td>
<td>ControllerClass</td>
<td>Fully qualified class name to create when controller requests a PageController object for this bindingContainer.</td>
</tr>
<tr>
<td></td>
<td>EnableTokenValidation</td>
<td>Enables currency validation for this bindingContainer when a postback occurs. This is to confirm that the web tier state matches the state that particular page was rendered with.</td>
</tr>
<tr>
<td></td>
<td>FindMode</td>
<td>FindMode is for legacy (10.1.2) use only and indicates whether this bindingContainer should start out in findMode when initially prepared.</td>
</tr>
<tr>
<td></td>
<td>MsgBundleClass</td>
<td>Fully qualified package name. Identifies the class which contains translation strings for any bindings.</td>
</tr>
<tr>
<td></td>
<td>SkipValidation</td>
<td>Determines if data validation occurs. The supported values are:</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• true: skips data validation. Note that attribute validation on the client side at the binding level still occurs. For example, validates non-null and type conversion errors.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• false: validates all rows for all data controls referenced in the current page. This is the default value.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• skipDataControls: validates the current rows of iterator bindings modified in the current page.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>• custom: set to custom if your application implements an instance of the oracle.binding.BindingContainerValidator interface and references it through an EL expression entry named CustomValidator in the binding container.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Setting a value for this attribute can be useful if you want to skip data validation on, for example, a train component. For more information see the &quot;How to Create the Train Model&quot; section of Developing Web User Interfaces with Oracle ADF Faces.</td>
</tr>
<tr>
<td></td>
<td>Viewable</td>
<td>An EL expression that should resolve at runtime to whether this binding and the associated component should be rendered or not.</td>
</tr>
</tbody>
</table>

Table A-3 describes the attributes of the child element of <parameters>.
Table A-3  Attributes of the PageDef.xml File <parameters> Element

<table>
<thead>
<tr>
<th>Element Syntax</th>
<th>Attributes</th>
<th>Attribute Description</th>

</thead>
<tbody>
<tr>
<td><code>&lt;accessorIterator&gt;</code></td>
<td>Accessor</td>
<td>Specifies any other accessor defined by this binding.</td>
</tr>
<tr>
<td></td>
<td>Binds</td>
<td>Specifies the view or action to which the iterator is bound.</td>
</tr>
<tr>
<td></td>
<td>BeanClass</td>
<td>Identifies the Java type of beans in the associated iterator or collection.</td>
</tr>
<tr>
<td></td>
<td>CacheResults</td>
<td>If true, manages the data collection between requests.</td>
</tr>
<tr>
<td></td>
<td>ChangeEventRate</td>
<td>Specifies the rate of events when a component is wired to data via this iterator and is in polling event mode.</td>
</tr>
<tr>
<td></td>
<td>DataControl</td>
<td>Interprets and returns the collection referred to by this iterator binding.</td>
</tr>
<tr>
<td></td>
<td>id</td>
<td>Unique identifier. May be referenced by any ADF value binding.</td>
</tr>
<tr>
<td></td>
<td>MasterBinding</td>
<td>Reference to the methodIterator (or iterator) that binds the data collection that serves as the master to the accessor iterator's detail collection.</td>
</tr>
<tr>
<td></td>
<td>ObjectType</td>
<td>Used for ADF Business Components only. A boolean value determines whether the collection is an object type or not.</td>
</tr>
<tr>
<td></td>
<td>RangeSize</td>
<td>Specifies the number of data objects in a range to fetch from the bound collection. The range defines a window you can use to access a subset of the data objects in the collection. Typically, when you create a component by dragging an object from the Data Controls panel, the range size is set to 25. Use RangeSize when you want to work with an entire set or when you want to limit the number of data objects to display in the page. Note that the values -1 and 0 have specific meaning: the value -1 returns all available objects from the collection, while the value 0 will return the same number of objects as the collection uses to retrieve from its data source. If the RangeSize attribute is not specified at all, all available objects are returned.</td>
</tr>
</tbody>
</table>
|                   | Refresh             | Determines when to invoke the executable. Oracle recommends that you do not change from the default value (deferred) for the Refresh attribute and that you do use an EL expression for the RefreshCondition attribute to determine if an executable should be refreshed. For completeness’ sake, the following is the list of valid attribute values:  
  • always: Invokes the executable each time the binding container is prepared. This occurs when the page displays and when the user submits changes, or when the application posts back to the page.  
  • deferred: Refresh occurs when another binding requires or refers to this executable. Since refreshing an executable may impact performance, you can set the refresh to occur only if deferred is used in a binding that is being rendered. This is the default value for ADF Faces applications.  
  • <default>: Always set to deferred by default.  
  • ifNeeded: Whenever the framework needs to refresh the accessor binding that has not been refreshed to this point. For example, when you have an accessor hierarchy such that a detail is listed first in the page hierarchy such that a detail is listed first in the page

</tr>
</tbody>
</table>

**A.9 adfc-config.xml**

The adfc-config.xml file is the source file for the ADF unbounded task flow that JDeveloper creates by default when you create an application using the ADF Fusion Web Application template. By default, JDeveloper stores the adfc-config.xml file in the following directory:

`application_root\ViewController\Web Content\WEB-INF`
If you create additional unbounded task flows, JDeveloper proposes the following file name for the source files of the additional unbounded task flows:

``adfc-configN.xml``

where `N` is a number that increments each time you create a new unbounded task flow. Alternatively, you choose the file name you want for an unbounded task flow’s source file.

Each source file for an unbounded task flow contains the metadata for activities, control flow rules, and managed beans that you added to an unbounded task flow so that end users can interact with the Fusion web application to complete a task.

The XML schema definition file (XSD) that defines valid metadata entries for the `adfc-config.xml` file is `adfc-config_1_0.xsd`. The `adfc-config_1_0.xsd` file is stored in the `adf-controller-schema.jar` file in the following directory of your JDeveloper installation:

``jdev_install\oracle_common\modules\oracle.adf.model_12.1.2``

Use JDeveloper’s XSD Visual Editor to view the `adfc-config_1_0.xsd` file. Using this editor, you can identify the valid metadata elements and attributes for the `adfc-config.xml` file.

The following example shows the source file for an unbounded task flow where view activities, control flow rules, and so on have yet to be added.

```xml
<?xml version="1.0" encoding="windows-1252"?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <view id="index">
    <page>/index.jsf</page>
  </view>
  <managed-bean id="__1">
    <managed-bean-name>login</managed-bean-name>
    <managed-bean-class>oracle.summit.bean.LoginBean</managed-bean-class>
    <managed-bean-scope>request</managed-bean-scope>
  </managed-bean>
  <managed-bean id="__2">
    <managed-bean-name>WelcomePageBean</managed-bean-name>
</adfc-config>
```

Figure A-4 shows the Diagram view of the Summit sample application for ADF task flows' `adfc-config.xml` file. Example A-3 shows the corresponding source view of the unbounded task flow that appears in Figure A-4.

For more information about unbounded task flows, see Getting Started with ADF Task Flows.

Figure A-4   Diagram View of Summit ADF Task Flow Sample Application's `adfc-config.xml` File

Example A-3   Source View of Summit ADF Task Flow Sample Application’s `adfc-config.xml` File

```xml
<?xml version="1.0" encoding="windows-1252"?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <view id="index">
    <page>/index.jsf</page>
  </view>
  <managed-bean id="__1">
    <managed-bean-name>login</managed-bean-name>
    <managed-bean-class>oracle.summit.bean.LoginBean</managed-bean-class>
    <managed-bean-scope>request</managed-bean-scope>
  </managed-bean>
  <managed-bean id="__2">
    <managed-bean-name>WelcomePageBean</managed-bean-name>
</adfc-config>
```
A.10 task-flow-definition.xml

The default file name that JDeveloper proposes for the source file of the first ADF bounded task flow that you create is `task-flow-definition.xml`. This file stores the metadata for a bounded task flow. It contains entries for each view activity, method call activity, task flow call, and so on that you add to the bounded task flow.

JDeveloper proposes the following file name for subsequent bounded task flows that you create:

`task-flow-definitionN.xml`

where \( N \) is a number that increments each time you create a new bounded task flow. Alternatively, you choose the file name you want for a bounded task flow's source file. By default, JDeveloper stores the `task-flow-definition.xml` file in the following directory:

`application_root\ViewController\Web Content\WEB-INF`

The XML schema definition files (XSD) that define the valid metadata entries for the source file of a bounded task flow are stored in the `adf-controller-schema.jar` file in the following directory of your JDeveloper installation:

`jdev_install\oracle_common\modules\oracle.adf.model_12.1.2`

Use JDeveloper's XSD Visual Editor to view these XSD files and identify the valid metadata elements and attributes for the source file of a bounded task flow.

The following example shows the content of a source file when you create a new bounded task flow using the Create Task Flow dialog. The `<task-flow-definition>` element identifies this file as a bounded task flow. JDeveloper generates the `<task-flow-definition>` element when you select the **Create as Bounded Task Flow** checkbox in the Create Task Flow dialog. The value of the `<task-flow-definition>` element's `id` attribute corresponds to the value that you enter in the **Task Flow ID** field of the Create Task Flow dialog. The `<use-page-fragments/>` element indicates that all view activities in this bounded task flow must be associated with page fragments. JDeveloper generates this entry when you select the **Create with Page Fragments** checkbox in the Create Task Flow dialog.

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
  <task-flow-definition id="task-flow-definition">
    <use-page-fragments/>
  </task-flow-definition>
</adf-config>
```

Example A-4 shows the Summit ADF task flow sample application's `customers-task-flow-definition.xml` file. You can view entries for the activities shown in the Structure window in Figure A-5.

For more information about bounded task flows, see Getting Started with ADF Task Flows.
<?xml version="1.0" encoding="windows-1252" ?>
<adfc-config xmlns="http://xmlns.oracle.com/adf/controller" version="1.2">
	<task-flow-definition id="customer-task-flow-definition">
		<default-activity id="__1">isCustomerLogin</default-activity>
		<managed-bean id="__11">
			<managed-bean-name id="__9">CustomersBackingBean</managed-bean-name>
			<managed-bean-class id="__10">oracle.summit.backing.CustomersBackingBean</managed-bean-class>
			<managed-bean-scope id="__8">backingBean</managed-bean-scope>

			</control-flow-case>
		</control-flow-rule>
	</task-flow-definition>
</adfc-config>
JDeveloper generates the adf-config.xml file when you create an application using the ADF Fusion Web Application template. JDeveloper stores this application-level descriptor file in the following directory:

`application_root\.adf\META-INF`

In JDeveloper, you can locate the file in the Application Resources panel of the Applications window by expanding the Descriptors > ADF META-INF nodes.

The adf-config.xml file specifies application-level settings that you define during development. You can use a deployment profile to specify settings that are used at application deploy time. You can change some of the settings at runtime using Oracle Enterprise Manager.

Examples of tasks that you can accomplish by changing settings in the adf-config.xml file include the following:

- Enable or disable the validation of ADF Controller metadata
- Replicate memory scope if you deploy your Fusion web application in a clustered environment
- Configure properties to manage the caching of resource bundles where your application uses EL expressions to retrieve strings at runtime from resource bundles

The properties that you can configure are:

- `initial-size`
  Specifies the initial number of resource bundles that your application can cache. The default value is 100.

- `max-size`
  Specifies the maximum number of resource bundles that your application can cache. The default value is 100.

- `load-factor`
  The default value is 0.75.

- `expire-time`
  The default value is 43200 seconds (12 hours).

You specify these properties as attribute values of the `<resource-bundle-cache>` element in the adf-config.xml file. Example A-5 demonstrates how you might configure these values for your application in the adf-config.xml file.
As an alternative to configuring the caching of resource bundles in the adf-config.xml file, you can specify the resource bundle caching properties as parameters for the Java Virtual Machine (JVM). If you specify the properties as parameters for the JVM, the changes apply to all applications managed by the JVM. For this reason, consider configuring the resource bundle caching properties in the adf-config.xml file for your application. Use the following property names if you decide to specify the resource bundle caching properties as parameters for the JVM:

- resource-bundle-cache-initial-size
- resource-bundle-cache-max-size
- resource-bundle-cache-load-factor
- resource-bundle-cache-expire-time

At runtime, the Fusion web application loads the adf-config.xml file from the META-INF directory. If the Fusion web application finds more than one adf-config.xml file, it stops loading the file and logs a warning.

The following tasks modify or require you to modify the adf-config.xml file:

- In the ADF Controller layer
  - Creating task flows
    By default, the ADF Controller uses a user session level cache to store the application's unbounded task flow metadata. This enables support for user specific seeded customization or design time at runtime customization of unbounded task flow metadata in your application. Clear the Allow Unbounded Task Flow Customizations checkbox in the Controller page of the adf-config.xml's file overview editor to disable this behavior and set the value of the <allow-unbounded-task-flow-customizations> element to false. You can still have customizations of the unbounded task flow metadata in your application. However, these customizations are shared by all users of the application. For more information about customizations, see Customizing Applications with MDS. For more information about task flows, see Getting Started with ADF Task Flows.
  - Configure an integer value for the root-view-port-request-lock-timeout property that specifies the number of seconds a request can hold a lock on the root view port before timing out and allowing other requests to acquire the lock. The default value is 600 seconds. For more information about the root view port, see About View Ports and ADF Regions.
  - Minimize the number of active root view ports in an application by specifying a value for the <max-root-view-ports> property. For more information, see Minimizing the Number of Active Root View Ports in an Application.
  - Modify the number of events collected or stop the collection of events by ADF Controller. Both tasks involve configuring the value of the <debug-history-size> element in your application's adf-config.xml file. For more information, see Reporting Incidents to the Diagnostic Framework.
  - Enabling implicit save points
    For more information, see How to Enable Implicit Save Points.
– Specify a bounded task flow that does not require authorization to invoke when a user attempts to invoke a bounded task flow in a region for which they do not have security permissions. For more information, see Handling Access to Secured Task Flows by Unauthorized Users.

– Enable ADF Controller to track changes to ADF memory scopes and replicate the page flow scope and view scope within the server cluster. You must set the ADF Controller parameter <adf-scope-ha-support> in the application’s adf-config.xml file to true. For more information, see How to Ensure Oracle ADF Receives Notifications From Managed Bean Changes.

• In the ADF Model layer

  – Disable automatic partial page rendering as the default behavior for an application. This requires you to change the value for the changeEventPolicy attribute from the default value of ppr:

        <defaults changeEventPolicy="ppr"/>

    For more information, see What You May Need to Know About Partial Page Rendering and Iterator Bindings.

  – Configure all Query components in the user interface project to render input search fields using a bind variable.

      For more information, see What You May Need to Know About Named Bind Variables in Search Forms.

  – Control the dispatch of contextual events

      For more information, see How to Control Contextual Events Dispatch.

• Persisting saved searches in MDS

      For more information, see How to Persist Saved Searches into MDS.

• Creating RESTful web services from ADF application modules and managing the release version identifiers of REST resources

      For more information, see Creating ADF REST Resources Using the Application Module and see Versioning the ADF REST Resource.

• Configuring ADF Business Components global settings

      For more information, see Using Fetch Size to Limit the Maximum Number of Records Fetched for a View Object and How to Initialize the Data Model Project With a Database Connection.

• Enabling or disabling Oracle ADF Security

      For more information, see Enabling ADF Security and Disabling ADF Security.

• Enabling seeded customizations

      For more information, see How to Enable Seeded Customizations for User Interface Projects and How to Enable Seeded Customizations in Existing Pages.

• Configuring change persistence

      For more information, see How to Enable User Customizations.

• Enabling user customizations
For more information, see What Happens When You Enable User Customizations.

Example A-5 shows example entries for an application's adf-config.xml file.

Example A-5  Sample adf-config.xml File

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adf-config xmlns="http://xmlns.oracle.com/adf/config"
    xmlns:sec="http://xmlns.oracle.com/adf/security/config">
        <CredentialStoreContext credentialStoreClass="oracle.adf.share.security.providers.jps.CSFCredentialStore"
            credentialStoreLocation="../../src/META-INF/jps-config.xml"/>
        <!-- The Configure ADF Security wizard modifies JaasSecurityContext settings -->
        <JaasSecurityContext initialContextFactoryClass="oracle.adf.share.security.JAASInitialContextFactory"
            jaasProviderClass="oracle.adf.share.security.providers.jps.JpsSecurityContext" authorizationEnforce="true" authenticationRequire="true"/>
    </sec:adf-security-child>
    <adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
        <savepoint-datasource>java:comp/env/jdbc/summit_adfDS</savepoint-datasource>

                        <persist-changes>true</persist-changes>
                    </attribute>
                </tag>
                <!-- Additional tags omitted to make this example concise -->
                <tag name="table">
                    <attribute name="filterVisible">
                        <persist-changes>true</persist-changes>
                    </attribute>
                </tag>
            </taglib>
        </taglib-config>
    </adf-faces-config>
    <adf-mds-config xmlns="http://xmlns.oracle.com/adf/mds/config">
        <mds-config xmlns="http://xmlns.oracle.com/mds/config" version="11.1.1.000">
            <cust-config>
                <match path="/">
                    <customization-class name="oracle.adf.share.config.UserCC"/>
                </match>
            </cust-config>
        </mds-config>
    </adf-mds-config>
</adf-config>
```
A.12 adf-settings.xml

The adf-settings.xml file holds project-level and library-level settings such as ADF Faces help providers and ADF Controller phase listeners.

The configuration settings for adf-settings.xml are fixed and cannot be changed during or after application deployment. There can be multiple adf-settings.xml files in an application. The users of adf-settings.xml files are responsible for merging the contents of their configuration.

JDeveloper creates an adf-settings.xml file when you:

- Create an application using the ADF Fusion Web Application template
- Add ADF Page Flow (ADF Controller) as a feature to an existing project

By default, JDeveloper stores the adf-settings.xml file in the following directory:

```
application_root\ViewController\src\META-INF
```

The following tasks modify or require you to modify the adf-settings.xml file:

- Registering a phase listener
  For more information, see How to Register a Listener Globally.

- Creating help for ADF Faces components
  For more information, see the "Displaying Help for Components" section in Developing Web User Interfaces with Oracle ADF Faces.

For information about how to edit the adf-settings.xml file, see the "How to Configure for ADF Faces in adf-settings.xml" section in Developing Web User Interfaces with Oracle ADF Faces.

Example A-6 shows a sample adf-setting.xml file with settings configured for a phase listener and a help provider.

**Example A-6   Sample adf-settings.xml File**

```xml
<?xml version="1.0" encoding="windows-1252" ?>
<adf-settings xmlns="http://xmlns.oracle.com/adf/config">
```
<adf-controller-config xmlns="http://xmlns.oracle.com/adf/controller/config">
  <lifecycle>
    <phase-listener>
      <listener-id>SummitPhaseListener</listener-id>
      <class>oracle.summit.listeners.SummitPhaseListener</class>
    </phase-listener>
  </lifecycle>
</adf-controller-config>
<adf-faces-config>
  <help-provider prefix="MYAPP">
    <help-provider-class>oracle.summit.MyHelpProvider</help-provider-class>
    <property>
      <property-name>myCustomProperty</property-name>
      <value>someValue</value>
    </property>
  </help-provider>
</adf-faces-config>
</adf-settings>

A.13 web.xml

Oracle ADF has specific configuration settings for the standard web.xml deployment descriptor file.

When you create a project in JDeveloper that uses JSF technology, a starter web.xml file with default settings is created for you in the /WEB-INF folder. To edit the file, double-click web.xml in the Applications window to open it in the XML editor.

The following must be configured in web.xml for all applications that use JSF and ADF Faces:

- ADF Library resource servlet and mapping: Serves up web application resources (images, style sheets, JavaScript libraries) from ADF Library JAR files on the application class path.

  By default, static web application resources (including resources in ADF Libraries), such as images, have a staleness period setting of 364 days. This staleness period setting requests that the client not make a request to the server to validate the static web application resources until one of the following events occur:
  
  - Staleness period expires
  - Browser cache no longer contains the static resource
  - User executes a page refresh

If the client does make a request to the server and the resources have not changed, the server returns a HTTP 304 response (Not Modified) with no body.

You can override the staleness period setting of 364 days for all static web application resources in ADF Libraries by adding initialization parameters to the web.xml file. The following example demonstrates how to set these initialization parameters using a number of examples.

<!-- Expires all static resources in 30 days -->
<init-param>
  <param-name>expires</param-name>
  <param-value>60*60*24*30</param-value>
</init-param>

<!-- Expires static resources with the .js file extension in 1 day -->
The following example shows the default file extensions. You can add additional file extensions by configuring the `extensions` parameter value to include the file extensions that you want. Note that you must prepend and append "." to the file extension. The example also shows how you specify visibility for cache control.

<!-- Specify file extensions for a number of different file formats -->
<init-param>
  <param-name>extensions</param-name>
  <param-value>.png.jpg.jpeg.gif.js.css.</param-value>
</init-param>

<!-- Specify visibility for cache control, for example -->
<init-param>
  <param-name>visibility</param-name>
  <param-value>Public</param-value>
</init-param>

- **JSF servlet and mapping**: The servlet `javax.faces.webapp.FacesServlet` that manages the request-processing lifecycle for web applications utilizing JSF to construct the user interface.

- **ADF Faces filter and mapping**: A servlet filter to ensure that ADF Faces is properly initialized by establishing a `AdfFacesContext` object. This filter also processes file uploads.

The JSF servlet and mapping configuration settings are automatically added to the starter `web.xml` file when you first create a JSF project. When you insert an ADF Faces component into a JSF page for the first time, JDeveloper automatically inserts the configuration settings for ADF Faces filter and mapping, and resource servlet and mapping.

For more information, see the "ADF Faces Configuration" appendix in *Developing Web User Interfaces with Oracle ADF Faces*.

A.14 logging.xml

ADF Logger is a diagnostic tool that you can use in JDeveloper to capture runtime traces messages when you debug an application. You configure the use of this tool by editing the `logging.xml` file.

For more information about the `logging.xml` file and using the ADF Logger, see *Using the ADF Logger*. 
Oracle ADF Binding Properties

This appendix describes the properties of the ADF bindings that you use can access at runtime in an Oracle ADF application.

Table B-1 shows the properties that you can use in EL expressions to access values of the ADF binding objects at runtime. The properties appear in alphabetical order.

<table>
<thead>
<tr>
<th>Runtime Property</th>
<th>Description</th>
<th>Iterator</th>
<th>Action</th>
<th>Attribute</th>
<th>Button</th>
<th>List</th>
<th>Table</th>
<th>Tree</th>
</tr>
</thead>
<tbody>
<tr>
<td>actionEnabled</td>
<td>Use operationEnabled instead.</td>
<td>n/a</td>
<td>yes</td>
<td>n/a</td>
<td>n/a</td>
<td>n/a</td>
<td>n/a</td>
<td>n/a</td>
</tr>
<tr>
<td>allRowsInRange</td>
<td>Returns an array of the current set of rows from the associated collection. Calls getAllRowsInRange() on the RowSetIterator object.</td>
<td>yes</td>
<td>n/a</td>
<td>n/a</td>
<td>n/a</td>
<td>n/a</td>
<td>n/a</td>
<td>n/a</td>
</tr>
<tr>
<td>attributeDef</td>
<td>Returns the attribute definition for the first attribute with which the binding is associated.</td>
<td>n/a</td>

<td>n/a</td>
<td>yes</td>
<td>n/a</td>
</tr>
</tbody>
</table>
| displayData      | Returns a list of map elements. Each map entry contains the following elements:  
|                  | • selected: A boolean true if the current entry should be selected.       | n/a      | n/a    | n/a       | n/a    | yes  | n/a   | n/a  |
|                  | • index: The index value of the current entry.                             |          |        |           |        |      |       |      |
|                  | • prompt: A string value that may be used to render the entry in the UI.   |          |        |           |        |      |       |      |
|                  | • displayValues: An ordered list of display attribute values for all display attributes in the list binding. |          |        |           |        |      |       |      |
| displayHint      | Returns the display hint for the first attribute to which the binding is associated. The hint identifies whether the attribute should be displayed or not. For more information, see oracle.jbo.AttributeHints.displayHint. | n/a      | n/a    | n/a       | n/a    | yes  | n/a   | n/a  |
### Table B-1 (Cont.) EL Properties of Oracle ADF Bindings

<table>
<thead>
<tr>
<th>Runtime Property</th>
<th>Description</th>
<th>Iterator</th>
<th>Action</th>
<th>Attribute</th>
<th>Button</th>
<th>List</th>
<th>Table</th>
<th>Tree</th>
</tr>
</thead>
</table>
| displayHints     | Returns a list of name-value pairs for UI hints for all display attributes to which the binding is associated. The map contains the following elements:  
  • label: The label to display for the current attribute.  
  • tooltip: The tooltip to display for the current attribute.  
  • displayHint: The display hint for the current attribute.  
  • displayHeight: The height in lines for the current attribute.  
  • displayWidth: The width in characters for the current attribute.  
  • controlType: The control type hint for the current attribute.  
  • format: The format to be used for the current attribute. | n/a | n/a | n/a | yes | yes | n/a | n/a |
<p>| enabled          | Use the operationEnabled property. | n/a | n/a | n/a | n/a | n/a | n/a | n/a |
| enabledString    | Returns disabled if the action binding is not ready to be invoked. Otherwise, returns an empty string (&quot;&quot;). | n/a | yes | n/a | n/a | n/a | n/a | n/a |
| error            | Returns any exception that was cached while updating the associated attribute value for a value binding or when invoking an operation bound by an operation binding. | yes | yes | yes | yes | yes | yes | yes |
| estimatedRowCount | Returns the maximum row count of the rows in the collection with which this iterator binding is associated | yes | n/a | n/a | n/a | n/a | yes | yes |
| findMode         | Returns true if the iterator is currently operating in find mode. Otherwise, returns false. | yes | n/a | n/a | n/a | n/a | n/a | n/a |</p>
<table>
<thead>

</tr>
</tbody>
</table>
| rangeSet         | Returns a list of map elements over the range of rows from the associated iterator binding. The elements in this list are wrapper objects over the indexed row in the range that restricts access to the attributes to which the binding is bound. The properties returned on the reference object are:  
  * `index`: The range index of the row this reference is pointing to.  
  * `key`: The key of the row this reference is pointing to.  
  * `keyStr`: The string format of the key of the row this reference is pointing to.  
  * `currencyString`: The current indexed row as a string. Returns "*" if the current entry belongs to the current row; otherwise, returns " ". This property is useful in JSP applications to display the current row.  
  * `attributeValues`: The array of applicable attribute values from the row.  
You may also access an attribute value by name on a range set like `rangeSet.dname` if `dname` is a bound attribute in the range binding. | n/a | n/a | n/a | n/a | n/a | yes | yes |

ADF Security Permission Grants

This appendix lists the security-aware components of Oracle ADF and the actions that their Permission implementation classes define.

Table C-1 shows the ADF components and their permission grants that you can define to create ADF security policies. You add grants to the policy store using the overview editor for ADF security policies. A permission grant specifies the fully qualified permission class name, the fully qualified resource name, the action that can be performed against the resource, and the application role target of the grant. When you enable ADF security to enforce authorization checking against the security policies of the policy store, the operations supported by ADF components will be inaccessible to users who do not possess sufficient access rights as defined by grants to their application role.

For complete details about defining ADF security policies in Fusion web applications, see Enabling ADF Security in a Fusion Web Application.

Note:

<table>
<thead>
<tr>

</tbody>
</table>
This appendix lists the most commonly used methods in the interfaces and classes of the ADF Business Components layer of Oracle ADF.

This appendix contains the following sections:

- **Methods for Creating Your Own Layer of Framework Base Classes**
- **Methods Used in the Client Tier**
- **Methods Used in the Business Service Tier**

### D.1 Methods for Creating Your Own Layer of Framework Base Classes

Before you begin to develop application-specific business components, you can create a layer of classes that extend all of the ADF Business Components framework base implementation classes described in this appendix. An example of a customized framework base class for application module components might look like this:

```java
package com.yourcompany.adfextensions;
import oracle.jbo.server.ApplicationModuleImpl;
public class CustomApplicationModuleImpl extends ApplicationModuleImpl {
  /*
   * We might not yet have any custom code to put here yet, but
   * the first time we need to add a generic feature that all of
   * our company's application modules need, we will be very happy
   * that we thought ahead to leave ourselves a convenient place
   * in our class hierarchy to add it so that all of the application
   * modules we have created will instantly benefit by that new feature,
   * behavior change, or even perhaps, bug workaround.
   */
}
```

A common set of customized framework base classes in a package name of your own choosing like `com.yourcompany.adfextensions`, each importing the `oracle.jbo.server.*` package, would consist of the following classes:

- public class CustomEntityImpl extends EntityImpl
- public class CustomEntityDefImpl extends EntityDefImpl
- public class CustomViewObjectImpl extends ViewObjectImpl
- public class CustomViewRowImpl extends ViewRowImpl
- public class CustomApplicationModuleImpl extends ApplicationModuleImpl
D.2 Methods Used in the Client Tier

All of the interfaces described in this section are designed so that you may expose
method for use in the client tier. These interface methods part of the oracle.jbo.* package.

This section provides a summary of the most frequently called, written, and
overridden methods for the key ADF Business Components interfaces.

Note:
The corresponding implementation classes for these oracle.jbo.* interfaces are intentionally designed to not be directly accessed by client code. Methods Used in the Business Service Tier shows that the implementation classes reside in the oracle.jbo.server.* package and generally have the suffix Impl in their name to help remind you not to use them in your client-layer code.

D.2.1 ApplicationModule Interface

An application module is a business service component that acts as a transactional
container for other ADF components and coordinates with them to implement a
number of Java EE design patterns important to business application developers.
These design pattern implementations enable your client code to work easily with
updatable collections of value objects, based on fast-lane reader SQL queries that
retrieve only the data needed by the client, in the way the client wants to view it.
Changes made to these value objects are automatically coordinated with your
persistent business domain objects in the business service tier to enforce business rules
consistently and save changes back to the database. Table D-1 describes the operations
that you can perform on an application module using the ApplicationModule interface.

Note:
For the complete list of design patterns that ADF Business Components implements, see ADF Business Components Java EE Design Pattern Catalog.
<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this ApplicationModule interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Access an existing view object instance using the assigned instance name (for example, MyVOInstanceName)</td>
<td>findViewObject()</td>
</tr>
<tr>
<td>Create a new view object instance from an existing definition</td>
<td>createViewObject()</td>
</tr>
<tr>
<td>Create a new view object instance from a SQL Statement</td>
<td>createViewObjectFromQueryStmt()</td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td></td>
</tr>
<tr>
<td>This incurs runtime overhead to describe the &quot;shape&quot; of the dynamic query's SELECT list. Use this method only when you cannot know the SELECT list for the query at design time. Furthermore, if you are creating the dynamic query based on some kind of custom runtime repository, you can follow the steps to create (both read-only and updatable) dynamic view objects without the runtime-describe overhead, as described in Creating a View Object with Multiple Updatable Entities. If only the WHERE needs to be dynamic, create the view object at design time, then set the WHERE clause dynamically as needed using ViewObject APIs.</td>
<td></td>
</tr>
<tr>
<td>Access a nested application module instance by name</td>
<td>findApplicationModule()</td>
</tr>
<tr>
<td>Create a new nested application module instance from an existing definition</td>
<td>createApplicationModule()</td>
</tr>
<tr>
<td>Find a view object instance in a nested application module using a dot-notated name (for example, MyNestedAMInstanceName.OneOfItsVONames)</td>
<td>findViewObject()</td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td></td>
</tr>
<tr>
<td>You can use this method to find an instance of a view object belonging to a nested application module in a single method call. This way you do not need to first call findApplicationModule() to find the nested application module, before calling findViewObject() on that nested application module.</td>
<td></td>
</tr>
<tr>
<td>Access the current transaction object</td>
<td>getTransaction()</td>
</tr>
</tbody>
</table>

In addition to generic application module access, JDeveloper can generate a custom YourApplicationModuleName interface containing service-level custom methods that you’ve chosen to expose to the client. You use the Client Interface page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.
D.2.2 Transaction Interface

The Transaction interface exposes methods allowing the client to manage pending changes in the current transaction. Table D-2 describes the operations that you can perform on the transaction using the Transaction interface.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this Transaction interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Commit pending changes</td>
<td>commit()</td>
</tr>
<tr>
<td>Roll back pending changes</td>
<td>rollback()</td>
</tr>
<tr>
<td>Execute a one-time database command or block of PL/SQL</td>
<td>executeCommand()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>Validate all pending invalid changes in the transaction</td>
<td>validate()</td>
</tr>
<tr>
<td>Change the default locking mode</td>
<td>setLockingMode()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>Decide whether to use bundled exception reporting mode or not</td>
<td>setBundledExceptionMode()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>Decide whether entity caches will be cleared upon a successful commit of the transaction</td>
<td>setClearCacheOnCommit()</td>
</tr>
<tr>
<td>Notes:</td>
<td>Default is false.</td>
</tr>
<tr>
<td>Decide whether entity caches will be cleared upon a rollback of the transaction</td>
<td>setClearCacheOnRollback()</td>
</tr>
<tr>
<td>Notes:</td>
<td>Default is true.</td>
</tr>
<tr>
<td>Clear the entity cache for a specific entity object</td>
<td>clearEntityCache()</td>
</tr>
</tbody>
</table>

Notes:
- Do not use this command with methods that require retrieving OUT parameters and that will be executed more than once, or that could benefit from using bind variables. Instead, expose a custom method on your application module.
- You can set the locking mode in your configuration by setting the property jbo.locking.mode to one of the four supported values: none, optimistic, pessimistic, optupdate. If you don’t explicitly set the locking mode, it will default to optimistic. For Fusion web applications, use optimistic or optupdate modes.
- The ADF Controller layer support sets this parameter to true automatically for Fusion web applications.
- Default is false.
D.2.3 ViewObject Interface

A view object is a component that encapsulates a database query and simplifies working with the row set of results it produces. You use view objects to project, filter, join, or sort business data using SQL from one or more tables to cast the data into exactly the format that the user should see on the page or panel. You can create "master-detail" hierarchies of any depth or complexity by connecting view objects together using view links. View objects can produce read-only query results, or when associated with one or more entity objects at design time, can be fully updatable. Updatable view objects can support insertion, modification, and deletion of rows in the result collection, with automatic delegation to the correct business domain objects.

Every view object contains a "default row set" for simplifying the 90 percent of use cases where you work with a single row set of results for the view object's query. A view object implements all the methods on the RowSet interface by delegating them to this default RowSet. That means you can invoke any RowSet methods on any view object as well.

Every view object implements the StructureDef interface to provide information about the number and types of attributes in a row of its row sets. So you can call StructureDef methods directly on any view object.

Table D-3 describes the operations that you can perform on a view object using the ViewObject interface.

Table D-3  ViewObject Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this ViewObject interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Set an additional runtime WHERE clause on the row set</td>
<td>setWhereClause()</td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td></td>
</tr>
<tr>
<td>This WHERE clause augments any WHERE clause specified at design time in the base view object. It does not replace it.</td>
<td></td>
</tr>
<tr>
<td>Set a dynamic ORDER BY clause</td>
<td>setOrderByClause()</td>
</tr>
<tr>
<td>Create a Query-by-Example criteria collection</td>
<td>createViewCriteria()</td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td></td>
</tr>
<tr>
<td>You then create one or more ViewCriteriaRow objects using the createViewCriteriaRow() method on the ViewCriteria object you created. Then you add() these view criteria rows to the view criteria collection and apply the criteria using the applyViewCriteria() method.</td>
<td></td>
</tr>
<tr>
<td>Apply a Query-by-Example criteria collection</td>
<td>applyViewCriteria()</td>
</tr>
<tr>
<td>Set a query optimizer hint</td>
<td>setQueryOptimizerHint()</td>
</tr>
<tr>
<td>Access the attribute definitions for the key attributes in the view object</td>
<td>getKeyAttributeDefs()</td>
</tr>
<tr>
<td>Add a dynamic attribute to rows in this view object's row sets</td>
<td>addDynamicAttribute()</td>
</tr>
<tr>
<td>Clear all row sets produced by a view object</td>
<td>clearCache()</td>
</tr>
</tbody>
</table>
Table D-3 (Cont.) ViewObject Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this ViewObject interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Remove a view object instance and its resources</td>
<td>remove()</td>
</tr>
<tr>
<td>Set an upper limit on the number of rows that the view object will attempt to fetch from the database</td>
<td>setMaxFetchSize()</td>
</tr>
<tr>
<td>Notes: Default is -1, which means to impose no limit on how many rows would be retrieved from the database if you iterated through them all. By default, as you iterate through them, they are fetched lazily.</td>
<td></td>
</tr>
</tbody>
</table>

In addition to generic ViewObject access, JDeveloper can generate you a custom YourViewObjectName interface containing view object-level custom methods that you've chosen to expose to the client. You use the Client Interface page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

D.2.4 RowSet Interface

A row set is an object that contains a set of rows, typically produced by executing a view object's query.

Every RowSet aggregates a "default row set iterator" for simplifying the 90 percent of use cases where you need only a single iterator over the row set. A RowSet object implements all the methods on the RowSetIterator interface by delegating them to this default RowSetIterator. This means you can invoke any RowSetIterator method on any RowSet object (or view object, since it implements RowSet, as well for its default RowSet).

Table D-4 describes the operations that you can perform on a row set using the RowSet interface.

Table D-4 RowSet Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSet interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Set a WHERE clause bind variable value</td>
<td>setWhereClauseParams()</td>
</tr>
<tr>
<td>Notes: Bind variable ordinal positions are zero-based.</td>
<td></td>
</tr>
<tr>
<td>Avoid view object row caching if data is being read only once</td>
<td>setForwardOnly()</td>
</tr>
</tbody>
</table>
Table D-4  (Cont.) RowSet Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSet interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Force a row set's query to be (re)executed (in the case of exclusive view object instances) or potentially executed (in the case of shared view object instances)</td>
<td><code>executeQuery()</code></td>
</tr>
</tbody>
</table>

**Notes:**
The behavior of this method differs depending on whether the view object belongs to a shared application module or not. When reexecuting the query for an exclusive view object (not an instance of a shared module), a new query collection is created. Before executing the query for a shared view object instance, a check is performed to determine whether the results already exist. Already cached results will be reused for the shared view object instance instead of reexecuting the query. If you want to ensure that the results for a shared view object instance are refreshed, you can invoke the `forceExecuteQueryOfSharedVO()` method. However, if at the time of invoking force execute a user is iterating over the collection of a shared view object instance, then the behavior is undefined and exceptions may result.

- Estimate the number of rows in a view object's query result: `getEstimatedRowCount()`
- Produce an XML document for rows in a view object row set: `writeXML()`
- Process all rows from an incoming XML document: `readXML()`
- Set whether a row set will automatically see new rows based on the same entity object created through other row sets: `setAssociationConsistent()`
- Create a secondary iterator to use for programmatic iteration: `createRowSetIterator()`

**Notes:**
If you plan to find and use the secondary iterator by name later, then pass in a string name as the argument; otherwise, pass null for the name and make sure to close the iterator when done iterating by calling its `closeRowSetIterator()` method.

D.2.5 RowSetIterator Interface

A row set iterator is an iterator over the rows in a row set. By default it allows you to iterate both forward and backward through the rows. Table D-5 describes the operations that you can perform on a row set using the `RowSetIterator` interface.
### Table D-5  RowSetIterator Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSetIterator interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the first row of the iterator's row set</td>
<td><code>first()</code></td>
</tr>
<tr>
<td>Test whether there are more rows to iterate</td>
<td><code>hasNext()</code></td>
</tr>
<tr>
<td>Get the next row of an iterator's row set</td>
<td><code>next()</code></td>
</tr>
<tr>
<td>Find a row in this iterator's row set with a given key value</td>
<td><code>findByKey()</code></td>
</tr>
<tr>
<td></td>
<td>Notes: It's important that the Key object that you pass to <code>findByKey</code> be created using the exact same data types as the attributes that comprise the key of the rows in the view object you're working with.</td>
</tr>
<tr>
<td>Create a new row to populate for insertion</td>
<td><code>createRow()</code></td>
</tr>
<tr>
<td></td>
<td>Notes: The new row will already have default values set for attributes which either have a static default value supplied at the entity object or view object level, or if the values have been populated in an overridden <code>create()</code> method of the underlying entity object(s).</td>
</tr>
<tr>
<td>Create a view row with an initial set of foreign key and/or discriminator attribute values</td>
<td><code>createAndInitRow()</code></td>
</tr>
<tr>
<td></td>
<td>Notes: You use this method when working with view objects that can return one of a &quot;family&quot; of entity object subtypes. By passing in the correct discriminator attribute value in the call to create the row, the framework can create you the correct matching entity object subtype underneath.</td>
</tr>
<tr>
<td>Insert a new row into the iterator's row set</td>
<td><code>insertRow()</code></td>
</tr>
<tr>
<td></td>
<td>Notes: It's a good habit to always immediately insert a newly created row into the rowset. That way you will avoid a common gotcha of creating the row but forgetting to insert it into the rowset.</td>
</tr>
<tr>
<td>Get the last row of the iterator's row set</td>
<td><code>last()</code></td>
</tr>
<tr>
<td>Get the previous row of the iterator's row set</td>
<td><code>previous()</code></td>
</tr>
<tr>
<td>Reset the current row pointer to the slot before the first row</td>
<td><code>reset()</code></td>
</tr>
<tr>
<td>Close an iterator when done iterating</td>
<td><code>closeRowSetIterator()</code></td>
</tr>
<tr>
<td>Set a given row to be the current row</td>
<td><code>setCurrentRow()</code></td>
</tr>
<tr>
<td>Remove the current row</td>
<td><code>removeCurrentRow()</code></td>
</tr>
</tbody>
</table>
Table D-5  (Cont.) RowSetIterator Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this RowSetIterator interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Remove the current row to later insert it at a different location in the same iterator</td>
<td>removeCurrentRowAndRetain()</td>
</tr>
<tr>
<td>Remove the current row from the current collection but do not remove it from the transaction.</td>
<td>removeCurrentRowFromCollection()</td>
</tr>
<tr>
<td>Set/change the number of rows in the range (a &quot;page&quot; of rows the user can see)</td>
<td>setRangeSize()</td>
</tr>
<tr>
<td>Scroll to view the \textit{n}th page of rows (1-based)</td>
<td>scrollToRangePage()</td>
</tr>
<tr>
<td>Scroll to view the range of rows starting with row number \textit{n}</td>
<td>scrollRangeTo()</td>
</tr>
<tr>
<td>Set row number \textit{n} in the range to be the current row</td>
<td>setCurrentRowAtRangeIndex()</td>
</tr>
<tr>
<td>Get all rows in the range as a row array</td>
<td>getAllRowsInRange()</td>
</tr>
</tbody>
</table>

D.2.6 Row Interface

A row is generic value object. It contains attributes appropriate in name and Java type for the view object that it is related to. Table D-6 describes the operations that you can perform on a view object row using the Row interface.

Table D-6  Row Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this Row interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the value of an attribute by name</td>
<td>getAttribute()</td>
</tr>
<tr>
<td>Set the value of an attribute by name</td>
<td>setAttribute()</td>
</tr>
<tr>
<td>Produce an XML document for a single row</td>
<td>writeXML()</td>
</tr>
<tr>
<td>Eagerly validate a row</td>
<td>validate()</td>
</tr>
<tr>
<td>Read row attribute values from XML</td>
<td>readXML()</td>
</tr>
<tr>
<td>Remove the row</td>
<td>remove()</td>
</tr>
<tr>
<td>Flag a newly created row as temporary (until updated again)</td>
<td>setNewRowState(Row.STATUS_INITIALIZED)</td>
</tr>
<tr>
<td>Retrieve the attribute structure definition information for a row</td>
<td>getStructureDef()</td>
</tr>
<tr>
<td>Get the Key object for a row</td>
<td>getKey()</td>
</tr>
</tbody>
</table>

In addition to generic Row access, JDeveloper can generate a custom \texttt{YourViewObjectNameRow} interface containing your type-safe attribute getter and setter methods, as well as any desired row-level custom methods that you've chosen to expose to the client. You use the Client Row Interface page of the Edit View Object dialog to select the methods that you want to appear in your client interface.
D.2.7 StructureDef Interface

The StructureDef interface provides access to runtime metadata about the structure of a Row object.

In addition, for convenience every view object implements the StructureDef interface as well, providing access to metadata about the attributes in the resulting view rows that its query will produce.

Table D-7 describes the operations that you can perform on a view object row using the StructureDef interface.

<table>
<thead>
<tr>
<th>If you want to…</th>
<th>Call this StructureDef interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Access attribute definitions for all attributes in the view object row</td>
<td>getAttributeDefs()</td>
</tr>
<tr>
<td>Find an attribute definition by name</td>
<td>findAttributeDef()</td>
</tr>
<tr>
<td>Get attribute definition by index</td>
<td>getAttributeDef()</td>
</tr>
<tr>
<td>Get number of attributes in a row</td>
<td>getAttributeCount()</td>
</tr>
</tbody>
</table>

D.2.8 AttributeDef Interface

The AttributeDef interface provides attribute definition information for any attribute of a view object row or entity object instance like attribute name, Java type, and SQL type. It also provides access to custom attribute-specific metadata properties that can be inspected by generic code you write, as well as UI hints that can assist in rendering an appropriate user interface display for the attribute and its value. Table D-8 describes the operations that you can perform on an attribute using the AttributeDef interface.

<table>
<thead>
<tr>
<th>If you want to…</th>
<th>Call this AttributeDef interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the Java type of the attribute</td>
<td>getJavaType()</td>
</tr>
<tr>
<td>Get the SQL type of the attribute</td>
<td>getSQLType()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>The int value corresponds to constants in the JDBC class java.sql.Types.</td>
<td></td>
</tr>
<tr>
<td>Determine the kind of attribute</td>
<td>getAttributeKind()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>A simple attribute is one that returns one of the constants ATTR_PERSISTENT, ATTR_SQL_DERIVED, ATTR_TRANSIENT, ATTR_DYNAMIC, ATTR_ENTITY_DERIVED. If the attribute is a 1-to-1 or many-to-1 association/viewlink accessor, it returns ATTR_ASSOCIATED_ROW. If the attribute is a 1-to-many or many-to-many association/viewlink accessor, it returns ATTR_ASSOCIATED_ROW_ITERATOR.</td>
<td></td>
</tr>
</tbody>
</table>
Table D-8  (Cont.) AttributeDef Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this AttributeDef interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the Java type of elements contained in an</td>
<td>getElemJavaType()</td>
</tr>
<tr>
<td>Array-valued attribute</td>
<td></td>
</tr>
<tr>
<td>Get the SQL type of elements contained in an Array-</td>
<td>getElemSQLType()</td>
</tr>
<tr>
<td>valued attribute</td>
<td></td>
</tr>
<tr>
<td>Get the name of the attribute</td>
<td>getName()</td>
</tr>
<tr>
<td>Get the index position of the attribute</td>
<td>getIndex()</td>
</tr>
<tr>
<td>Get the precision of a numeric attribute or the</td>
<td>getPrecision()</td>
</tr>
<tr>
<td>maximum length of a string attribute</td>
<td></td>
</tr>
<tr>
<td>Get the scale of a numeric attribute</td>
<td>getScale()</td>
</tr>
<tr>
<td>Get the underlying column name corresponding to the</td>
<td>getColumnNameForQuery()</td>
</tr>
<tr>
<td>attribute</td>
<td></td>
</tr>
<tr>
<td>Get attribute-specific custom property values</td>
<td>getProperty(), getProperties()</td>
</tr>
<tr>
<td>Get the UI AttributeHints object for the attribute</td>
<td>getUIHelper()</td>
</tr>
<tr>
<td>Test whether the attribute is mandatory</td>
<td>isMandatory()</td>
</tr>
<tr>
<td>Test whether the attribute is queriable</td>
<td>isQueriable()</td>
</tr>
<tr>
<td>Test whether the attribute is part of the primary key</td>
<td>isPrimaryKey()</td>
</tr>
<tr>
<td>for the row</td>
<td></td>
</tr>
</tbody>
</table>

D.2.9 AttributeHints Interface

The AttributeHints interface exposes UI hint information that you can use to render an appropriate user interface display for the attribute and its value. Table D-9 describes the operations that you can perform on an attribute using the AttributeHints interface.

Table D-9  AttributeHints Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this AttributeHints interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the UI label for the attribute</td>
<td>getLabel()</td>
</tr>
<tr>
<td>Get the tooltip for the attribute</td>
<td>getTooltip()</td>
</tr>
<tr>
<td>Get the formatted value of the attribute, using any</td>
<td>getFormattedAttribute()</td>
</tr>
<tr>
<td>format mask supplied</td>
<td></td>
</tr>
<tr>
<td>Get the display hint for the attribute</td>
<td>getDisplayHint()</td>
</tr>
<tr>
<td>Notes: The display hint will have a string value of</td>
<td></td>
</tr>
<tr>
<td>either Display or Hide.</td>
<td></td>
</tr>
<tr>
<td>Get the preferred control type for the attribute</td>
<td>getControlType()</td>
</tr>
</tbody>
</table>
### Table D-9  (Cont.) AttributeHints Interface

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this AttributeHints interface method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Parse a formatted string value using any format mask supplied for the attribute</td>
<td>parseFormattedAttribute()</td>
</tr>
</tbody>
</table>

### D.3 Methods Used in the Business Service Tier

The implementation classes corresponding to the oracle.jbo.* interfaces, as described in Methods Used in the Client Tier, are intentionally designed to not be directly accessed by client code. They reside in a different package named oracle.jbo.server.* and have the impl suffix in their name to help remind you not to use them in your client-layer code.

In your business service tier implementation code, you can use any of the same methods that are available to clients, but in addition you can also:

- Safely cast any oracle.jbo.* interface to its oracle.jbo.server.* package implementation class and use any methods on that Impl class as well.
- Override any of the public or protected methods for the base framework implementation classes and write custom code in your component subclass before or after calling super.methodName() to augment or change the default functionality.

This section provides a summary of the most frequently called, written, and overridden methods for the key ADF Business Components classes.

### D.3.1 Controlling Custom Java Files for Your Components

Before examining the specifics of individual classes, it’s important to understand how you can control which custom Java files each of your components will use. When you don’t need a customized subclass for a given component, you can just let the base framework class handle the implementation at runtime.

Each business component you create comprises a single XML component descriptor, and zero or more related custom Java implementation files. Each component that supports Java customization has a Java page in its component overview editor in the JDeveloper IDE. By selecting or deselecting the different Java classes, you control which ones will be created for your component. If none of the classes is specified, then your component will be an XML-only component, which simply uses the base framework class as its Java implementation. Otherwise, tick the checkbox of the related Java classes for the current component that you need to customize. JDeveloper will create a custom subclass of the framework base class in which you can add your code.

**Note:**

You can set up global IDE preferences for the Java classes to be generated by default for each ADF business component type by choosing Tools > Preferences > Business Components and ticking the checkboxes to indicate what you want your defaults to be.
A best practice is to *always* generate entity object and view row classes, even if you don’t require any custom code in them other than the automatically generated getter and setter methods. These getter and setter methods offer you compile-time type checking that prevents errors surfacing at runtime in response to an attribute having been set to an incorrect kind of value.

**D.3.2 ApplicationModuleImpl Class**

The `ApplicationModuleImpl` class is the base class for application module components. Since the application module is the ADF component used to implement a business service, think of the application module class as the place where you can write your service-level application logic. The application module coordinates with view object instances to support updatable collections of value objects that are automatically "wired" to business domain objects. The business domain objects are implemented as ADF entity objects.

**D.3.2.1 Methods You Typically Call on ApplicationModuleImpl**

Table D-10 describes the operations that you can perform on an application module using the `ApplicationModuleImpl` class.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method of the <code>ApplicationModuleImpl</code> class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform any of the common application module operations from inside your class, which can also be done from the client</td>
<td>For a list of these methods, see <code>ApplicationModule Interface</code>.</td>
</tr>
<tr>
<td>Access a view object instance that you added to the application module’s data model at design time</td>
<td><code>getViewObjectInstanceName()</code></td>
</tr>
<tr>
<td>Access the current <code>DBTransaction</code> object</td>
<td><code>getDBTransaction()</code></td>
</tr>
<tr>
<td>Access a nested application module instance that you added to the application module at design time</td>
<td><code>getAppModuleInstanceName()</code></td>
</tr>
</tbody>
</table>

**Notes:**

JDeveloper generates this type-safe view object instance getter method for you to reflect each view object instance in the application module’s design time data model.

**D.3.2.2 Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass**

Table D-11 describes the operations that you can perform on an application module using your custom `ApplicationModuleImpl` class.
### Table D-11  Methods You Typically Write in Your Custom ApplicationModuleImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your custom ApplicationModuleImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Invoke a database stored procedure</strong></td>
<td><code>someCustomMethod()</code></td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td>Use the appropriate method on the <code>DBTransaction</code> interface to create a JDBC <code>PreparedStatement</code>. If the stored procedure has <code>OUT</code> parameters, then create a <code>CallableStatement</code> instead.</td>
</tr>
<tr>
<td></td>
<td>For sample code that demonstrates encapsulating a call to a PL/SQL stored procedure inside your application module, see Invoking Stored Procedures and Functions.</td>
</tr>
<tr>
<td><strong>Expose custom business service methods on your application module</strong></td>
<td><code>someCustomMethod()</code></td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td>Select the method name on the <code>Client Interface</code> page of the Edit Application Module dialog to expose it for client access if required.</td>
</tr>
</tbody>
</table>

JDeveloper can generate a custom `YourApplicationModuleName` interface containing service-level custom methods that you’ve chosen to expose to the client. You can use the `Client Interface` page of the Edit Application Module dialog to select the methods that you want to appear in your client interface.

### D.3.2.3 Methods You Typically Override in Your Custom ApplicationModuleImpl Subclass

Table D-12 describes the operations that you can override on an application module using your custom `ApplicationModuleImpl` class.
<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom ApplicationModuleImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform custom setup code the first time an application module is created and each subsequent time it gets used by a different client session.</td>
<td>prepareSession()</td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td>This is the method you’d use to set up per-client context info for the current user in order to use Oracle's Virtual Private Database (VPD) features. It can also be used to set other kinds of PL/SQL package global variables, whose values might be client-specific, on which other stored procedures might rely.</td>
</tr>
<tr>
<td></td>
<td>This method is also useful to perform setup code that is specific to a given view object instance in the application module. If instead of the view object setup code being instance-specific, you want it to be initialized for every instance ever created of that view object component, then put the setup logic in an overridden create() method in your ViewObjectImpl subclass instead.</td>
</tr>
<tr>
<td>Perform custom setup code after the application module's transaction is associated with a database connection from the connection pool</td>
<td>afterConnect()</td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td>Can be a useful place to write a line of code that uses getDBTransaction().executeCommand() to perform an ALTER SESSION SET SQL TRACE TRUE to enable database SQL trace logging for the current application connection. These logs can then be processed with the TKPROF utility to study the SQL statements being performed and the query optimizer plans that are getting used.</td>
</tr>
<tr>
<td></td>
<td>For details about working with the TKPROF utility, see section “Understanding SQL Trace and TKPROF” in the “Performing Application Tracing” chapter of the .</td>
</tr>
<tr>
<td>Perform custom setup code before the application module's transaction releases its database connection back to the database connection pool</td>
<td>beforeDisconnect()</td>
</tr>
<tr>
<td><strong>Notes:</strong></td>
<td>If you have set jbo.doconnectionpooling to true, then the connection is released to the database connection pool each time the application module is returned to the application module pool.</td>
</tr>
<tr>
<td>Write custom application module state to the state management XML snapshot</td>
<td>passivateState()</td>
</tr>
<tr>
<td>Read and restore custom application module state from the state management XML snapshot</td>
<td>activateState()</td>
</tr>
</tbody>
</table>
D.3.3 DBTransactionImpl2 Class

The DBTransactionImpl2 class — which extends the base DBTransactionImpl class, and is constructed by the DatabaseTransactionFactory class — is the base class that implements the DBTransaction interface, representing the unit of pending work in the current transaction.

D.3.3.1 Methods You Typically Call on DBTransaction

Table D-13 describes the operations that you can perform on a transaction using the DBTransaction class.

Table D-13  Methods You Typically Call on DBTransaction

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method on the DBTransaction class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Commit the transaction</td>
<td>commit()</td>
</tr>
<tr>
<td>Roll back the transaction</td>
<td>rollback()</td>
</tr>
<tr>
<td>Eagerly validate any pending invalid changes in the transaction</td>
<td>validate()</td>
</tr>
<tr>
<td>Create a JDBC PreparedStatement using the transaction's Connection object</td>
<td>createPreparedStatement()</td>
</tr>
<tr>
<td>Create a JDBC CallableStatement using the transaction's Connection object</td>
<td>createCallableStatement()</td>
</tr>
<tr>
<td>Create a JDBC Statement using the transaction's Connection object</td>
<td>createStatement()</td>
</tr>
<tr>
<td>Add a warning to the transaction's warning list</td>
<td>addWarning()</td>
</tr>
</tbody>
</table>

D.3.3.2 Methods You Typically Override in Your Custom DBTransactionImpl2 Subclass

Table D-14 describes the operations that you can perform on a transaction using your custom DBTransactionImpl2 subclass.

Table D-14  Methods You Typically Override in Your Custom DBTransactionImpl2 Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom DBTransactionImpl2 class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform custom code before or after the transaction commit operation</td>
<td>commit()</td>
</tr>
<tr>
<td>Perform custom code before or after the transaction rollback operation</td>
<td>rollback()</td>
</tr>
</tbody>
</table>

In order for your custom DBTransactionImpl2 subclass to be used at runtime, there are steps you must follow:

1. Create a custom subclass of DatabaseTransactionFactory that overrides the create method to return an instance of your custom DBTransactionImpl2 subclass like this:
public class CustomDatabaseTransactionFactory extends DatabaseTransactionFactory {
    /**
     * Return an instance of our custom CustomDBTransactionImpl class
     * instead of the default implementation.
     * @return An instance of our custom DBTransactionImpl2 implementation.
     */
    public DBTransactionImpl2 create() {
        return new CustomDBTransactionImpl();
    }
}

2. Tell the framework to use your custom transaction factory class by setting the value of the TransactionFactory configuration property to the fully qualified class name of your custom transaction factory. As with other configuration properties, if not supplied in the configuration XML file, it can be provided alternatively as a Java system parameter of the same name.

D.3.4 EntityImpl Class

The EntityImpl class is the base class for entity objects, which encapsulate the data, validation rules, and business behavior for your business domain objects.

D.3.4.1 Methods You Typically Call on EntityImpl

Table D-15 describes the operations that you can perform on an entity object using the EntityImpl class.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in the EntityImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Get the value of an attribute</td>
<td><code>getAttributeName()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>This code-generated getter method calls <code>getAttributeInternal()</code>, but provides compile-time type checking.</td>
</tr>
<tr>
<td>Set the value of an attribute</td>
<td><code>setAttributeName()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>This code-generated setter method calls <code>setAttributeInternal()</code>, but provides compile-time type checking.</td>
</tr>
<tr>
<td>Get the value of an attribute by name</td>
<td><code>getAttributeInternal()</code></td>
</tr>
<tr>
<td>Set the value of an attribute by name</td>
<td><code>setAttributeInternal()</code></td>
</tr>
<tr>
<td>Eagerly perform entity object validation</td>
<td><code>validate()</code></td>
</tr>
<tr>
<td>Refresh the entity from the database</td>
<td><code>refresh()</code></td>
</tr>
</tbody>
</table>
Table D-15  (Cont.) Methods You Typically Call on EntityImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in the EntityImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Populate the value of an attribute without marking it as being changed, but sending notification of its being changed so that the UI refreshes the value on the screen/page</td>
<td>populateAttributeAsChanged()</td>
</tr>
<tr>
<td>Access the Definition object for an entity</td>
<td>getDefinitionObject()</td>
</tr>
<tr>
<td>Get the Key object for an entity</td>
<td>getKey()</td>
</tr>
<tr>
<td>Determine the state of the entity instance, irrespective of whether it has already been posted (but not yet committed) in the current transaction</td>
<td>getEntityState()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This method will return one of the constants STATUS_UNMODIFIED, STATUS_INITIALIZED, STATUS_NEW, STATUS_MODIFIED, STATUS_DELETED, or STATUS_DEAD, indicating the status of the entity instance in the current transaction.</td>
</tr>
<tr>
<td>Determine the state of the entity instance</td>
<td>getPostState()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This method is typically relevant only if you are programmatically using the postChanges() method to post but not yet commit, entity changes to the database and need to detect the state of an entity with regard to its posting state.</td>
</tr>
<tr>
<td>Get the value originally read from the database for a given attribute</td>
<td>getPostedAttribute()</td>
</tr>
<tr>
<td>Eagerly lock the database row for an entity instance</td>
<td>lock()</td>
</tr>
</tbody>
</table>

D.3.4.2 Methods You Typically Write in Your Custom EntityImpl Subclass

Table D-16 describes the operations that you can perform on an entity object using your custom EntityImpl subclass.

Table D-16  Methods You Typically Write in Your Custom EntityImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your custom EntityImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform attribute-specific validation</td>
<td>public boolean validateSomething(AttrType value)</td>
</tr>
<tr>
<td>Notes:</td>
<td>Register the attribute validator method by adding a MethodValidator rule on the correct attribute in the Validation page of the Edit Entity Object dialog.</td>
</tr>
</tbody>
</table>
### Table D-16  (Cont.) Methods You Typically Write in Your Custom EntityImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your custom EntityImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform entity-level validation</td>
<td><code>public boolean validateSomething()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>Register the entity-level validator method by adding a MethodValidator rule on the entity in the Validation panel of the Edit Entity Object dialog.</td>
</tr>
<tr>
<td>Calculate the value of a transient attribute</td>
<td>Add your calculation code to the generated <code>getAttributeName()</code> method.</td>
</tr>
</tbody>
</table>

### D.3.4.3 Methods You Typically Override in Your Custom EntityImpl Subclass

**Table D-17** describes the operations that you can override on an entity object using your custom `EntityImpl` subclass.

#### Table D-17  Methods You Typically Override in Your Custom EntityImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your EntityImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Set calculated default attribute values, including programmatically populating the primary key attribute value of a new entity instance</td>
<td><code>create()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>After calling <code>super.create()</code>, call the appropriate <code>setAttrName()</code> method(s) to set the default values for the attributes.</td>
</tr>
<tr>
<td>Modify attribute values before changes are posted to the database</td>
<td><code>prepareForDML()</code></td>
</tr>
<tr>
<td>Augment or change the standard INSERT, UPDATE, or DELETE DML operation that the framework will perform on your entity object's behalf to the database</td>
<td><code>doDML()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>This method checks the value of the operation flag to the constants <code>DML_INSERT</code>, <code>DML_UPDATE</code>, or <code>DML_DELETE</code> to test what DML operation is being performed.</td>
</tr>
<tr>
<td>Perform complex, SQL-based validation after all entity instances have been posted to the database but before those changes are committed</td>
<td><code>beforeCommit()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>This method is invoked for each entity row in the transaction.</td>
</tr>
<tr>
<td>Perform custom processing after all entity instances have been committed to the database</td>
<td><code>afterCommit()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>This method is invoked for each entity row in the transaction list of pending changes.</td>
</tr>
</tbody>
</table>
Table D-17 (Cont.) Methods You Typically Override in Your Custom EntityImpl Subclass

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your EntityImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Insure that a related, newly created, parent entity gets posted to the database before the current child entity on which it depends</td>
<td>postChanges()</td>
</tr>
<tr>
<td>Notes:</td>
<td>- If the parent entity is related to this child entity via a composition association, then the framework already handles posting the changes automatically. If they are only associated (but not composed), then you need to override postChanges() to force a newly created parent entity to post before the current, dependent child entity. For an example of the code you typically write in your overridden postChanges() method to accomplish this, see Overriding postChanges() to Control Post Order.</td>
</tr>
<tr>
<td>Programmaticalll...</td>
<td>initDefaultExpressionAttributes()</td>
</tr>
<tr>
<td>Notes:</td>
<td>- This method is invoked just before the end of the initialization cycle, which makes it suitable for executing custom code.</td>
</tr>
</tbody>
</table>

**Note:**

It is possible to write attribute-level validation code directly inside the appropriate `setAttributeName` method of your EntityImpl class; however, adopting the `MethodValidator` approach suggested in Table D-16 conveniently places all the validations in effect on the Validation Rules page of the overview editor for the attributes of the entity object.

**Warning:**

It is also possible to override the `validateEntity()` method to write entity-level validation code; however, if you want to maintain the benefits of the ADF bundled exception mode — where the framework collects and reports a maximal set of validation errors back to the client user interface — use the `MethodValidator` approach suggested in Table D-16. This allows the framework to automatically collect all of your exceptions that your validation methods throw without your having to understand the bundled exception implementation mechanism. Overriding the `validateEntity()` method directly shifts the responsibility onto your `own` code to correctly catch and bundle the exceptions that Oracle ADF would have caught by default, which is nontrivial and a chore to remember and hand-code each time.

**D.3.5 EntityDefImpl Class**

The `EntityDefImpl` class is a singleton, shared metadata object for all entity objects of a given type in a single Java VM. For instance, if the Java VM contains two instances
of the EntityDefImpl class, one with the customers XML data and one with the orders, there would only ever be one instance of each. This class defines the structure of the entity instances and provides methods to create new entity instances and find existing instances by their primary key.

D.3.5.1 Methods You Typically Call on EntityDefImpl

Table D-18 describes the operations that you can perform on an entity object using the EntityDefImpl class.

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in the EntityDefImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Find an entity object of a given type by its primary key</td>
<td>findByPrimaryKey()</td>
</tr>
<tr>
<td>Notes:</td>
<td>For a tip about getting <code>findByPrimaryKey()</code> to find entity instances of subtype entities as well, see Subtype Entity Objects and the <code>findByPrimaryKey()</code> Method.</td>
</tr>
<tr>
<td>Access the current DBTransaction object</td>
<td>getDBTransaction()</td>
</tr>
<tr>
<td>Find any EntityDefImpl object by its fully qualified name</td>
<td>findDefObject() (static method)</td>
</tr>
<tr>
<td>Retrieve the value of an entity object's custom property</td>
<td>getProperty(), getProperties()</td>
</tr>
<tr>
<td>Set the value of an entity object's custom property</td>
<td>setProperty()</td>
</tr>
<tr>
<td>Create a new instance of an entity object</td>
<td>createInstance2()</td>
</tr>
<tr>
<td>Notes:</td>
<td>Alternatively, you can expose custom <code>createXXX()</code> methods with your own expected signatures in that same custom EntityDefImpl subclass. See Methods You Typically Write in Your Custom EntityDefImpl Class for details.</td>
</tr>
</tbody>
</table>

| Iterating over the entity instances in the cache of this entity type | getAllEntityInstancesIterator() |
| Access an array list of entity definition objects for entities that extend the current one. | getExtendedDefObjects() |

D.3.5.2 Methods You Typically Write in Your Custom EntityDefImpl Class

Table D-19 describes the operations that you can perform on an entity object using your custom EntityDefImpl class.
Table D-19  Methods You Typically Write on EntityDefImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your custom EntityDefImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Allow other classes to create an entity instance with an initial type-safe set of attribute values or setup information</td>
<td><code>createXXX(Type1arg1,..., TypeNargN)</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>Internally, using this method would create and populate an instance of a NameValuePairs object (which implements AttributeList) and call the protected method <code>createInstance()</code>, passing that NameValuePairs object. Make sure that the method is public if other classes need to be able to call it.</td>
</tr>
</tbody>
</table>

D.3.5.3 Methods You Typically Override in Your Custom EntityDefImpl
d

Table D-20 describes the operations that you can perform on an entity object using the EntityDefImpl class.

Table D-20  Methods You Typically Override on EntityDefImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom EntityDefImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform custom metadata initialization when this singleton metaobject is loaded</td>
<td><code>createDef()</code></td>
</tr>
<tr>
<td>Avoid using the RETURNING INTO clause to support refresh-on-insert or refresh-on-update attributes</td>
<td><code>isUseReturningClause()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>Set this method to return false to disable the use of RETURNING INTO, necessary sometimes when your entity object is based on a view with INSTEAD OF triggers that don’t support RETURNING INTO at the database level.</td>
</tr>
<tr>
<td>Control whether the UPDATE statements issued for this entity update only changed columns or for all columns</td>
<td><code>isUpdateChangedColumns()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>Defaults to true.</td>
</tr>
<tr>
<td>Find any EntityDefImpl object by its fully qualified name</td>
<td><code>findDefObject()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>Static method.</td>
</tr>
<tr>
<td>Set the value of an entity object’s custom property</td>
<td><code>setProperty()</code></td>
</tr>
</tbody>
</table>
Table D-20 (Cont.) Methods You Typically Override on EntityDefImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom EntityDefImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Allow other classes to create a new instance of an entity object without doing so implicitly via a view object</td>
<td>createInstance()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td>If you don't write a custom create method as noted in Methods You Typically Write in Your Custom EntityDefImpl Class, you'll need to override this method and widen the visibility from protected to public to allow other classes to construct an entity instance.</td>
<td></td>
</tr>
</tbody>
</table>

D.3.6 ViewObjectImpl Class

The ViewObjectImpl class is the base class for view objects.

D.3.6.1 Methods You Typically Call on ViewObjectImpl

Table D-21 describes the operations that you can perform on a view object using the ViewObjectImpl class.

Table D-21 Methods You Typically Call on ViewObjectImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in the ViewObjectImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform any of the common view object, row set, or row set iterator operations from inside your class, which can also be done from the client</td>
<td>For more information about operations at the view object, row set, or row set iterator level, see ViewObject Interface, RowSet Interface, and RowSetIterator Interface.</td>
</tr>
<tr>
<td>Search a view instance's in-memory row set without changing the default row set</td>
<td>findByViewCriteria()</td>
</tr>
<tr>
<td>Fetch all the rows from the database and then determine the total row count in the view object row set</td>
<td>getRowCount()</td>
</tr>
<tr>
<td>Notes:</td>
<td>Use this method carefully: Performance may be affected when a large number of rows is involved.</td>
</tr>
<tr>
<td>Determine the total number of rows in view object row set after each invocation by the client</td>
<td>getQueryHitCount()</td>
</tr>
<tr>
<td>Determine the total number of rows in the view object row set</td>
<td>getEstimatedRowCount()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This is the preferred way to find row count since it requires only one database query (after the count is obtained, it will be maintained as rows are added and removed).</td>
</tr>
<tr>
<td>Execute a count query but with a cap argument to manage execution in the case where a large number of rows may affect performance</td>
<td>getCappedQueryHitCount()</td>
</tr>
<tr>
<td>If you want to...</td>
<td>Call this method in the ViewObjectImpl class</td>

<tr>
<td>------------------------------------------------------</td>
<td>-----------------------------------------------</td>
</tr>
<tr>
<td>Define a named bind parameter</td>
<td><code>defineNamedWhereClauseParam()</code></td>
</tr>
<tr>
<td>Remove a named bind parameter</td>
<td><code>removeNamedWhereClauseParam()</code></td>
</tr>
<tr>
<td>Set bind variable values on the default row set by name</td>
<td><code>setNamedWhereClauseParam()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>Only works when you have formally defined named bind variables on your view object.</td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>Set bind variable values on the default row set</td>
<td><code>setWhereClauseParams()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>Use this method for view objects with binding style of &quot;Oracle Positional&quot; or &quot;JDBC Positional&quot; when you have not formally defined named bind variables.</td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>Retrieve a subset of rows in a view object's row set based on evaluating an in-memory filter expression</td>
<td><code>getFilteredRows()</code></td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>Retrieve a subset of rows in the current range of a view object's row set based on evaluating an in-memory filter expression</td>
<td><code>getFilteredRowsInRange()</code></td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>Override the runtime display of criteria items that appear inside an ADF query component. Subclasses may override to return custom <code>AttributeHints</code> implementation for the given criteria item. Returns null by default.</td>
<td><code>getCriteriaItemAttributeHints()</code></td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
<tr>
<td>Set the number of rows that will be fetched from the database per roundtrip for this view object</td>
<td><code>setFetchSize()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>The default fetch size is a single row at a time. This is definitely not optimal if your view object intends to retrieve many rows, so you should either set the fetch size higher at design time on the Tuning page of the Edit View Object dialog, or set it at runtime using this method.</td>
</tr>
</tbody>
</table>
### Table D-21  (Cont.) Methods You Typically Call on ViewObjectImpl

<table>
<thead>
<tr>
<th>If you want to…</th>
<th>Call this method in the ViewObjectImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Force a row set's query to be (re)executed specifically on a lookup view object instance in a shared application module</td>
<td>forceExecuteQueryOfSharedVO()</td>
</tr>
</tbody>
</table>

**Notes:**
Reexecuting the query forces a new query collection and will prevent the application module cache from being used. You should only use this method when you are sure that you are accessing the shared application module during setup and not during runtime. This method when used during normal runtime may have unintended side-effects that disrupt the navigation of users accessing the collection concurrently. If you want to refresh the collection from the cache without creating a new query collection, call executeQuery() instead.

### D.3.6.2 Methods You Typically Write in Your Custom ViewObjectImpl Subclass

Table D-22 describes the operations that you can perform on a view object using your custom ViewObjectImpl subclass.

### Table D-22  Methods You Typically Write in Your Custom ViewObjectImpl Subclass

<table>
<thead>
<tr>
<th>If you want to…</th>
<th>Write a method like this in your custom ViewObjectImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Provide clients with type-safe methods to set bind variable values without exposing positional details of the bind variables themselves</td>
<td>someMethodName(Type1arg1,..., TypeNargN)</td>
</tr>
</tbody>
</table>

**Notes:**
Internally, this method would call the setWhereClauseParams() method to set the correct bind variables with the values provided in the type-safe method arguments.

JDeveloper can generate a custom YourViewObjectName interface containing view object custom methods that you've chosen to expose to the client. You can use the Client Interface page of the Edit View Object to select the methods that you want to appear in your client interface.

### D.3.6.3 Methods You Typically Override in Your Custom ViewObjectImpl Subclass

Table D-23 describes the operations that you can perform on a view object using your custom ViewObjectImpl subclass.
<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Override this method in your custom ViewObjectImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initialize custom view object class members (not row attributes) when the view object instance is created for the first time</td>
<td>create()</td>
</tr>
<tr>
<td>Notes:</td>
<td>This method is useful to perform set up logic that is applicable to every instance of a view object that will ever get created, in the context of any application module.</td>
</tr>
<tr>
<td></td>
<td>If instead of <em>generic</em> view object setup logic, you need to perform logic specific to a given view object <em>instance</em> in an application module, then override the <code>prepareSession()</code> method of your application module's ApplicationModuleImpl subclass and perform the logic there after calling <code>findViewObject()</code> to find the view object instance whose properties you want to set.</td>
</tr>
<tr>
<td>Write custom view object instance state to the state management XML snapshot</td>
<td><code>passivateState()</code></td>
</tr>
<tr>
<td>Read and restore custom view object instance state from the state management XML snapshot</td>
<td><code>activateState()</code></td>
</tr>
<tr>
<td>Customize the execution of the view object query to utilize an alternative data source</td>
<td><code>executeQueryForCollection()</code></td>
</tr>
<tr>
<td>Notes:</td>
<td>By default view objects read their data from the database and automate the task of working with the JDBC layer to process the database result sets. However, by overriding appropriate methods in its custom Java class, you can create a view object that programmatically retrieves data from alternative data sources, as described in Using Programmatic View Objects for Alternative Data Sources.</td>
</tr>
<tr>
<td></td>
<td>It is not correct to override <code>executeQueryForCollection()</code> to make changes to WHERE clauses and parameters. By the time the method is called, ADF Business Components assumes that the parameters are already calculated and that row filters are constructed. If you change the query before it gets executed each time, ADF Business Components could never reuse an existing cached statement handle. Instead, when you want to specify bind parameters before the query is executed, you can override <code>prepareRowSetForQuery()</code> on ViewObjectImpl since it provides access to the row set that is being executed.</td>
</tr>
<tr>
<td>If you want to...</td>
<td>Override this method in your custom ViewObjectImpl subclass</td>
</tr>
<tr>
<td>---------------------------------------------------------------------------------</td>
<td>-------------------------------------------------------------</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and determine whether the query collection has more rows to fetch from the query execution.</td>
<td>hasNextForCollection()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and log bind parameter names and values used in the query.</td>
<td>bindParametersForCollection()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and populate each row of the retrieved data.</td>
<td>createRowFromResultSet()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and return a count of the number of rows that will be retrieved.</td>
<td>getQueryHitCount()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and to determine whether the query would return more rows than the capped value specified by a global row fetch limit.</td>
<td>getCappedQueryHitCount()</td>
</tr>
<tr>
<td>Customize the programmatic view object to access the row set that is being executed and change the view object WHERE clause and specify bind parameter values before the query is executed. This is the recommended hook point for overriding query and setting bind parameters. This method is invoked by the framework every time a row set is about to be executed.</td>
<td>prepareRowSetForQuery()</td>
</tr>
<tr>
<td>Customize the programmatic view object to utilize an alternative data source and release any resources that may be associated with a row set that is being closed.</td>
<td>releaseUserDataForCollection()</td>
</tr>
<tr>
<td>Change or augment the way that the ViewCriteria collection of ViewCriteriaRows is converted into a Query-by-Example WHERE clause.</td>
<td>getViewCriteriaClause(boolean)</td>
</tr>
<tr>
<td>Customize the programmatic view object to implement range paging.</td>
<td>buildRangePagingQuery()</td>
</tr>
<tr>
<td>Customize the programmatic view object to implement range paging and pass in parameters to control the range start and size for the current range of rows to fetch from a data source.</td>
<td>bindRangePagingParams()</td>
</tr>
</tbody>
</table>
D.3.7 ViewRowImpl Class

The ViewRowImpl class is the base class for view row objects.

D.3.7.1 Methods You Typically Call on ViewRowImpl

Table D-24 describes the operations that you can perform on a view object row using your custom ViewRowImpl class.

Table D-24  Methods You Typically Call on ViewRowImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Call this method in your custom ViewRowImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Perform any of the common view row operations from inside your class, which can also be done from the client</td>
<td>For more information about the row-level operations, see Row Interface.</td>
</tr>
<tr>
<td>Get the value of an attribute</td>
<td>getAttrName()</td>
</tr>
<tr>
<td>Set the value of an attribute</td>
<td>setAttrName()</td>
</tr>
<tr>
<td>Access the underlying entity instance to which this view row is delegating attribute storage</td>
<td>getEntityUsageAliasName()</td>
</tr>
<tr>
<td>Notes:</td>
<td>You can change the name of the entity usage alias name on the Entity Objects page of the Edit View Object dialog.</td>
</tr>
</tbody>
</table>

D.3.7.2 Methods You Typically Write in Your Custom ViewRowImpl Class

Table D-25 describes the operations that you can perform on a view object row using your custom ViewRowImpl class.

Table D-25  Methods You Typically Write on ViewRowImpl

<table>
<thead>
<tr>
<th>If you want to...</th>
<th>Write a method like this in your custom ViewRowImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Calculate the value of a view object-level transient attribute</td>
<td>getAttrName()</td>
</tr>
<tr>
<td>Notes:</td>
<td>JDeveloper generates the skeleton of the method for you, but you need to write the custom calculation logic inside the method body.</td>
</tr>
<tr>
<td>Perform custom processing of the setting of a view row attribute</td>
<td>setAttrName()</td>
</tr>
<tr>
<td>Notes:</td>
<td>JDeveloper generates the skeleton of the method for you, but you need to write the custom logic inside the method body if required.</td>
</tr>
<tr>
<td>Determine the updateability of an attribute in a conditional way</td>
<td>isAttributeUpdateable()</td>
</tr>
</tbody>
</table>
Table D-25  (Cont.) Methods You Typically Write on ViewRowImpl

<table>
<thead>
<tr>
<th>If you want to…</th>
<th>Write a method like this in your custom ViewRowImpl class</th>
</tr>
</thead>
<tbody>
<tr>
<td>Expose logical operations on the current row, optionally callable by clients</td>
<td>doSomething()</td>
</tr>
<tr>
<td>Notes:</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Often these view-row-level custom methods simply turn around and delegate to a method call on the underlying entity object related to the current row.</td>
</tr>
</tbody>
</table>

JDeveloper can generate a custom YourViewObjectNameRow interface containing view row custom methods that you’ve chosen to expose to the client. You can use the Client Row Interface page of the Edit View Object dialog to select the methods that you want to appear in your client interface.

D.3.7.3 Methods You Typically Override in Your Custom ViewRowImpl Subclass

Table D-26 describes the operations that you can perform on a view object row using your custom ViewRowImpl subclass.

Table D-26  Methods You Typically Override in Your Custom ViewRowImpl Subclass

<table>
<thead>
<tr>
<th>If you want to…</th>
<th>Write a method like this in your ViewRowImpl subclass</th>
</tr>
</thead>
<tbody>
<tr>
<td>Determine the updateability of an attribute in a conditional way</td>
<td>isAttributeUpdateable()</td>

</tbody>
</table>

ADF Business Components Java EE Design Pattern Catalog

This appendix summarizes the Java Platform, Enterprise Edition (Java EE) design patterns that ADF Business Components implements for you.

By using the Oracle Application Development Framework’s business components building-blocks and related design time extensions to JDeveloper, you get a prescriptive architecture for building richly functional and cleanly layered Java EE business services with great performance.

**Table E-1** provides a brief overview of the numerous design patterns that the ADF Business Components layer implements for you. Some are the familiar patterns from Sun’s Java EE BluePrints and some are design patterns that ADF Business Components adds to the list. For details about Java EE BluePrints, see the BluePrints page at the Oracle Technology Network website at [http://www.oracle.com/technetwork/java/index-jsp-136701.html](http://www.oracle.com/technetwork/java/index-jsp-136701.html).

**Table E-1  Java EE Design Patterns Implemented by ADF Business Components**

<table>
<thead>
<tr>
<th>Pattern Name and Description</th>
<th>How ADF Business Components Implements It</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model/View/Controller</td>
<td>The ADF application module provides a generic implementation of a Model/View/Controller &quot;application object&quot; that simplifies exposing the application data model for any application or service, and facilitates declaratively specifying the boundaries of a logical unit of work. Additional UI-centric frameworks and tag libraries provided in JDeveloper help you implement the view and controller layers.</td>
</tr>
<tr>
<td>Interface / Implementation Separation</td>
<td>ADF Business Components enforces a logical separation of client-tier accessible functionality (via interfaces) and its business tier implementation. JDeveloper handles the creation of custom interfaces and client proxy classes automatically.</td>
</tr>
</tbody>
</table>

Cleanly separates the roles of data and presentation, allowing multiple types of client displays to work with the same business information.

Cleanly separates the API or Interface for components from their implementation class.
<table>
<thead>
<tr>
<th>Pattern Name and Description</th>
<th>How ADF Business Components Implements It</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Service Locator</strong></td>
<td>ADF application modules are looked up using a simple configuration object which hides the low-level details of finding the service instance behind the scenes. For Fusion web applications, it also hides the implementation of the application module pool usage, a lightweight pool of service components that improves application scalability.</td>
</tr>
<tr>
<td><strong>Inversion of Control</strong></td>
<td>ADF components contain a number of easy-to-override methods that the framework invokes as needed during the course of application processing.</td>
</tr>
<tr>
<td><strong>Dependency Injection</strong></td>
<td>ADF Business Components configures all its components from externalized XML metadata definition files. At runtime, the framework automatically injects dependent objects like view object instances into your application module service component and entity objects into your view rows, implementing lazy loading. It supports runtime factory substitution of components by any customized subclass of that component to simplify onsite application customization scenarios. Much of the ADF Business Components functionality is implemented via dynamic injection of validator and listener subscriptions that coordinate the framework interactions depending on what declarative features have been configured for each component in their XML metadata.</td>
</tr>
<tr>
<td><strong>Active Record</strong></td>
<td>ADF entity objects handle the database mapping functionality you use most frequently, including inheritance, association, and composition support, so you don’t have to focus on object/relational mapping. They also provide a place to encapsulate both declarative business rules and one-off programmatic business domain.</td>
</tr>
</tbody>
</table>

They also provide a place to encapsulate both declarative business rules and one-off programmatic business domain.</td>
</tr>
<tr>
<td>Pattern Name and Description</td>
<td>How ADF Business Components Implements It</td>
</tr>
<tr>
<td>------------------------------</td>
<td>------------------------------------------</td>
</tr>
<tr>
<td><strong>Data Access Objects</strong></td>
<td>ADF view objects automate the implementation of data access for reading data using SQL statements. ADF entity objects automate persistent storage of lightweight business entities. ADF view objects and entity objects cooperate to provide a sophisticated, performant data access objects layer, where any data queried through a view object can optionally be made fully updatable without requiring that you write any “application plumbing” code.</td>
</tr>
<tr>
<td><strong>Session Facade</strong></td>
<td>ADF application modules are designed to implement a coarse-grained “service facade” architecture in any of their supported deployment modes. When deployed as a service interface, they provide an implementation of the Session Facade pattern automatically.</td>
</tr>
<tr>
<td><strong>Value Object</strong></td>
<td>ADF Business Components provides an implementation of a generic Row object, which is a metadata-driven container of any number and kind of attributes that need to be accessed by a client. The developer can work with the generic Row interface and do late-bound <code>getAttribute(&quot;Price&quot;)</code> and <code>setAttribute(&quot;Quantity&quot;)</code> calls, or optionally generate early-bound row interfaces like <code>OverdueOrdersRow</code>, to enable type-safe method calls like <code>getPrice()</code> and <code>setQuantity()</code>. Smarter than just a simple “bag ‘o attributes”, the ADF Row object can be introspected at runtime to describe the number, names, and types of the attributes in the row, enabling sophisticated, generic solutions to be implemented.</td>
</tr>
<tr>
<td><strong>Page-by-Page Iterator</strong></td>
<td>ADF Business Components provides an implementation of a generic RowSet interface which manages result sets produced by executing view object SQL queries. The RowSet interface allows you to set a desired page size, for example 10 rows, and page up and down through the query results in these page-sized chunks. Since data is retrieved lazily, only data the user actually visits will ever be retrieved from the database on the backend, and in the client tier the number of rows in the page can be returned over the network in a single roundtrip.</td>
</tr>
<tr>
<td>Pattern Name and Description</td>
<td>How ADF Business Components Implements It</td>
</tr>
<tr>
<td>-----------------------------</td>
<td>------------------------------------------</td>
</tr>
<tr>
<td>Fast-Lane Reader</td>
<td>ADF view objects read data directly from the database for best performance; however, they give you a choice regarding data consistency. If updateability and/or consistency with pending changes is desired, you need only associate your view object with the appropriate entity objects whose business data is being presented. If consistency is not a concern, view objects can simply perform the query with no additional overhead. In either case, you never have to write JDBC data access code. You need only provide appropriate SQL statements in XML descriptors.</td>
</tr>
<tr>
<td>(Bean) Factory</td>
<td>All ADF component instantiation is done based on XML configuration metadata through factory classes allowing runtime substitution of specialized components to facilitate application customization.</td>
</tr>
<tr>
<td>Entity Facade</td>
<td>ADF view objects can surface any set of attributes and methods from any combination of one or more underlying entity objects to furnish the client with a single, logical value object to work with.</td>
</tr>
<tr>
<td>Value Messenger</td>
<td>The ADF Business Components value object implementation coordinates with a client-side value object cache to batch attribute changes to the EJB tier and receive batch attribute updates which occur as a result of middle-tier business logic. The ADF Value Messenger implementation is designed to not require any kind of asynchronous messaging to achieve this effect.</td>
</tr>
<tr>
<td>Continuations</td>
<td>ADF Business Components application module pooling and state management functionality combine to deliver this value-add. Application module pooling eliminates the need to dedicate application server tier resources to individual users and supports a &quot;stateless with user affinity&quot; optimization that you can tune.</td>
</tr>
</tbody>
</table>
ADF Equivalents of Common Oracle Forms Triggers

This appendix provides a summary of how basic tasks performed with the most common Oracle Forms triggers are accomplished using Oracle ADF.

This appendix includes the following sections:

- Validation and Defaulting (Business Logic)
- Query Processing
- Database Connection
- Transaction "Post" Processing (Record Cache)
- Error Handling

F.1 Validation and Defaulting (Business Logic)

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>WHEN-VALIDATE-RECORD</td>
<td>Execute validation code at the record level In the custom EntityImpl class for your entity object, write a public method returning a boolean type with a method name like validateXXXX() and have it return true if the validation succeeds or false if the validation fails. Then, add a Method validator for this validation method to your entity object at the entity level. When doing that, you can associate a validation failure message with the rule.</td>
</tr>
<tr>
<td>WHEN-VALIDATE-ITEM</td>
<td>Execute validation code at the field level In the custom EntityImpl class for your entity object, write a public method returning a boolean type and accepting a single argument of the same data type as your attribute, having a method name like validateXXXX(). Have it return true if the validation succeeds or false if the validation fails. Then, add a Method validator for this validation method to the entity object at the attribute level for the appropriate attribute. When doing that, you can associate a validation failure message with the rule.</td>
</tr>
<tr>
<td>WHEN-DATABASE-RECORD</td>
<td>Override the addToTransactionManager() method of your entity object. Write code after calling the super.</td>
</tr>
</tbody>
</table>
**Table F-1 (Cont.) ADF Equivalents for Oracle Forms Validation and Defaulting Triggers**

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>WHEN-CREATE-RECORD</td>
<td>Override the <code>create()</code> method of your entity object and after calling the super, use appropriate <code>setAttrName()</code> methods to set default values for attributes as necessary. To immediately set a primary key attribute to the value of a sequence, construct an instance of the <code>SequenceImpl</code> helper class and call its <code>getSequenceNumber()</code> method to get the next sequence number. Assign this value to your primary key attribute. If you want to wait to assign the sequence number until the new record is saved, but still without using a database trigger, you can use this technique in an overridden <code>prepareForDML()</code> method in your entity object. If instead you want to assign the primary key from a sequence using your own <code>BEFOREINSERTFOREACHROW</code> database trigger, then use the special data type called <code>DBSequence</code> for your primary key attribute instead of the regular <code>Number</code> type.</td>
</tr>
<tr>
<td>WHEN-REMOVE-RECORD</td>
<td>Override the <code>remove()</code> method of your entity object and write code either before or after calling the super.</td>
</tr>
</tbody>
</table>

**F.2 Query Processing**

**Table F-2 ADF Equivalents for Oracle Forms Query Processing Triggers**

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>PRE-QUERY</td>
<td>Override the <code>executeQueryForCollection()</code> method on your <code>view object</code> class and write code before calling the super.</td>
</tr>
<tr>
<td>ON-COUNT</td>
<td>Override the <code>getQueryHitCount()</code> method in your <code>view object</code> and do something instead of calling the super.</td>
</tr>
</tbody>
</table>
Table F-2  (Cont.) ADF Equivalents for Oracle Forms Query Processing Triggers

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>POST-QUERY</td>
<td>Execute logic after retrieving each row from the data source for a data block. Generally instead of using a POST-QUERY style technique to fetch descriptions from other tables based on foreign key values in the current row, in ADF it's more efficient to build a view object that has multiple participating entity objects, joining in all the information you need in the query from the main table, as well as any auxiliary or lookup-value tables. This way, in a single roundtrip to the database you get all the information you need. If you still need a per-fetched-row trigger like POST-QUERY, override the createInstanceFromResultSet() method in your view object class.</td>
</tr>
<tr>
<td>ON-LOCK</td>
<td>Override default behavior to attempt to acquire a lock on the current row in the data block. Override the lock() method in your entity object class and do something instead of calling the super.</td>
</tr>
</tbody>
</table>

F.3 Database Connection

Table F-3  ADF Equivalents for Oracle Forms Database Connection Triggers

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>POST-LOGON</td>
<td>Execute logic after logging into the database                                Override the afterConnect() method on your custom application module. Since an application module instance can stay connected while serving different logical client sessions, you can override the prepareSession() method, which is fired after initial login, as well as after any time the application module is accessed by a user that was different from the one that accessed it last time.</td>
</tr>
<tr>
<td>PRE-LOGOUT</td>
<td>Execute logic before logging out of the database                             Override the beforeDisconnect() method on your custom application module class.</td>
</tr>
</tbody>
</table>

F.4 Transaction "Post" Processing (Record Cache)

Table F-4  ADF Equivalents for Oracle Forms Transactional Triggers

<table>
<thead>
<tr>
<th>Forms Trigger</th>
<th>ADF Equivalent</th>
</tr>
</thead>
<tbody>
<tr>
<td>PRE-COMMIT</td>
<td>Execute code before commencing processing of the changed rows in all data blocks in the transaction. Override the commit() method in a custom DBTransactionImpl class and write code before calling the super. Note: For an overview of creating and using a custom DBTransaction implementation, see Creating a Custom Database Transaction Framework Extension Class.</td>
</tr>

</thead>
<tbody>
<tr>
<td>ON-ERROR</td>
<td>Override default behavior for handling an error.</td>
</tr>
<tr>
<td></td>
<td>Install a custom error handler (DCErrrorHandler) on the ADF BindingContext.</td>
</tr>
</tbody>
</table>
Performing Common Oracle Forms Tasks in Oracle ADF

This appendix describes how common Oracle Forms tasks are implemented in Oracle ADF. In Oracle Forms, you do some tasks in the data block, and others in the UI. For this reason, the appendix is divided into two sections: tasks that relate to data, and tasks that relate to the UI.

This appendix includes the following sections:

- Concepts Familiar to Oracle Forms Developers
- Performing Tasks Related to Data
- Performing Tasks Related to the User Interface

G.1 Concepts Familiar to Oracle Forms Developers

**ADF Business Components** implements all of the data-centric aspects of Oracle Forms runtime functionality, but in a way that is independent of the user interface. Responsibilities between the querying and entity-related functions are cleanly separated, resulting in better reuse, as described in Table G-1.

<table>
<thead>
<tr>
<th>This concept</th>
<th>Maps to Oracle ADF</th>
<th>With these similarities</th>
</tr>
</thead>
<tbody>
<tr>
<td>Headless Form Module</td>
<td>Application Module</td>
<td>The application module component is the &quot;data portion&quot; of the form. The application module is a smart data service containing a data model of master-detail-related queries that your client interface needs to work with. It also provides a transaction and database connection used by the components it contains. It can contain form-level procedures and functions, referred to as service methods, that are encapsulated within the service implementation. You can decide which of these procedures and functions should be private and which ones should be public.</td>
</tr>
<tr>
<td>Forms Record Manager</td>
<td>Entity Object</td>
<td>The entity object component implements the &quot;validation and database changes&quot; portion of the data block functionality. In the Forms runtime, this duty is performed by the record manager. The record manager is responsible for keeping track of which of the rows in the data block have changed, for firing the block-level and item-level validation triggers when appropriate, and for coordinating the saving of changes to the database. This is exactly what an entity object does for you. The entity object is a component that represents your business domain entity through an underlying database table. The entity object gives you a single place to encapsulate business logic related to validation, defaulting, and database modification behavior for that business object.</td>
</tr>
</tbody>
</table>
Table G-1 Concepts for Oracle Forms Developers

<table>
<thead>
<tr>
<th>This concept</th>
<th>Maps to Oracle ADF</th>
<th>With these similarities</th>
</tr>
</thead>
<tbody>
<tr>
<td>Data Block</td>
<td>View Object</td>
<td>The view object component performs the “data retrieval” portion of the data block functionality. Each view object encapsulates a SQL query, and at runtime each one manages its own query result set. If you connect two or more view objects in a master-detail relationship, that coordination is handled automatically. While defining a view object, you can link any of its query columns to underlying entity objects. By capturing this information, the view object and entity object can cooperate automatically for you at runtime to enforce your domain business logic, regardless of the “shape” of the business data required by the user’s task.</td>
</tr>
</tbody>
</table>

G.2 Performing Tasks Related to Data

In Oracle Forms, tasks that relate solely to data are performed in the data block. In Oracle ADF, these tasks are done on the business components that persist data (entity objects) and on the objects that query data (view objects).

G.2.1 How to Retrieve Lookup Display Values for Foreign Keys

In Oracle Forms, an editable table often has foreign key lookup columns to other tables. The user-friendly display values corresponding to the foreign key column values exist in related tables. You often need to present these related display values to the user.

In Oracle Forms, this was a complicated task that required adding nondatabase items to the data block, adding a block-level POST-QUERY trigger to the data block, and writing a SQL select statement for each foreign key attribute. Additionally, if the user changed the data, you needed to sync the foreign key values with an item-level WHEN-VALIDATE-ITEM trigger. This process is much easier in Oracle ADF.

Implementation of the task in Oracle ADF

1. Create a view object that includes the following:
   a. The main, editable entity object as the primary entity usage
   b. Secondary “reference” entity usages for the one or more associated entities whose underlying tables contain the display text

   For more information, see How to Create Joins for Entity-Based View Objects.

2. Select the desired attributes (at least the display text) from the secondary entity usages as described in How to Select Additional Attributes from Reference Entity Usages.

   At runtime, the data for the main entity and all related lookup display fields is retrieved from the database in a single join.

   If the user can change the data, no additional steps are required. If the user changes the value of a foreign key attribute, the reference information is automatically retrieved for the new, related row in the associated table.
G.2.2 How to Get the Sysdate from the Database

In Oracle Forms, when you wanted to get the current date and time, you retrieved the `sysdate` from the database. In Oracle ADF, you also have the option of getting the system date using a Java method or a Groovy expression.

Implementation of the task in Oracle ADF

To get the system date from the database, you can use the following Groovy expression at the entity level:

`DBTransaction.currentDbTime`

**Note:**

The `DBTransaction` reference is for entity-level Groovy expressions only.

If you want to assign a default value to an attribute using this Groovy expression, see How to Define a Default Value Using an Expression.

To get the system date from Java, you call the `getCurrentDate()` method. For more information, see Accessing the Current Date and Time.

G.2.3 How to Implement an Isolation Mode That Is Not Read Consistent

In Oracle Forms, you might have been concerned with read consistency, that is, the ability of the database to deliver the state of the data at the time the SQL statement was issued.

Implementation of the task in Oracle ADF

If you use an entity-based view object, the query sees the changes currently in progress by the current user’s session in the pending transaction. This is the default behavior, and the most accurate.

If instead, you want a snapshot of the data on the database without considering the pending changes made by the current user, you can use a read-only view object and reexecute the query to see the latest committed database values. For more information on read-only view objects, see How to Create a Custom SQL Mode View Object.

G.2.4 How to Implement Calculated Fields

Calculated fields are often used to show the sum of two values, but they could also be used for the concatenated value of two or more fields, or the result of a method call.

Implementation of the task in Oracle ADF

Calculated attributes are usually not stored in the database, as their values can easily be obtained programmatically. Attributes that are used in the middle tier, but that are not stored in the database are called transient attributes. Transient attributes can be defined at the entity object level or the view object level.

If a transient attribute will be used by more than one view object that might be based on an entity object, then define the attribute at the entity object level. Otherwise, define the transient attribute at the view object level for a particular view object.

To define transient attributes at the entity object level, see Adding Transient and Calculated Attributes to an Entity Object. To define transient attributes at the view object level, see Adding Calculated and Transient Attributes to a View Object.
G.2.5 How to Implement Mirrored Items

In Oracle Forms, you may be used to using mirrored items to show two or more fields that share identical values.

Implementation of the task in Oracle ADF

There is no need to have mirrored items in Oracle ADF, because the UI and data are separated. The same view object can appear on any number of pages, so you don’t need to create mirrored items that have the same value. Likewise, a form could have the same field represented in more than one place and it would not have to be mirrored.

G.2.6 How to Use Database Columns of Type CLOB or BLOB

If you are used to working with standard database types, you may be wondering how to use the CLOB and BLOB types in Oracle ADF.

Implementation of the task in Oracle ADF

In Oracle ADF, use the built-in data types ClobDomain or BlobDomain. These are automatically created when you reverse-engineer entity objects or view objects from existing tables with these column types. For more information, see How to Set Database and Java Data Types for an Entity Object Attribute.

G.3 Performing Tasks Related to the User Interface

In Oracle ADF, common UI-related tasks (such as master-detail screens, popup list of values, and page layout) are handled quite differently than they were in Oracle Forms.

G.3.1 How to Lay Out a Page

Oracle Forms is based on an absolute pixel or point-based layout, as compared to the container-based approach of JSF.

Implementation of the task in Oracle ADF

See Developing Web User Interfaces with Oracle ADF Faces for information on how to lay out a page in Oracle ADF.

G.3.2 How to Stack Canvases

In Oracle Forms, stacked canvases were often used to hide and display areas of the screen.

Implementation of the task in Oracle ADF

The analog of stacked canvases in Oracle ADF is panels (layout containers) with the rendered property set to true or false. See Developing Web User Interfaces with Oracle ADF Faces for more information.

G.3.3 How to Implement a Master-Detail Screen

Master-detail relationships in Oracle ADF are coordinated through a view link. A view link is conceptually similar to an Oracle Forms relation.

Implementation of the task in Oracle ADF

For information on how create view links, see Working with Multiple Tables in a Master-Detail Hierarchy. Once you have established a relationship between two view objects with a view link, see How to Enable Active Master-Detail Coordination in the Data Model.
G.3.4 How to Implement an Enter Query Screen

In Oracle Forms, another common task was creating an enter query screen. That is, a screen that starts in Find mode.

Implementation of the task in Oracle ADF

In Oracle ADF, this accomplished with a search form. Complete information on how to create a search form is covered in Creating ADF Databound Search Forms. In particular, you may want to look at How to Set Search Form Properties on the View Criteria.

G.3.5 How to Implement an Updatable Multi-Record Table

In Oracle Forms, you may be used to creating tables where you can edit and insert many records at the same time. This can be slightly more complicated when using a JSF page in Oracle ADF, because the operations to edit an existing record and to create a new record are not the same.

Implementation of the task in Oracle ADF

In Oracle ADF, this is done using an input table. To create an input table, see Creating an Input Table.

G.3.6 How to Create a Popup List of Values

In Oracle Forms, it was simple to create a list of values (LOV) object and then associate that object with a field in a declarative manner. This LOV would display a popup window and provide the following capabilities:

- Selection of modal values
- Query area at the top of the LOV dialog
- Display of multiple columns
- Automatic reduction of LOV contents, possibly based on the contents of the field that launched the LOV
- Automatic selection of the list value when only one value matches the value in the field when the LOV function is invoked
- Validation of the field value based on the values cached by the LOV
- Automatic popup of the LOV if the field contents are not valid

Implementation of the task in Oracle ADF

To implement a popup list in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select Input Text with List of Values as the style for its UI hint. For a description of how to do this, see Working with List of Values (LOV) in View Object Attributes.

G.3.7 How to Implement a Dropdown List as a List of Values

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement an LOV (lookup-value) screen with a search item, usable for a lookup field with many possible values.

Implementation of the task in Oracle ADF
To implement a dropdown list in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select *Input Text with List of Values* as the style for its UI hint. For a description of how to do this, see *Working with List of Values (LOV) in View Object Attributes*.

**G.3.8 How to Implement a Dropdown List with Values from Another Table**

In Oracle Forms, you could create a list of values (LOV) object and then associate that object with a field in a declarative manner. In Oracle ADF, you can implement a dropdown list with string values from a different table. These string values populate the field with an id code that is valid input in the table that the screen is based on.

Implementation of the task in Oracle ADF

To implement a dropdown list of this type in Oracle ADF, you configure one of the view object's attributes to be of LOV type, and select *Choice List* as the style for its UI hint. For a description of how to do this, see *Working with List of Values (LOV) in View Object Attributes*.

**G.3.9 How to Implement Immediate Locking**

In Oracle ADF, you can lock a record in the database at the first moment it is obvious that the user is going to change a specific record.

Implementation of the task in Oracle ADF

Immediate row locking can be configured in ADF Business Components, although it is not the default and is typically not used in web application scenarios. For web applications, use the default configuration setting `jbo.locking.mode=optimistic`. For more information, see *How to Confirm That Fusion Web Applications Use Optimistic Locking*.

**G.3.10 How to Throw an Error When a Record Is Locked**

When a record has been locked by a user, it's helpful to throw an error to let other users know that the record is not currently updatable.

Implementation of the task in Oracle ADF

Locking rows and throwing an exception if the row is already locked is built-in ADF Business Components functionality. There are a couple of different ways that you can handle the error message, depending on whether you want a static error message or a custom message with information about the current row.

- To throw a static message, register a custom message bundle in your data model project to substitute the default `RowAlreadyLockedException`'s error message with something more meaningful or user-friendly.

- To throw a message that contains information about the row, override the `lock()` method on the entity object, using a `try/catch` block to catch the `RowAlreadyLocked` exception. After you catch the exception, you can throw an error message that might contain more specific information about the current row.
Deploying ADF Applications to GlassFish

This appendix describes how to deploy Oracle ADF applications to a GlassFish application server. It describes how to create deployment profiles, how to create deployment descriptors, and how to deploy the application.

This appendix includes the following sections:

- About Deploying ADF Applications to GlassFish Server
- Running an ADF Application in Integrated WebLogic Server
- Preparing the Application
- Deploying the Application
- Testing the Application and Verifying Deployment

H.1 About Deploying ADF Applications to GlassFish Server

Deployment is the process of packaging application files as an archive file and transferring that file to a target GlassFish application server. You can use JDeveloper to deploy ADF applications directly to the GlassFish Server, or indirectly to an archive file as the deployment target, and then install this archive file to the target GlassFish Server. For application development, you can also use JDeveloper to run an application in Integrated WebLogic Server.

You can use JDeveloper to:

- Run applications in Integrated WebLogic Server
  
  You can run and debug applications using Integrated WebLogic Server and then deploy to standalone GlassFish Server.

- Deploy directly to the standalone GlassFish Server
  
  You can deploy applications directly to the standalone GlassFish Server by creating a connection to the server and choosing the name of that server as the deployment target.

- Deploy to an archive file
  
  You can deploy applications indirectly by choosing an EAR file as the deployment target. The archive file can subsequently be installed on the target GlassFish Server.

H.1.1 Developing Applications with Integrated WebLogic Server

If you are developing an application in JDeveloper and you want to run the application in Integrated WebLogic Server, you do not need to perform the tasks required for deploying directly to Oracle WebLogic Server or to an archive file. JDeveloper has a default connection to Integrated WebLogic Server and does not
require any deployment profiles or descriptors. Integrated WebLogic Server has a preconfigured domain that includes the ADF libraries, as well as the `-Djps.app.credential.overwrite.allowed=true` setting, that are required to run ADF applications. You can run an application by choosing Run from the JDeveloper main menu.

You debug the application using the features described in Testing and Debugging ADF Components.

**H.1.2 Developing Applications to Deploy to Standalone GlassFish Server**

Typically, for deployment to standalone application servers, you test and develop your application by running it in Integrated WebLogic Server. You can then test the application further by deploying it to standalone GlassFish Server.

In general, you use JDeveloper to prepare the application or project for deployment by:

- Creating a connection to the target GlassFish Server
- Creating deployment profiles (if necessary)
- Creating deployment descriptors that are specific to GlassFish
- Updating `application.xml` and `web.xml` to be compatible with the GlassFish Server (if required)

You must already have an installed GlassFish Server. For instructions on obtaining and installing GlassFish, see [http://glassfish.java.net/download.html](http://glassfish.java.net/download.html).

You must also prepare the GlassFish Server for ADF application deployment. For more information, see the "Configuring GlassFish Server" appendix in Administering Oracle ADF Applications.

- Installing the ADF runtime into the GlassFish Server installation:
- Setting JVM cache size and `simple` option
- Enabling Secure Admin on the GlassFish Server to allow for remote logins and remote connections in order for JDeveloper to run on a different machine than GlassFish.
- Creating a global JDBC data source for applications that require a connection to a data source

After the application and the GlassFish Server have been prepared, you can:

- Use JDeveloper to:
  - Directly deploy to the GlassFish Server using the deployment profile and the application server connection.
  - Deploy to an EAR file using the deployment profile. For ADF applications, WAR files can be deployed only as part of an EAR file.
- Use the GlassFish Server's administration tools to deploy the EAR file created in JDeveloper.
H.2 Running an ADF Application in Integrated WebLogic Server

JDeveloper is installed with Integrated WebLogic Server which you can use to test and develop your application. For most development purposes, Integrated WebLogic Server will suffice. When your application is ready to be tested, you can select the run target and then choose the Run command from the main menu.

**Note:**

The first time you run an application in Integrated WebLogic Server, the Create Default Domain dialog appears for you to define an administrative password for the new domain.

When you run the application target, JDeveloper detects the type of Java EE module to deploy based on artifacts in the projects and workspace. JDeveloper then creates an in-memory deployment profile for deploying the application to Integrated WebLogic Server. JDeveloper copies project and application workspace files to an "exploded EAR" directory structure. This file structure closely resembles the EAR file structure that you would have if you were to deploy the application to an EAR file. JDeveloper then follows the standard deployment procedures to register and deploy the "exploded EAR" files into Integrated WebLogic Server. The "exploded EAR" strategy reduces the performance overhead of packaging and unpackaging an actual EAR file.

In summary, when you select the run target and run the application in Integrated WebLogic Server, JDeveloper:

- Detects the type of Java EE module to deploy based on the artifacts in the project and application
- Creates a deployment profile in memory
- Copies project and application files into a working directory with a file structure that would simulate the "exploded EAR" file of the application.
- Performs the deployment tasks to register and deploy the simulated EAR into Integrated WebLogic Server

**Note:**

JDeveloper ignores the deployment profiles that were created for the application when you run the application in Integrated WebLogic Server.

The application will run in the base domain in Integrated WebLogic Server. This base domain has the same configuration as a base domain in a standalone WebLogic Server instance. In other words, this base domain will be the same as if you had used the Oracle Fusion Middleware Configuration Wizard to create a base domain with the default options in a standalone WebLogic Server instance.

JDeveloper will extend this base domain with the necessary domain extension templates, based on the JDeveloper technology extensions. For example, if you have installed JDeveloper Studio, JDeveloper will automatically configure the Integrated WebLogic Server environment with the ADF runtime template (JRF Fusion Middleware runtime domain extension template).
You can explicitly create a default domain for Integrated WebLogic Server. You can use the default domains to run and test your applications. Open the Application Servers window, right-click IntegratedWebLogicServer and choose Create Default Domain.

H.2.1 How to Run an Application in Integrated WebLogic Server

You can test an application by running it in Integrated WebLogic Server. You can also set breakpoints and then run the application within the ADF Declarative Debugger.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you run an application in Integrated WebLogic Server. For more information, see Running an ADF Application in Integrated WebLogic Server.

To run an application in Integrated WebLogic Server:

1. In the Applications window, select the project, unbounded task flow, JSF page, or file as the run target.
2. Right-click the run target and choose Run or Debug.

The Create Default Domain dialog displays the first time you run your application and start a new domain in Integrated WebLogic Server. Use the dialog to define an administrator password for the new domain. Passwords you enter can be eight characters or more and must have a numeric character.

H.3 Preparing the Application

Before you deploy an ADF application to a standalone GlassFish Server, you must perform prerequisite tasks within JDeveloper to prepare the application for deployment.

The tasks are:

- How to Create a Connection to the Target Application Server
- How to Create Deployment Profiles
- How to Create and Edit Deployment Descriptors
- How to Enable JDBC Data Source for GlassFish
- How to Change Initial Context Factory

Note:

ADF Security is not supported on ADF Essentials for GlassFish. You should configure GlassFish-specific security within the ADF application. For more information about configuring GlassFish security, see http://docs.oracle.com/cd/E18930_01/html/821-2418/beabg.html#scrolltoc.

H.3.1 How to Create a Connection to the Target Application Server

You can deploy applications to the GlassFish Server via JDeveloper application server connections.
Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an application server connection. For more information, see Preparing the Application.

You will need to complete this task:

Install the GlassFish Server.

To create a connection to an application server:

1. Launch the Application Server Connection wizard.

   You can:
   
   - In the Application Servers window, right-click Application Servers and choose New Application Server.
   - In the New Gallery, expand General, select Connections and then Application Server Connection, and click OK.
   - In the Resources window, choose New > IDE Connections > Application Server.

2. In the Create Application Server Connection dialog, on the Usage page, select Standalone Server.

3. On the Name and Type page, enter a connection name.

4. In the Connection Type dropdown list, choose:

   - GlassFish 3.1 to create a connection to the GlassFish Server

5. Click Next.

6. On the Authentication page, enter a user name and password for the administrative user authorized to access the GlassFish Server.

7. Click Next.

8. On the Configuration page, enter the information for the GlassFish Server:

   - **Host Name**: Enter the name of the machine where the GlassFish Server is running. If no name is entered, the name defaults to localhost.
   - **RMI Port**: If necessary, change to the RMI port number for the server. The default is 8686.
   - **HTTP Port**: By default, GlassFish listens to port 8080 for HTTP requests. If necessary, you can change the port number here.
   - **Admin HTTP Port**: By default, GlassFish uses port 4848 for administration. If necessary, you can change the port number here.
   - **Secure Admin Enabled**: select if you want GlassFish to allow remote logins and remote connections

Note:
If you are using GlassFish 3.1.2 and you are running JDeveloper on a different machine than GlassFish, you need to enable Secure Admin in GlassFish to allow remote logins. You do not need to enable Secure Admin if both JDeveloper and GlassFish are on the same machine.

9. Click Next.

10. On the Test page, click Test Connection to test the connection.

JDeveloper performs several types of connections tests. The JSR-88 test must pass for the application to be deployable. If the test fails, return to the previous pages of the wizard to fix the configuration.

11. Click Finish.

H.3.2 How to Create Deployment Profiles

A deployment profile defines the way the application is packaged into the archive that will be deployed to the target environment. The deployment profile:

- Specifies the format and contents of the archive file that will be created
- Lists the source files, deployment descriptors, and other auxiliary files that will be packaged
- Describes the type and name of the archive file to be created
- Highlights dependency information, platform-specific instructions, and other information

You need a WAR deployment profile for each web user interface project that you want to deploy in your application. You need an application-level EAR deployment profile and you must select the projects (such as WAR profiles) to include from a list. When the application is deployed, the EAR file will include all the projects that were selected in the deployment profile.

Note:

If you create your project or application using the ADF Fusion Web Application template, JDeveloper automatically creates default WAR and EAR deployment profiles. Typically, you would not need to edit or create deployment profiles manually.

For ADF applications, you can deploy the application only as an EAR file. The WAR files that are part of the application should be included in the EAR file when you create the deployment profile.

H.3.2.1 Creating a WAR Deployment Profile

You will need to create a WAR deployment profile for each web-based project you want to package into the application. Typically, the WAR profile will include the dependent data model projects it requires.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you create a WAR deployment profile. For more information, see Preparing the Application.

You will need to complete this task:

Create web-based projects. If you used the ADF Fusion Web Application template, you should already have a default WAR deployment profile.

To create WAR deployment profiles for an application:

1. In the Applications window, right-click the web project that you want to deploy and choose New and then From Gallery.

   You will create a WAR profile for each web project.

2. In the New Gallery, expand General, select Deployment Profiles and then WAR File, and click OK.

   If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- WAR File dialog, enter a name for the project deployment profile and click OK.

4. In the Edit WAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog. Note that some items list below may not be in your particular application.

   • Ensure that ADF Faces Runtime 11, JSTL 1.2, and the ADFm, ADFc, and ADFv libraries are marked deployed in the WEB-INF/lib/Contributors panel.

   • Select File Groups > Web Files > Filters > WEB-INF and deselect weblogic.xml.

   • Select File Groups > Web Files/Classes > Filters > META-INF and deselect ejb-jar.xml.

   • Select File Groups > Web Files/Classes > Filters > path and deselect serviceinterface.

   • Select File Groups > Web Files/Classes > Filters > path and deselect server.

   • You might also want to change the Java EE web context root setting. To do so, choose General in the left pane.

     By default, when Use Project's Java EE Web Context Root is selected, the associated value is set to the project name, for example, Application1-Project1-context-root. You need to change this if you want users to use a different name to access the application.

     • Select Glassfish 3.1 as the Platform

5. Click OK to exit the Deployment Profile Properties dialog.

6. Click OK again to exit the Project Properties dialog.

7. Repeat Steps 1 through 6 for all web projects that you want to deploy.
H.3.2.2 Creating an Application-Level EAR Deployment Profile

The EAR file contains all the necessary application artifacts for the application to run in the application server. If you used the ADF Fusion Web Application template, you should already have a default EAR deployment profile. For more information about the EAR file, see What You May Need to Know About EAR Files and Packaging.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an application-level EAR deployment profile. For more information, see Preparing the Application.

You will need to complete this task:

Create the WAR deployment profiles, as described in Creating a WAR Deployment Profile.

To create an EAR deployment profile for an application:

1. In the Applications window, right-click the application and choose New and then From Gallery.

   You will create an EAR profile for the application.

2. In the New Gallery, expand General, select Deployment Profiles and then EAR File, and click OK.

   If you don’t see Deployment Profiles in the Categories tree, click the All Features tab.

3. In the Create Deployment Profile -- EAR File dialog, enter a name for the application deployment profile and click OK.

4. In the Edit EAR Deployment Profile Properties dialog, choose items in the left pane to open dialog pages in the right pane. Configure the profile by setting property values in the pages of the dialog.

   • Select File Groups > Application Descriptors > Filters and deselect weblogic-application.xml.

   • Select Application Assembly and then in the Java EE Modules list, select all the project profiles that you want to include in the deployment, including any WAR profiles.

   • Select Platform, select the application server you are deploying to, and then select the target application connection from the Target Connection dropdown list. For GlassFish, select GlassFish 3.1.

5. Click OK again to exit the Edit EAR Deployment Profile Properties dialog.

6. Click OK again to exit the Application Properties dialog.

Note:

To verify that your customization classes are put correctly in the EAR class path, you can deploy the EAR profile to file system. Then you can examine the EAR to make sure that the customization class JAR is available in the EAR.
class path (the EAR/lib directory) and not available in the WAR class path (the WEB-INF/lib and WEB-INF/classes directories).

H.3.2.3 Viewing and Changing Deployment Profile Properties

After you have created a deployment profile, you can view and change its properties.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you view and change deployment profile properties. For more information, see Preparing the Application.

To view, edit, or delete a project's deployment profile:

1. In the Applications window, right-click the project and choose Project Properties.
2. In the Project Properties dialog, click Deployment.

   The Deployment Profiles list displays all profiles currently defined for the project.
3. In the list, select a deployment profile.
4. To edit or delete a deployment profile, click Edit or Delete.

H.3.3 How to Create and Edit Deployment Descriptors

Deployment descriptors are server configuration files that define the configuration of an application for deployment and that are deployed with the Java EE application as needed. The deployment descriptors that a project requires depend on the technologies the project uses and on the type of the target application server. Deployment descriptors are XML files that can be created and edited as source files, but for most descriptor types, JDeveloper provides dialogs or an overview editor that you can use to view and set properties. If you cannot edit these files declaratively, JDeveloper opens the XML file in the source editor for you to edit its contents.

In addition to the standard Java EE deployment descriptors (for example, application.xml and web.xml), you can also have deployment descriptors that are specific to your target application server.

H.3.3.1 Creating Deployment Descriptors

JDeveloper automatically creates many of the required deployment descriptors for you. If they are not present, or if you need to create additional descriptors, you can use JDeveloper to create them.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create deployment descriptors. For more information, see Preparing the Application.

You will need to complete this task:

Check to see whether JDeveloper has already generated deployment descriptors.

To create a deployment descriptor:

1. In the Applications window, expand the user interface project, select WEB-INF and click New and then From Gallery.
2. In the New Gallery, expand General, choose XML Document and click OK.

3. In the Create XML File dialog, enter a name for your descriptor and click OK.
   For instance, you may want to create a glassfish-web.xml to define GlassFish-specific information.

4. In the overview editor, add entries for GlassFish.
   The following example shows a sample glassfish-web.xml descriptor.

   The glassfish-web.xml descriptor can be used to add additional settings that are not defined in web.xml or to modify the settings that are already defined in web.xml. For instance, you can override the jdbc/Connections1DS setting defined in web.xml by adding the entries res-ref-name and jndi-name to glassfish-web.xml as shown below. After setting glassfish-web.xml, jdbc/NewConnections1DS will be used instead of jdbc/Connections1DS. Note that the res-ref-name section is optional.

   ```xml
   <glassfish-web-app>
     <context-root>DeptApp-ViewController-context-root</context-root>
     <resource-ref>
       <res-ref-name>jdbc/Connection1DS</res-ref-name>
       <jndi-name>jdbc/NewConnection1DS</jndi-name>
     </resource-ref>
     <class-loader delegate="false"/>
     <property value="true" name="useBundledJsf"/>
   </glassfish-web-app>
   
   Note:
   For EAR files, do not create more than one deployment descriptor file of the same type per application or workspace. These files can be assigned to projects, but have application workspace scope. If multiple projects in an application have the same deployment descriptor, the one belonging to the launched project will supersede the others. This restriction applies to application.xml.

   The best place to create an application-level descriptor is in the Descriptors node of the Application Resources panel in the Applications window. This ensures that the application is created with the correct descriptors.

   Application-level descriptors created in the project will be ignored at runtime. Only the application resources descriptors or descriptors generated at the EAR level will be used by the runtime.

   H.3.3.2 Viewing or Modifying Deployment Descriptor Properties

   After you have created a deployment descriptor, you can change its properties by using JDeveloper dialogs or by editing the file in the source editor. The deployment descriptor is an XML file (for example, application.xml) typically located under the Application Sources node.

   Before you begin:

   It may be helpful to have an understanding of the options that are available to you when you view or modify deployment descriptors. For more information, see Preparing the Application.

   To view or change deployment descriptor properties:
1. In the Applications window or in the Application Resources panel, double-click the deployment descriptor.

2. In the overview editor, select either the **Overview tab** or the **Source tab**, and configure the descriptor by setting property values.

   If the overview editor is not available, JDeveloper opens the file in the source editor.

### H.3.3.3 Configuring the application.xml File for Application Server Compatibility

You may need to configure your application.xml file to be compliant with your Java EE 1.5.

**Note:**

Typically, your project has an application.xml file that is compatible and you would not need to perform this procedure.

---

**Before you begin:**

It may be helpful to have an understanding of the options that are available to you when you configure the application.xml file. For more information, see Preparing the Application.

To configure the application.xml file:

1. In the Applications window, right-click the application and choose **New** and then **From Gallery**.

2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor Wizard**, and click **OK**.

3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select **application.xml** and click **Next**.

4. On the Select Version page, select **5.0** to be compatible with Java EE 5.0 or higher and click **Next**.

5. On the Summary page, click **Finish**.

6. Edit the application.xml file with the appropriate values.

### H.3.3.4 Configuring the web.xml File for GlassFish Server Compatibility

You may need to configure your web.xml file to be compliant with your Java EE version.

The following example shows a web.xml file with a setting for a JDBC connection. For more information and other settings that are required, see web.xml.

```xml
<resource-ref>
  <description>DB Connection</description>
  <res-ref-name>jdbc/Connection1DS</res-ref-name>
  <res-type>javax.sql.DataSource</res-type>
  <res-auth>Container</res-auth>
</resource-ref>
```

**Note:**
Typically, your project has a `web.xml` file that is compatible and you would not need to perform this procedure. JDeveloper creates a starter `web.xml` file when you create a project.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you configure the `web.xml` file. For more information, see Preparing the Application.

To configure the `web.xml` file:

1. In the Applications window, right-click the project and choose **New** and then **From Gallery**.
2. In the New Gallery, expand **General**, select **Deployment Descriptors** and then **Java EE Deployment Descriptor**, and click **OK**.
3. In the Create Java EE Deployment Descriptor dialog, on the Select Descriptor page, select `web.xml` and click **Next**.
4. On the Select Version page, select the version you want to use and click **Next**.
   - Version 3.0 is compatible with Java EE 6.0 or higher, and version 2.5 is compatible with Java EE 5.0.
5. On the Summary page, click **Finish**.
6. Open the `web.xml` file in the overview editor.
7. Select the **Filters** tab and remove **JpsFilter**.

**H.3.4 How to Enable JDBC Data Source for GlassFish**

If you are using **ADF Business Components** in your application, you may need to check that the data source defined for the ADF Business Components as part of the application matches the data source defined in the GlassFish container.

You can configure the ADF application to use a JDBC Data Source in the application by editing the application's `bc4j.xcfg` file.

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you configure JDBC. For more information, see Preparing the Application.

To configure the `bc4j.xcfg` file to enable JDBC data source:

1. In the Applications window, expand the model project and click the application module.
2. In the overview editor for the application module, choose **Configurations** and click `bc4j.xcfg`.
3. In the overview editor for `bc4j.xcfg`, select the **Source** tab.
4. Check that the **Custom JDBCDataSource** entry defined in the file matches the JDBC datasource defined for the GlassFish Server as described in the “Configuring GlassFish Server” appendix in **Administering Oracle ADF Applications**.
For instance, the following example shows the JDBCDataSource property defined in the bc4j.xcfg file:

```xml
<BC4JConfig version="11.1" xmlns="http://xmlns.oracle.com/bc4j/configuration">
  <AppModuleConfigBag ApplicationName="model.AppModule">
    <AppModuleConfig name="AppModuleLocal" jbo.project="model.Model" ApplicationName="model.AppModule" DeployPlatform="LOCAL">
      <Database jbo.TypeMapEntries="OracleApps"/>
      <Security AppModuleJndiName="model.AppModule"/>
      <Custom ns0:JDBCDataSource="jdbc/OracleDS" xmlns:ns0="http://xmlns.oracle.com/bc4j/configuration"/>
    </AppModuleConfig>
    <AppModuleConfig name="AppModuleShared" jbo.project="model.Model" ApplicationName="model.AppModule" DeployPlatform="LOCAL">
      <AM-Pooling jbo.ampool.maxpoolsize="1" jbo.ampool.isuseexclusive="false"/>
      <Database jbo.TypeMapEntries="OracleApps"/>
      <Security AppModuleJndiName="model.AppModule"/>
      <Custom ns0:JDBCDataSource="jdbc/OracleDS" xmlns:ns0="http://xmlns.oracle.com/bc4j/configuration"/>
    </AppModuleConfig>
  </AppModuleConfigBag>
</BC4JConfig>
```

H.3.5 How to Change Initial Context Factory

If your application requires JNDI lookup, such as in EJB-based applications, you need to change the initial context factory class name to the GlassFish context factory.

To change the initial context factory:

1. In the Applications window, expand the model project and double-click the DataControls.dcx file
2. In the overview editor, click the Source tab.
3. Edit the initial-context-factory entry to be initial-context-factory="com.sun.enterprise.naming.SerialInitContextFactory"

H.4 Deploying the Application

You can use JDeveloper to deploy ADF applications directly to the GlassFish Server or you can create an archive file and use other tools to deploy to the application server.

Note:

Before you begin to deploy applications that use Oracle ADF to the standalone application server, you need to prepare the GlassFish Server environment by performing tasks such as installing the ADF runtime libraries and setting configuration values. For more information, see the "Configuring GlassFish Server" appendix in Administering Oracle ADF Applications.

Table H-1 describes some common deployment techniques that you can use during the application development and deployment cycle. The deployment techniques are listed in order from deploying on development environments to deploying on production environments. It is likely that in the production environment, the system administrators deploy applications by using the GlassFish Administration Console or scripts.
### Table H-1  Deployment Techniques for Development or Production Environments

<table>
<thead>
<tr>
<th>Deployment Technique</th>
<th>Environment</th>
<th>When to Use</th>
</tr>
</thead>
<tbody>
<tr>
<td>Run directly from JDeveloper</td>
<td>Test or</td>
<td>When you are developing your application. You want deployment to be quick because you will be repeating the editing and deploying process many times. JDeveloper contains Integrated WebLogic Server, on which you can run and test your application. Note that you are testing your application in an integrated WebLogic Server and not in an Integrated GlassFish Server. After testing on the Integrated WebLogic Server, you can test further by deploying to the standalone GlassFish Server.</td>
</tr>
<tr>
<td></td>
<td>Development</td>
<td></td>
</tr>
<tr>
<td>Use JDeveloper to directly deploy to the target GlassFish Server</td>
<td>Test or</td>
<td>When you are ready to deploy and test your application on an application server in a test environment. You can also use the test environment to develop your deployment scripts, for example, using Ant.</td>
</tr>
<tr>
<td></td>
<td>Development</td>
<td></td>
</tr>
<tr>
<td>Use JDeveloper to deploy to an EAR file, then use the target GlassFish Server's tools for deployment</td>
<td>Test or</td>
<td>When you are ready to deploy and test your application on an application server in a test environment. As an alternative to deploying directly from JDeveloper, you can deploy to an EAR file and then use other tools to deploy to the application server. You can also use the test environment to develop your deployment scripts, for example, using Ant.</td>
</tr>
<tr>
<td></td>
<td>Development</td>
<td></td>
</tr>
<tr>
<td>Use GlassFish asadmin commands or GlassFish Administration Console</td>
<td>Production</td>
<td>When your application is in a test and production environment. In production environments, system administrators usually use GlassFish asadmin commands or the GlassFish Administration Console.</td>
</tr>
</tbody>
</table>

#### H.4.1 How to Deploy to the Application Server from JDeveloper

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you deploy to the application server from JDeveloper. For more information, see Preparing the Application.

You will need to complete this task:

Create an application-level deployment profile that deploys to an EAR file.

To deploy to the target application server from JDeveloper:

1. In the Applications window, right-click the application and choose **Deploy > deployment profile**.

   Make sure you choose a GlassFish deployment profile.

2. In the Deploy wizard, on the Deployment Action page, select **Deploy to Application Server** and click **Next**.

3. On the Select Server page, select the application server connection, and click **Next**.

4. Click **Finish**.
During deployment, you can see the process steps displayed in the deployment Log window. You can inspect the contents of the modules (archives or exploded EAR) being created by clicking on the links that are provided in the log window. The archive or exploded EAR file will open in the appropriate editor or directory window for inspection.

**Note:**
If you are deploying a Java EE application, click the application menu next to the Java EE application in the Applications window.

For more information on creating application server connections, see How to Create a Connection to the Target Application Server.

**H.4.2 What You May Need to Know About Deploying from JDeveloper**

When you deploy an application using the EAR deployment profile created for GlassFish, JDeveloper:

- Inserts the required ADF Model, ADF Controller, and ADF View library JARs into the EAR file.
- Inserts `adf-share-glassfish.jar` into the WAR.
- Inserts an entry for the GlassFish application lifecycle listener `ADFGlassFishAppLifeCycleListener` into the `web.xml` file.

**H.4.3 How to Create an EAR File for Deployment**

You can also use the deployment profile to create an archive file (EAR file). You can then deploy the archive file using GlassFish Administration Console.

Although an ADF application is encapsulated in an EAR file (which usually includes WAR components), it may have parts that are not deployed with the EAR.

Before you begin:

It may be helpful to have an understanding of the options that are available to you when you create an EAR file for deployment. For more information, see Preparing the Application.

You will need to complete this task:

Create an application-level deployment profile that deploys to an EAR file.

To create an EAR archive file:

- In the Applications window, right-click the application containing the deployment profile, and choose **Deploy > deployment profile > to EAR file**.

  If an EAR file is deployed at the application level, and it has dependencies on a JAR file in the data model project and dependencies on a WAR file in the user interface project, then the files will be located in the following directories by default:

  - `ApplicationDirectory/deploy/EARdeploymentprofile.EAR`
Tip:
Choose View > Log to see messages generated during creation of the archive file.

H.4.4 What You May Need to Know About ADF Libraries

An ADF Library is a JAR file that contains JAR services registered for ADF components such as ADF task flows, pages, or application modules. If you want the ADF components in a project to be reusable, you create an ADF Library deployment profile for the project and then create an ADF Library JAR based on that profile.

An application or project can consume the ADF Library JAR when you add it using the Resources window or manually by adding it to the library classpath. When the ADF Library JAR is added to a project, it will be included in the project's WAR file if the Deployed by Default option is selected.

For more information, see Reusing Application Components.

H.4.5 What You May Need to Know About EAR Files and Packaging

When you package an ADF application into an EAR file, it can contain the following:

- WAR files: Each web-based view controller project should be packaged into a WAR file.
- ADF Library JAR files: If the application consumes ADF Library JARs, these JAR files may be packaged within the EAR.
- Other JAR files: The application may have other dependent JAR files that are required. They can be packaged within the EAR.

H.4.6 How to Deploy to the Application Server using asadmin Commands

Before you begin:
It may be helpful to have an understanding of the options that are available to you when you deploy to the application server from JDeveloper. For more information, see Preparing the Application.

To deploy to the target application server using asadmin command:

1. Start an asadmin shell for GlassFish Server.
2. Invoke the deploy command.
   For instance, the following command deploys application1.ear to the GlassFish Server.
   
   ```
   deploy \--target=server \--force /path/application1.ear
   ```

H.4.7 How to Deploy the Application Using Scripts and Ant

You can deploy the application using commands and automate the process by putting those commands in scripts. The ojdeploy command can be used to deploy an application without JDeveloper. You can also use Ant scripts to deploy the
application. JDeveloper has a feature to help you build Ant scripts. Depending on your requirements, you may be able to integrate regular scripts with Ant scripts.

For more information about commands, scripts, and Ant, see *Administering Oracle ADF Applications*.

### H.5 Testing the Application and Verifying Deployment

After you deploy the application, you can test it from the application server. To test-run your ADF application, open a browser window and enter a URL:

- For non-Faces pages: `http://<host>:port/<context root>/<page>`
- For Faces pages: `http://<host>:port/<context root>/faces/<view_id>`

where `<view_id>` is the view ID of the ADF task flow view activity.

**Tip:**

The context root for an application is specified in the user interface project settings by default as `ApplicationName/ProjectName/context-root`. You can shorten this name by specifying a name that is unique across the target application server. Right-click the user interface project, and choose *Project Properties*. In the Project Properties dialog, select *Java EE Application* and enter a unique name for the context root.

**Note:**

`/faces` has to be in the URL for Faces pages. This is because JDeveloper configures your `web.xml` file to use the URL pattern of `/faces` in order to be associated with the Faces Servlet. The Faces Servlet does its per-request processing, strips out `/faces` part in the URL, then forwards the URL to the JSP. If you do not include the `/faces` in the URL, then the Faces Servlet is not engaged (since the URL pattern doesn’t match). Your JSP is run without the necessary JSF per-request processing.
